Abstract

The Office of Surface Mining Reclamation and Enforcement (OSMRE) has prepared a final Environmental Impact Statement (FEIS) on proposed revisions to regulations (at 30 CFR Chapter VII) for implementation of the Surface Mining Control and Reclamation Act (SMCRA or the Act) of 1977. The proposed revisions would better protect streams, fish, wildlife, and related environmental values from the adverse impacts of surface coal mining operations and provide mine operators with a regulatory framework to avoid water pollution and the long-term costs associated with water treatment, more completely implement the requirements of SMCRA, remedy deficiencies in existing rules, and remove obsolete or unneeded provisions from existing rules. The FEIS analyzes the proposed revisions in accordance with the National Environmental Policy Act (NEPA) of 1969 as amended, 42 U.S.C. 4321-4347; the Council on Environmental Quality's (CEQ's) regulations for implementing NEPA, 40 CFR Parts 1500 through 1508; and the U.S. Department of the Interior's NEPA regulations, 43 CFR Part 46.

The proposed action is intended to balance all relevant purposes of the Act, as listed in Section 102 of SMCRA, 30 U.S.C. § 1202. Those purposes include ensuring that surface coal mining operations are conducted in a manner that protects the environment, establishing a nationwide program to protect society and the environment from the adverse effects of surface coal mining operations, and ensuring a coal supply adequate for our Nation's energy needs.

APPENDICES:

Executive Summary

ES.1 Background and Overview

The Office of Surface Mining Reclamation and Enforcement (OSMRE) has prepared this Final Environmental Impact Statement (FEIS) on proposed revisions to regulations (at 30 CFR Chapter VII) for implementation of the Surface Mining Control and Reclamation Act (SMCRA or the Act) of 1977. The proposed revisions would better protect streams, fish, wildlife, and related environmental values from the adverse impacts of surface coal mining operations and provide mine operators with a regulatory framework to avoid water pollution and the long-term costs associated with water treatment, more completely implement the requirements of SMCRA, remedy deficiencies in existing rules, and remove obsolete or unneeded provisions from existing rules. The FEIS analyzes the proposed revisions in accordance with the National Environmental Policy Act (NEPA) of 1969 as amended, 42 U.S.C. 4321-4347; the Council on Environmental Quality's (CEQ's) regulations for implementing NEPA, 40 CFR Parts 1500 through 1508; and the U.S. Department of the Interior's NEPA regulations, 43 CFR Part 46.

Scientific studies published since the adoption in 1983 of our principal regulations have indicated that surface coal mining operations continue to have significant negative impacts on streams, fish, and wildlife despite the enactment of SMCRA and the federal regulations implementing that law. The principal purpose of the current proposed action is to update and revise the regulations to reflect the best available science in order to avoid or minimize these negative impacts, and provide regulatory certainty to industry.

The FEIS analyzes the impacts of implementing rule changes that would do the following:

- Define the term "material damage to the hydrologic balance outside the permit area" and require that each permit establish the point at which adverse mining-related impacts on groundwater and surface water reach an unacceptable level; i.e., the point at which adverse impacts from mining would cause material damage to the hydrologic balance outside the permit area.
- Set forth how to collect adequate premining data about the site of the proposed mining operation and adjacent areas to establish a comprehensive baseline that will facilitate evaluation of the effects of mining operations.
- Set forth how to conduct effective, comprehensive monitoring of groundwater and surface water during and after both mining and reclamation and during the revegetation responsibility period to provide real-time information documenting mining-related changes in water quality and quantity.
- Address the need for required monitoring of the biological condition of streams during and after mining and reclamation to evaluate changes in aquatic life. Proper monitoring would enable timely detection of any adverse trends and allow timely implementation of any necessary corrective measures.

- Promote the protection or restoration of perennial and intermittent streams and related resources, especially the headwater streams that are critical to maintaining the ecological health and productivity of downstream waters.
- Ensure that permittees and regulatory authorities make use of advances in information, technology, science, and methodologies related to surface and groundwater hydrology, surface-runoff management, stream restoration, soils, and revegetation, all of which relate directly or indirectly to protection of water resources.
- Ensure that land disturbed by surface coal mining operations is restored to a condition capable of supporting the uses that it was capable of supporting before mining. Soil characteristics and the degree and type of revegetation have a significant impact on surface-water runoff quantity and quality as well as on aquatic life and the terrestrial ecosystems dependent upon perennial and intermittent streams.
- Update and codify requirements and procedures to protect threatened and endangered species and designated critical habitat under the Endangered Species Act of 1973 (16 U.S.C. 1531 et seq), and better explain how the fish and wildlife protection and enhancement provisions of SMCRA should be implemented.

As with the existing regulations, implementation of the revised regulations would be the responsibility of the applicable regulatory authority. OSMRE is headquartered in Washington, D.C. and is the regulatory authority in the states of Tennessee and Washington, and on Indian lands. All other coal-producing states have received approval of their proposed regulatory programs and thus function as the regulatory authorities in their respective states. OSMRE has oversight responsibility of the states' implementation of their OSMRE-approved regulatory programs. When a state or Indian tribe submits and receives approval of its proposed regulatory program from us, it becomes the primary regulator within that state or on reservation lands, respectively, and assumes responsibility over permitting, inspection, and enforcement activities. OSMRE then provides oversight of the state's or tribe's implementation of the regulatory program, technical assistance and support.

The proposed action would also help fulfill OSMRE's responsibilities under a Memorandum of Understanding (MOU) that the Secretary of the Department of the Interior, the Administrator of the U.S. Environmental Protection Agency (EPA), and the Acting Assistant Secretary of the Army (Civil Works) entered into on June 11, 2009. This MOU, referred to in this FEIS as the CWA MOU from this point forward, implemented an interagency action plan designed to significantly reduce the harmful environmental consequences of surface coal mining operations in six Appalachian states, while ensuring that future mining remains consistent with federal law. Specifically, Part III.A of the CWA MOU provides that the parties to the CWA MOU will review "existing regulatory authorities and procedures to determine whether regulatory modifications should be proposed to better protect the environment and public health from the impacts of Appalachian surface coal mining." It also provides that, at a minimum, revisions will be considered to the Stream Buffer Zone (SBZ) Rule published December 12, 2008 and the regulatory requirements concerning approximate original contour.

Finally, the proposed action is intended to balance all relevant purposes of the Act, as listed in Section 102 of SMCRA, 30 U.S.C. § 1202. Those purposes include ensuring that surface coal mining operations are conducted in a manner that protects the environment, establishing a nationwide program to protect society and the environment from the adverse effects of surface coal mining operations, and ensuring a coal supply adequate for our Nation's energy needs.

ES.2 Public Involvement

On November 30, 2009, OSMRE published an Advance Notice of Proposed Rulemaking (ANPR) soliciting comments on ten potential rulemaking Alternatives. Approximately 32,750 comments were received during the 30-day comment period on various issues related to stream protection. After evaluating the comments, it was determined that development of a comprehensive Stream Protection Rule (SPR) (one that is much broader in scope than OSMRE's 2008 SBZ rule) would be the most appropriate and effective method of achieving the goals set forth in the CWA MOU and the ANPR. OSMRE published a notice of intent (NOI) to prepare an EIS in the *Federal Register* on April 30, 2010 (75 FR 22723) followed by an additional notice on June 18, 2010 (75 FR 34666). The additional notice informed the public of scoping opportunities to include open houses and to outline possible Alternatives that were being considered. Approximately 400 people attended the open houses and provided almost 450 written and oral comments. In addition, 20,126 comments were received through the mail and website. The scoping period closed July 30, 2010.

Most comments were specific to the elements of the Proposed Rule and possible Alternatives set out in the June 18, 2010 NOI. Some commenters recommended clarifications to existing rules as opposed to a new rulemaking, made suggestions pertaining to specific elements or Alternatives within the Proposed Rulemaking, or raised new issues or rule elements for consideration.

Comments were generally divided into two categories: (1) comments in support of rule revisions that would provide greater environmental protection for streams and other natural resources; and (2) comments that support the adequacy of the existing regulations. Some commenters favoring greater environmental protections advocated interpretation of the 1983 Stream Buffer Zone Rule as an absolute prohibition on stream impacts. This group of comments described the 1983 rules as a bright-line prohibition against any adverse impacts within the stream buffer zone, although the courts have not always agreed with this interpretation by the commenters as explained below in the scope section. Other comments suggested that this FEIS assess the effects of an Alternative that would ban surface mining of coal in or near streams.

Comments that opposed changes to current rules asserted that additional regulation would impair mining operations, increase costs, endanger jobs at a time of high unemployment, and provide little, if any, additional protection for the environment. Some comments questioned OSMRE's authority under SMCRA to adopt certain measures under consideration. Others asserted that OSMRE had failed to articulate a need for new regulations so soon after adopting the 2008 Stream Buffer Zone Rule.

Some comments from the coal-producing regions of the Midwest and the West also questioned the need to promulgate a nationwide Stream Protection Rule, arguing that there is no evidence of adverse impacts on streams outside of Appalachia. These comments also argued that because of regional differences, many elements under consideration would be inapplicable, cumbersome, costly, or impractical to apply outside Appalachia.

On July 16, 2015, OSMRE announced that the Proposed Rule, Draft EIS (DEIS), and Draft Regulatory Impact Analysis (RIA) were available for review at www.regulations.gov, on our website (www.osmre.gov), and at selected OSMRE offices. On July 17, 2015, OSMRE published a notice in the Federal Register announcing the availability of the DEIS for the Proposed Rule. See 80 FR 42535-42536. The notice reiterated that the DEIS was available for review at www.regulations.gov, www.osmre.gov, and the OSMRE offices listed in the notice. The comment period for the DEIS was originally scheduled to close on September 15, 2015. On July 27, 2015, OSMRE also published the Proposed Stream Protection Rule in the Federal Register. See 80 FR 44436-44698. That document reiterated that the Proposed Rule, DEIS, and Draft RIA were available for review at www.regulations.gov, www.osmre.gov, and the OSMRE offices listed in the notice. The comment period for the Proposed Rule and Draft RIA was originally scheduled to close on September 25, 2015. In response to requests for additional time to review and prepare comments on all three documents, OSMRE extended the comment period for the Proposed Rule, DEIS, and Draft RIA through October 26, 2015. See 80 FR 54590-54591 (Sept. 10, 2015).

Interested parties, therefore, received a total of 102 days to review the Proposed Rule and supporting documents. During that time, OSMRE also held six public hearings in Colorado, Kentucky, Missouri, Pennsylvania, Virginia, and West Virginia. OSMRE received approximately 95,000 comments from all sources on the Proposed Rule, DEIS, and Draft RIA.

ES.3 Scope of the Proposed Stream Protection Rule

Historically, OSMRE and some state regulatory authorities applied the 1983 stream buffer zone rule in a manner that allowed the placement of excess spoil fills, refuse piles, slurry impoundments, and sedimentation ponds in intermittent and perennial streams within the permit area. However, as discussed at length in the preamble to a 2004 Proposed Rule (see 69 FR 1038-1042 (Jan. 7, 2004)), which OSMRE never finalized, there has been considerable controversy over the proper interpretation of both the Clean Water Act and our 1983 rules as they apply to the placement of fill material in or near perennial and intermittent streams.

One interpretation of the 1983 stream buffer zone rules appears in our annual oversight reports for West Virginia for 1999 and 2000, which state that the stream buffer zone rule does not apply to the footprint of a fill placed in a perennial or intermittent stream as part of a surface coal mining operation. On June 4, 1999, in West Virginia Highlands Conservancy v. Babbitt, Civ. No. 1:99CV01423 (D.D.C.), the plaintiffs challenged the validity of that interpretation, alleging that it constituted rulemaking in violation of the Administrative Procedure Act.

However, on August 9, 1999, OSMRE, the U.S. Army Corps of Engineers, EPA, and the West Virginia Division of Environmental Protection (WVDEP) signed a MOU in which all four agencies in effect agreed to an interpretation that allowed valley fills in intermittent or perennial streams to be approved only if the buffer zone findings were made for the filled stream segments. The MOU, referred to in this FEIS from this point forward as the WV MOU, also stated that the Clean Water Act Section 404(b)(1) Guidelines at 40 CFR part 230 contain requirements comparable to the findings required by the combination of OSMRE's 1983 stream buffer zone rule and the West Virginia stream buffer zone rule. Consequently, the WV MOU found that, "where a proposed fill is consistent with the requirements of the Section 404(b)(1) Guidelines and applicable requirements for Section 401 certification of compliance with water quality standards, the fill would also satisfy the criteria for granting a stream buffer zone variance under SMCRA and WVDEP regulations."[1] As a result of the signing of the WV MOU, the court approved an unopposed motion to dismiss the case mentioned above[2] as moot in an order filed September 23, 1999.

In a lawsuit filed in the U.S. District Court for the Southern District of West Virginia in July 1998, plaintiffs asserted that the 1983 stream buffer zone rule should be interpreted to allow mining activities through a perennial or intermittent stream or within the buffer zone for a perennial or intermittent stream only if the activities are minor incursions.[3] They argued that the rule did not allow substantial segments of a perennial or intermittent stream to be buried underneath excess spoil fills or other mining-related structures.[4] On October 20, 1999, the district court ruled in favor of the plaintiffs on this point, holding that the West Virginia version of the stream buffer zone rule applies to all segments of a stream, including those segments within the footprint of an excess spoil fill, not just to the stream as a whole.[5] The court stated that the construction of fills in perennial or intermittent streams is inconsistent with the language of the West Virginia counterpart to 30 CFR 816.57(a)(1), which provides that the regulatory authority may authorize surface mining activities within a stream buffer zone only after making certain findings, including a finding that the proposed activities would not "adversely affect the normal flow or gradient of the stream, adversely affect fish migration or related environmental values, materially damage the water quantity or quality of the stream…."[6] The court also concluded that, contrary to the August 1999 WV MOU, satisfaction of the Section 404(b)(1) Guidelines is not equivalent to satisfaction of the SMCRA buffer zone rule.[7]

On appeal, the U.S. Court of Appeals for the Fourth Circuit vacated the judgment of the district court and remanded the case with instructions to dismiss the counts concerning the stream buffer zone rule as barred by the Eleventh Amendment to the U.S. Constitution. See Bragg v. West Virginia Coal Ass'n, 248 F.3d 275, 296 (4th Cir. 2001), cert. denied, 534 U.S. 1113 (2002). While the Fourth Circuit did not interpret the 1983 version of the stream buffer zone rule, the brief for the federal appellants in that case included another interpretation of the regulation in their brief. In sum, the federal appellants supported an

[6] Id. at 650-653, 661. In a related matter, a consent decree filed on January 3, 2000, and approved on February 17, 2000, stated that the West Virginia stream buffer zone rules only apply downstream from the toes of downstream faces of embankments of sediment control structures in perennial and intermittent streams. Bragg v. Robertson, 83 F. Supp. 2d 713, 718 n.4 (S.D. W. Va. 2000).

[7] Id. at 660.

interpretation based on the district court decision and stated that 30 CFR 816.57 "prohibits the burial of substantial portions of intermittent and perennial streams beneath excess mining spoil."[8]

In a different case related to the issuance of a nationwide section 404 permit under the Clean Water Act, the U.S. District Court for the Southern District of West Virginia stated in an opinion that SMCRA and the 1983 stream buffer zone rule do not authorize disposal of overburden in streams: "SMCRA contains no provision authorizing disposal of overburden waste in streams, a conclusion further supported by the buffer zone rule."[9] Yet, on appeal, the U.S. Court of Appeals for the Fourth Circuit rejected the district court's conclusion, stating that "SMCRA does not prohibit the discharge of surface coal mining excess spoil in waters of the United States."[10] The court further stated that "it is beyond dispute that SMCRA recognizes the possibility of placing excess spoil material in waters of the United States even though those materials do not have a beneficial purpose." [11]

In subsequent litigation, the federal appellants stated that "OSM[RE] has historically interpreted its 'stream buffer zone' rule . . . to allow for the construction of valley fills in intermittent and perennial streams, even if such fills cover a stream segment. The traditional interpretation of the [stream buffer zone] is in harmony with this Court's decision in Rivenburgh."[12] Additionally, the U.S. Court of Appeals for the Fourth Circuit has discussed SMCRA's role in the regulation of valley fills in the context of a challenge to individual permits under section 404 of the Clean Water Act.[13] See Ohio Valley Envtl. Coal. v. Aracoma Coal Co., 556 F.3d 177, 195 (4th Cir. 2009) ("Congress clearly contemplated that the regulation of the disposal of excess spoil and the creation of valley fills falls under the SMCRA rubric.").

By 2004, OSMRE had concluded that "[t]he issues and allegations raised indicate that there remains considerable misunderstanding regarding the meaning of the [1983 stream buffer zone] regulation . . . particularly as it applies to the placement of excess spoil fills within and near intermittent and perennial streams." *See* 69 Fed. Reg. 1,038-40. As a result it began a rulemaking effort to replace the 1983 SBZ rule, which resulted in adoption of a new stream buffer zone rule in 2008 (73 Fed. Reg. 75,818 (the 2008 rule)).

The 2008 SBZ rule was immediately challenged by 10 environmental groups in two lawsuits. In July 2013, the government moved for partial summary judgment on the grounds that it had failed to comply with the Endangered Species Act (ESA) when it adopted the rule. In the context of briefing that motion, the National Mining Association (NMA) recognized the confusion created by the 1983 SBZ rule:

[13] 33 U.S.C. 1344.

"Vacating the entire [2008 SBZ] Rule would undo the clarification it provides on non-ESA issues and return the regulatory program to its previous confused and uncertain state, which would remain in place for years to come until OSM[RE] issues a new notice of proposed rulemaking (currently promised for 2014) and, eventually, a new final rule." Brief of the Intervenor-Defendant at 32-33, *Nat'l Parks Conservation Ass'n v. Jewell*, 2014 U.S. Dist. LEXIS 152383 (D.D.C. Aug. 30, 2013) (No. 09-115). Despite NMA's protest, on February 20, 2014, the district court vacated the 2008 SBZ rule and reinstated the 1983 version. *Nat'l Parks Conservation Ass'n v. Jewell*, 2014 U.S. Dist. LEXIS 152383 at *31, *35 (D.D.C. Feb. 20, 2014)). The court in that case did not discuss any interpretation of the 1983 SBZ rule and instead focused on OSMRE's failure to comply with the Endangered Species Act.

Although the 2008 Stream Buffer Zone Rule that was in place when the 2009 ANPR was published has since been vacated (*NPCA v. Jewell*, No. 09-115, Memorandum Decision at 13-14 (D.D.C. Feb. 20, 2014)), and the prior rules have been reinstated, the conclusion that a comprehensive Stream Protection Rule is needed is still valid. Through the process of considering comments received on the Proposed Rulemaking and issues identified during scoping, it was determined that improved protection of the hydrologic balance, especially streams, fish, wildlife, and related environmental values is needed throughout the country. One of the reasons SMCRA was enacted was to ensure a minimum level of environmental protection nationwide by establishing national surface coal mining and reclamation standards to prevent competition for coal markets from undermining the ability of states to maintain adequate regulatory programs for coal mining operations within their borders. See Section 101(g) of SMCRA, 30 U.S.C. § 1201(g). Thus, OSMRE concluded that a nationwide rule is required.

Both the 2008 Stream Buffer Zone Rule and its predecessors focused primarily on activities in or within 100 feet of the stream itself and, in the case of the 2008 rule, on minimization of excess spoil creation and limiting the footprint of excess spoil fills. Yet, mining activities beyond the 100-foot stream buffer zone can have significant impacts on the quality and quantity of water in streams by disturbing aquifers and altering the physical and chemical nature of recharge zones, as well as surface-water runoff rates, drainage patterns, and fish, wildlife, and related environmental values.

Thus, there are many components of our regulations, not just the ones related to stream buffer zones, that could be revised to improve implementation of SMCRA with regard to stream protection and conservation of fish, wildlife, and related environmental values. In particular, six areas have been identified in which regulations to better protect streams and associated environmental values have been proposed.

First, there is a need to clearly define the point at which adverse mining-related impacts on both groundwater and surface water reach an unacceptable level; that is, the point at which adverse impacts from mining cause material damage to the hydrologic balance outside the permit area. Neither SMCRA nor the existing regulations define the term "material damage to the hydrologic balance outside the permit area" or establish criteria for determining what level of adverse impacts would constitute material damage. In particular, there is no requirement that the SMCRA regulatory authority establish a specific standard for conductivity or selenium, both of which can have deleterious effects on aquatic life at elevated levels.

Second, there is a need to collect adequate premining data about the site of the proposed mining operation and adjacent areas to establish a comprehensive baseline that will facilitate evaluation of the effects of mining. The existing rules require data only for a limited number of water-quality parameters rather than the full suite needed to establish a complete baseline against which the impacts of mining can be compared. The existing rules also contain no requirement for determining the biological condition of streams within the proposed permit and adjacent areas, so there is no assurance that the permit application will include baseline data on aquatic life.

Third, there is a need for effective, comprehensive monitoring of groundwater and surface water during and after both mining and reclamation and during the revegetation responsibility period to provide real-time information documenting mining-related changes in the values of the parameters being monitored. Similarly, there is a need to require monitoring of the biological condition of streams during and after mining and reclamation to evaluate changes in aquatic life. Proper monitoring will enable timely detection of any adverse trends and timely implementation of any necessary corrective measures. The existing rules require monitoring of only water quantity and a limited number of water-quality parameters, not all parameters necessary to evaluate the impact of mining and reclamation. The existing rules do not ensure that the number and location of monitoring points will be adequate to determine the impact of mining and reclamation. They also allow discontinuance or reduction of water monitoring too early to ascertain the impacts of mining and reclamation on water quality with a reasonable degree of confidence, especially for groundwater.

Fourth, there is a need to ensure protection or restoration of streams and related resources, including the headwater streams that are important to maintaining the ecological health and productivity of downstream waters. The existing rules have not always been applied in a manner sufficient to ensure protection or restoration of streams, especially with respect to the ecological function of streams. Maintenance, restoration, or establishment of streamside vegetative corridors or buffers, comprised of native species, for streams is a critical element of stream protection. In forested areas, riparian buffers for streams moderate the temperature of water in the stream, provide food (in the form of fallen leaves and other plant parts) for the aquatic food web, roots that stabilize stream banks, reduce surface runoff, and filter sediment and nutrients in surface runoff.

Fifth, there is a need to ensure that permittees and regulatory authorities make use of advances in information, technology, science, and methodologies related to surface and groundwater hydrology, surface-runoff management, stream restoration, soils, and revegetation, all of which relate directly or indirectly to protection of water resources.

Sixth, there is a need to ensure that land disturbed by surface coal mining operations is restored to a condition capable of supporting the uses that it was capable of supporting before any mining, including both those uses dependent upon stream protection or restoration and those uses that promote or support protection and restoration of streams and related environmental values. Existing rules and permitting practices have focused primarily on the land's suitability for a single approved postmining land use and they have not always been applied in a manner that results in the construction of postmining soils that provide a growth medium suitable for restoration of premining site productivity. A corollary need is to ensure that reclaimed mine sites are revegetated with native species unless and until a conflicting postmining land use, such as intensive agriculture, is implemented. Soil characteristics and the degree and type of revegetation have a major impact on surface-water runoff quantity and quality as well as on aquatic life and the terrestrial ecosystems dependent upon perennial and intermittent streams. Under the existing rules, sites with certain postmining land uses have been revegetated with non-native species even when the postmining land use is not implemented prior to final bond release and even on those portions of the site where non-native species are not necessary to achieve the postmining land use.

These needs form the basis for our development of a reasonable range of Alternatives for the Proposed Stream Protection Rule. Nine Alternatives were carried forward for analysis in the FEIS, including the No Action Alternative and the Preferred Alternative. The Alternatives consist of a spectrum of combinations of the rule elements, with each Alternative including shared characteristics with other Alternatives but differing in some aspects of new requirements or the degree of improvement to existing regulations.

The following sections briefly describe the No Action Alternative, the Preferred Alternative, and then provide a comparison of all nine Alternatives carried forward in the FEIS. The sections are organized into four major groups of rule elements: protection of the hydrologic balance, activities in or near streams, approximate original contour (AOC) and AOC variances, and revegetation, topsoil, and fish and wildlife protection and enhancement.

Changes have occurred to the Preferred Alternative since the publication of the DEIS, and these are reflected in the summaries below. These changes were made after careful consideration of agency and public comment on the Proposed Rule, the DEIS, and the associated RIA. OSMRE also received comments on the other Alternatives presented in this EIS, as well as comments on potential Alternatives that OSMRE had not analyzed. The comments on the other Alternatives OSMRE considered were primarily questioning the practicality and cost of aspects of the Alternatives, and in many cases these comments also pertained to the Proposed Rule (the Preferred Alternative). No additional Alternatives were added to the EIS in response to comments for the reasons provided in the responses to comments (see the responses as included in Appendix K of this FEIS). In the year since the DEIS was published, OSMRE has taken a hard look at the body of comments received, and has coordinated closely with our federal and state regulatory partners to address concerns. As a result, OSMRE has determined that the Alternative 8 (Preferred), as revised, continues to provide the greatest effect towards reaching the objectives stated in the purpose and need for this rulemaking.

ES.4 Alternative 1 (No Action Alternative)

The No Action Alternative consists of the existing regulatory environment; it provides a baseline against which to compare the Action Alternatives. If the No Action Alterative is selected for implementation, no proposed regulatory revisions would be implemented. Thus, mining under this Alternative would continue to occur under our existing regulations. For reasons of brevity, OSMRE has described below only the requirements for surface coal mining operations. However, in most instances, analogous requirements apply to underground mining operations.

ES.4.1.1 Protection of the Hydrologic Balance (No Action Alternative)

ES.4.1.1.1 Baseline Data Collection and Analysis (No Action Alternative)

Under the current regulations, the applicant for a mining permit is required to submit, at a minimum, the following baseline information, and any additional hydrologic or geologic information required by the regulatory authority.[14]

Groundwater: Under 30 CFR 780.21, the applicant must submit data for existing wells, springs, and other groundwater resources within or adjacent to the proposed permit area. These data characterize the quality and quantity of groundwater and provide information on usage sufficient to demonstrate seasonal variation. Information on water quality must include total dissolved solids (TDS) or specific conductance, pH, total iron, and total manganese. Groundwater quantity information must include approximate rates of discharge or usage, as well as depth to the water in the coal seam, each water-bearing stratum above the coal seam, and each potentially affected stratum below the coal seam.

Surface water*:* Under 30 CFR 780.21, the applicant must submit information on surface water quality and quantity sufficient to demonstrate seasonal variation and water usage. At a minimum, water-quality information must include baseline information on total suspended solids (TSS), TDS or specific conductance, pH, total iron, and total manganese. The applicant must provide additional information on baseline acidity and alkalinity if there is a potential for acidic drainage from the proposed mining operation. Water quantity information must contain information on seasonal flow rates.

Geology*:* Under 30 CFR 780.22, the permit application must describe the geology of the proposed permit area and the adjacent area down to and including the deeper of either (1) the stratum immediately below the lowest coal seam to be mined or (2) any aquifer below that seam that could be adversely affected by mining. The description must include the areal and structural geology of the proposed permit area and the adjacent area. The description must also address other parameters that influence the required reclamation and the occurrence, availability, movement, quantity, and quality of potentially impacted surface water and groundwater. The geologic information must also include analyses of samples collected from test borings, drill cores, or samples from rock outcrops from the permit area. This requirement includes lithologic characterization and chemical analysis of strata and the coal seam for acid-forming or toxic-forming materials (including total sulfur, pyritic sulfur, and alkalinity-producing materials). The regulatory authority may waive analysis for alkalinity-producing materials and pyritic sulfur if sufficient data exists to document that the data is not needed.

ES.4.1.1.2 Monitoring During Mining and Reclamation (No Action Alternative)

The current regulations at 30 CFR 780.21(i) and (j) and 816.41(c) and (e) require monitoring of the quantity and quality of surface water and groundwater. The monitoring plan must include parameters related to the suitability of the water for current and approved postmining land uses, the hydrologic reclamation plan, and (for surface water) the effluent limitations in 40 CFR Part 434. At a minimum, pH,

[14] Unless otherwise specifically stated, the term "regulatory authority" as used in this EIS refers to the SMCRA regulatory authority.

total iron, total manganese, TDS or specific conductance, water levels (for groundwater), flow (for surface water), and TSS (for surface water) must be monitored every three months until final bond release. The permittee must monitor point-source discharges in accordance with their National Pollutant Discharge Elimination System (NPDES) permit. The monitoring plan must identify the monitoring locations, but the regulations do not establish criteria for the number or placement of monitoring locations.

The regulatory authority may modify or waive the monitoring requirements at any time if the permittee demonstrates that monitoring, in whole or in part, is no longer necessary to achieve the purposes set forth in the monitoring plan; that the operation has minimized disturbance to the hydrologic balance within the permit area and prevented material damage to the hydrologic balance outside the permit area; that water quality and quantity are suitable to support the approved postmining land uses; and that the water rights of other users have been protected or adequately replaced. However, the regulatory authority may not modify or waive NPDES monitoring requirements.

ES.4.1.1.3 Definition of Material Damage to the Hydrologic Balance Outside the Permit Area (No Action Alternative)

The current regulations do not define material damage to the hydrologic balance outside the permit area. However, the preamble to existing 30 CFR 780.21(g) and 784.14(f) states that "because the gauges for measuring material damage may vary from area to area and from operation to operation," OSMRE has not established fixed criteria, except for those established under §§ 816.42 and 817.42 related to compliance with water quality standards and effluent limitations (48 FR 43973, Sept. 26, 1983). OSMRE further noted in the preamble to the existing rules that each regulatory authority should establish criteria to measure material damage to the hydrologic balance for purposes of cumulative hydrologic impact assessments (48 FR 43973, Sept. 26, 1983). Most state regulatory programs have not defined this term.

ES.4.1.1.4 Evaluation Thresholds (No Action Alternative)

The current regulations contain no requirement for specific evaluation thresholds. However, permit applicants proposing to conduct surface or underground coal mining are required under § 780.21(h) or § 784.14(g) respectively, to provide a plan of measures the applicant would take to avoid adverse potential adverse hydrologic consequences, including preventative and remedial measures. Under 30 CFR 816.41(c)(2) and (e)(2) and 817.41(c)(2) and (e)(2), if monitoring results demonstrate noncompliance with permit conditions or federal, state, or tribal water quality laws and regulations, the permittee must promptly notify the regulatory authority. The applicant must then take all possible steps to minimize any adverse impact to the environment or public health and safety, and must immediately implement measures necessary to comply with permit condition (30 CFR 773.17(e)).

ES.4.1.2 Activities in or Near Streams (No Action Alternative)

ES.4.1.2.1 Stream Definitions (No Action Alternative)

The current regulatory definitions of perennial, intermittent, and ephemeral streams use hydrologic characteristics and watershed size to define these waters (30 CFR 701.5). The current definitions do not include biological or chemical characteristics.

- Under the current regulations, a perennial stream is a stream or part of a stream that flows continuously during all of the calendar year because of groundwater discharge or surface runoff.
- An intermittent stream is (1) a stream or reach of a stream that drains a watershed of at least one square mile, *or* (2) a stream or reach of a stream that is below the local water table for at least some part of the year, and obtains flow from both surface runoff and groundwater discharge.
- An ephemeral stream is a stream that flows only in direct response to precipitation in the immediate watershed or in response to the melting of a cover of snow and ice, and which has a channel bottom that is always above the local water table.

The definition in the second bullet has sometimes been incorrectly interpreted as if the "or" was an "and;" i.e., the one-square-mile criterion has sometimes been applied as a threshold for all intermittent streams, when, in fact, a stream in a smaller watershed that meets the second criterion is an intermittent stream regardless of the size of its watershed.

ES.4.1.2.2 Activities in or near Streams (Including Disposal of Excess Spoil and Coal Mine Waste Facilities) (No Action Alternative)

The 1983 SBZ rule, 30 CFR 816.57, which is now back in effect (see 79 FR 76227-76233 (Dec. 22, 2014)), provides that mining activities may not disturb land within 100 feet of a perennial or an intermittent stream unless the regulatory authority specifically authorizes activities closer to, or through, such a stream. The regulatory authority may authorize such activities only after finding that the proposed activities would not cause or contribute to a violation of applicable federal or state water quality standards under the Clean Water Act and would not adversely affect the water quantity and quality or other environmental resources of the stream.

The 1983 SBZ rule does not specifically mention placement of excess spoil and coal mine waste in or within 100 feet of streams, but OSMRE and most state regulatory authorities generally have applied the 1983 SBZ rule in a manner that allows the construction of excess spoil fills, refuse piles, slurry impoundments, and sedimentation ponds in all types of streams and their buffer zones.

The existing regulations at 30 CFR 816.71 through 816.74 require that excess spoil fills be constructed by controlled placement of the excess spoil in lifts no greater than four feet thick, except that durable rock fills may be constructed by end-dumping, which is intended to result in the formation of underdrains by gravity segregation.

In general, only surface coal mining operations in steep-slope terrain generate excess spoil. Although not expressly required by regulation, most states with mining operations in steep-slope terrain have adopted policies intended to minimize the generation of excess spoil and thus reduce the size of excess spoil fills, which in turn would reduce the length of stream covered by those fills. In addition, the agencies administering the Clean Water Act have implemented policies that have reduced both the number of excess spoil fills and the length of stream covered by those fills. Furthermore, the regulations in 40 CFR

Part 230 for implementation of section 404(b)(1) of the Clean Water Act require an analysis of all practicable alternatives to placement of fill material in waters of the United States, which would include most streams. Under those regulations, the applicant must select the Alternative with the least adverse effect on the aquatic ecosystem and mitigate any remaining adverse impacts on the aquatic environment.

ES.4.1.2.3 Mining Through Streams (No Action Alternative)

The 1983 version of the stream-channel diversion rules at 30 CFR 816.43 is now back in effect. Under 30 CFR 816.43(b)(1), the regulatory authority may approve diversion of perennial or intermittent streams within the permit area only after making the finding related to stream buffer zones in 30 CFR 816.57 that the diversion would not adversely affect the water quantity and quality and related environmental resources of the stream. Under 30 CFR 816.43(a), the applicant must design the diversion to minimize adverse impacts to the hydrologic balance within the permit and adjacent areas, prevent material damage to the hydrologic balance outside the permit area, and to assure the safety of the public. In addition, the applicant must design, locate, construct, maintain, and use the diversion to prevent, to the extent possible using the best technology currently available, additional contributions of suspended solids to streamflow outside the permit area.

Under 30 CFR 816.43(b)(4), both the design and construction of stream-channel diversions for perennial and intermittent streams must be certified by a qualified registered professional engineer as meeting applicable performance standards and any design criteria established by the regulatory authority. Under 30 CFR 816.43(a)(3), the design for restored stream channels for perennial and intermittent streams (or permanent diversion channels for those streams) must restore or approximate the premining characteristics of the original stream channel, including the natural riparian vegetation. Under 30 CFR 816.43(b)(2), the design capacity for both temporary and permanent stream-channel diversions must at least equal the capacity of the unmodified stream channel immediately upstream and downstream of the diversion.

ES.4.1.3 Approximate Original Contour (AOC) and AOC Variances (No Action Alternative)

ES.4.1.3.1 Surface Configuration (No Action Alternative)

Under existing 30 CFR 780.18(b) (3), each permit application must include a plan for backfilling, soil stabilization, and compacting and grading. Contour maps or cross-sections must show the anticipated final surface configuration. The performance standards at 30 CFR 816.102, 816.104, 816.105, 816.106, and 816.107 require that disturbed areas be backfilled and regraded to closely resemble the premining surface configuration, with exceptions for thin and thick overburden situations, previously mined areas, and certain other circumstances. The regulations allow permanent impoundments, including final-cut impoundments, provided they do not otherwise create conflicts with achieving AOC and they meet the design, construction, maintenance, postmining land use, and other requirements in 30 CFR 800.40(c)(2), 816.49(b), and 816.133.

ES.4.1.3.2 AOC Variances (No Action Alternative)

The current regulations provide for the approval of permits for mountaintop removal mining operations, which are exempt from AOC restoration requirements if the postmining land use and postmining surface topography requirements of paragraphs (3) and (4) of Section 515(c) of SMCRA are met. The regulations also provide for the approval of AOC variances for steep-slope mining operations under certain conditions.

As described in 30 CFR 785.14(b), mountaintop removal mining operations are surface mining activities in which the mining operation removes an entire coal seam or seams running through the upper fraction of a mountain, ridge or hill by removing substantially all of the overburden off the bench and creating a level plateau or gently rolling contour, with no highwalls remaining. To obtain a permit for mountaintop removal mining operations, the proposed postmining land use must be a commercial, industrial, residential, agricultural, or public facility land use. The regulatory authority must find that the proposed postmining land use meets all requirements for alternative postmining land uses and is an equal or better economic or public use of the land compared to its premining use. The permit application must include specific plans for the proposed postmining land use, including assurance of investment in public facilities and documentation of private financial capability to ensure completion. The current regulations do not require implementation of the approved postmining land use prior to final bond release or thereafter.

Under 30 CFR 824.11(a)(9), the regulatory authority may approve a permit for a mountaintop removal mining operation only upon a demonstration that there would be no damage to natural watercourses below the lowest coal seam to be mined. The regulations do not define the term "no damage." Natural watercourses above the lowest coal seam mined are not protected from damage.

Under 30 CFR 824.11(a) (6), the permittee must leave an outcrop barrier in place at the toe of the lowest coal seam mined to ensure stability.

As defined in 30 CFR 701.5, steep slopes are any slope of more than 20° or a lesser slope designated by the regulatory authority after consideration of soil, climate, and other characteristics of a region or State. To obtain an AOC variance for steep-slope mining operations under 30 CFR 785.16, the proposed postmining land use must be of an industrial, commercial, residential, or public (including recreational facilities) nature. It also must meet the requirements in 30 CFR 816.133 for approval of alternative postmining land uses, which, among other things, means that the postmining use must be an equal or better economic or public use. The applicant must demonstrate that the proposed operation will improve the watershed when compared to either premining conditions or the conditions that would exist if the applicant restored the area to AOC after mining. The regulatory authority can concur that the operation would improve the watershed only if the operation would reduce the amount TSS or other pollutants discharged from the permit area to surface water or groundwater *or* reduce the flood hazards within the watershed by a reduction of the peak-flow discharge from precipitation events or thaws. In both cases, the total volume of flow from the proposed permit area during every season of the year must not vary in a way that adversely affects the ecology of any surface water or any existing or planned use of surface water or groundwater.

ES.4.1.4 Revegetation, Topsoil, and Fish and Wildlife Protection and Enhancement (No Action Alternative)

ES.4.1.4.1 Revegetation, Reforestation and Topsoil Management (No Action Alternative)

Under 30 CFR 816.133(a), the permittee must restore all disturbed areas to a condition in which they are capable of supporting the uses that they were capable of supporting before any mining or higher or better uses.

Under 30 CFR 816.22, the permittee must salvage and redistribute all topsoil (the A and E soil horizons), unless alternative overburden materials are approved as being equal to or better than the existing available topsoil to support vegetation. The permittee also must demonstrate that the selected overburden materials they propose to use as topsoil substitutes and supplements are the best available material within the permit area. Paragraph (e) of 30 CFR 816.22 provides that the regulatory authority may require salvage and redistribution of the subsoil (the B and C soil horizons) or other underlying strata if it finds that those layers are necessary to comply with the revegetation performance standards in 30 CFR 816.111 through 816.116.

Paragraph (d) of 30 CFR 816.22 requires that the permittee redistribute topsoil and topsoil substitutes and supplements in a manner that achieves an approximately uniform, stable thickness when consistent with the approved postmining land use, contours, and surface water drainage systems. Soil thickness may vary to the extent necessary to meet the specific revegetation goals identified in the permit. The permittee also must redistribute soil materials in a manner that prevents excess compaction and protects the materials from wind and water erosion before and after seeding and planting.

Under 30 CFR 816.116, revegetation success standards must be based upon the effectiveness of the vegetation to support the approved postmining land use, the extent of ground cover compared to the cover provided by the natural vegetation of the area, and the general requirements of 30 CFR 816.111. These general requirements provide that the vegetative cover must be diverse, effective, and permanent; comprised of species native to the area (with certain exceptions); at least equal in extent of cover to the natural vegetation of the area; capable of stabilizing the soil surface from erosion; compatible with the postmining land use; have the same seasonal characteristics of growth as the original vegetation; be capable of self-regeneration and plant succession; be compatible with the plant and animal species of the area; and meet the requirements of state and federal laws and regulations concerning seeds, poisonous and noxious plants, and introduced species. The regulations provide exceptions to some of these requirements for agricultural crops and for plantings used to establish temporary cover.

ES.4.1.4.2 Fish and Wildlife Protection and Enhancement (No Action Alternative)

Under 30 CFR 780.16(a), each permit application must include fish and wildlife resource information for the proposed permit area and the adjacent area. The regulatory authority must determine the scope and level of detail of that information in consultation with state and federal agencies with responsibility for fish and wildlife. Paragraph (b) of 30 CFR 780.16 requires that the permit application also include a fish and wildlife protection and enhancement plan. Paragraph (c) of 30 CFR 780.16 requires that the regulatory authority provide the fish and wildlife resource information and the fish and wildlife protection and enhancement plan to the U.S. Fish and Wildlife Service (U.S. FWS) upon request.

Under the current regulations at 30 CFR 816.97(a), the mine operator must, to the extent possible using the best technology currently available minimize disturbances and adverse impacts to fish, wildlife, and related environmental values and enhance such resources where practicable.

Under 30 CFR 816.97(b), surface mining activities must not jeopardize the continued existence of endangered or threatened species or result in the destruction or adverse modification of designated critical habitats of such species in violation of the Endangered Species Act of 1973 (16 U.S.C. §§1531 to 1599). On September 24, 1996, the U.S. FWS issued a biological opinion and conference report to OSMRE (1996 biological opinion) on the continuation and approval and conduct of surface coal mining and reclamation operations under state and federal regulatory programs adopted pursuant SMCRA where such operations may adversely affect species listed as threatened or endangered or designated critical habitat under the Endangered Species Act (ESA). The 1996 biological opinion explains how this requirement is designed to be implemented; it also provides an incidental take statement. The 1996 biological opinion states that the regulatory authority must "implement and require compliance with any species-specific protective measures developed by the U.S. FWS field office and the regulatory authority (with the involvement, as appropriate, of the permittee and OSM[RE])." The 1996 biological opinion further provides that, "[w]henever the regulatory authority decides not to implement one or more of the species-specific measures recommended by the U.S. FWS, it must provide a written explanation to the U.S. FWS. If the U.S. FWS field office concurs with the regulatory authority's action, it would provide a concurrence letter as soon as possible. However, if the U.S. FWS does not concur, the issue must be elevated through the chain of command of the regulatory authority, the U.S. FWS, and (to the extent appropriate) OSM[RE] for resolution." OSMRE is coordinating with the U.S. FWS on a MOU, from this point forward in the FEIS to be referred to as the ESA MOU, to provide guidance to OSMRE, the U.S. FWS, and the regulatory authorities for demonstrating compliance with the terms and conditions of the Incidental Take Statement accompanying the 1996 biological opinion, which provides incidental take coverage for any take resulting from a proposed coal mining and reclamation operation. The ESA MOU, while still in development as of publication of this document, is part of the current regulatory environment because it adds no new requirements but instead merely provides guidance on existing ones.

Under 30 CFR 816.97(f), the permittee must avoid disturbances to wetlands and riparian vegetation along rivers and streams and bordering ponds and lakes; permittees must enhance where practicable, restore, or replace these resources. Likewise, surface mining activities must also avoid disturbances to habitats of unusually high value for fish and wildlife; these resources must be restored or enhanced where practicable.

Where fish and wildlife habitat is to be a postmining land use, 30 CFR 816.97(g) requires that the plant species to be used on reclaimed areas be selected based upon their proven nutritional value for fish or wildlife, their use as cover for fish or wildlife, and their ability to support and enhance fish or wildlife habitat after bond release. Paragraph (g) also requires that the plants selected be grouped and distributed in a manner that optimizes edge effect, cover, and other benefits to fish and wildlife.

The remaining paragraphs of 30 CFR 816.97 identify assorted other measures that permittees must implement during and after mining to minimize damage to fish and wildlife resources and their habitats or to ensure that all postmining land uses provide some fish and wildlife habitat or travel corridors to the extent practicable.

ES.5 Alternative 8 (Preferred Alternative)

The Preferred Alternative (Alternative 8 in the EIS) is comprised of selected primary stream protection and fish and wildlife conservation elements of the other Action Alternatives analyzed. These elements include: defining material damage to the hydrologic balance outside the permit area, enhancing baseline data collection, monitoring and regulatory authority review, requiring restoration of the ecological function of perennial and intermittent streams that are mined through, requiring fish and wildlife enhancements for perennial and intermittent stream reaches buried by excess spoil or coal mine waste, prohibiting mountaintop removal mining operations from damaging natural watercourses, and requiring reforestation of previously forested areas.

ES.5.1.1 Protection of the Hydrologic Balance (Preferred Alternative)

ES.5.1.1.1 Baseline Data Collection and Analysis (Preferred Alternative)

The Preferred Alternative (Alternative 8) requires that the applicant to obtain information on stream flow, sediment load, all rainfall/storm events, stream chemical, physical and hydrologic form and stream ecological function for streams as a baseline. The information required is summarized as follows:

- Surface water: The applicant must provide surface-water quantity descriptions for perennial and intermittent streams within the proposed permit and adjacent areas and collect surface water samples for 12 consecutive months at approximately equally spaced monthly intervals. Under the final version of the Preferred Alternative, OSMRE has revised the collection requirements (since initially proposed) to allow the applicant to modify the interval between samples to allow for adverse weather conditions that would make it unsafe to travel to sampling locations.
- Groundwater: The applicant must measure the levels of groundwater in perched, regional, and local aquifers within the proposed permit and adjacent areas at approximately equally spaced monthly intervals for a minimum of 12 consecutive months. As with surface waters under the final version of the Preferred Alternative, OSMRE has revised the requirements to allow the applicant to modify the interval between groundwater samples to allow for adverse weather conditions that would make it unsafe to travel to sampling locations. OSMRE has also revised this Alternative to allow the applicant, with regulatory authority approval, to measure groundwater levels on a quarterly basis instead of monthly, but this would extend the minimum data-gathering period to 24 consecutive months.
- Parameters: The applicant must analyze surface water and groundwater samples and expand the suite of parameters subject to analysis to include: temperature, aluminum, bicarbonate, sulfate, chloride, calcium, magnesium, sodium, potassium, hot acidity, total alkalinity, major anions and cations, pH, selenium, specific conductance, total dissolved solids (TDS), total iron, total manganese, total suspended solids, and any other parameter identified in any applicable National Pollutant Discharge Elimination System permit. Under the final version of the Preferred Alternative, OSMRE deleted the six parameters (ammonia, arsenic, cadmium, copper, nitrogen, zinc), which were previously requested by EPA in the Proposed Rule. Our research found that those parameters have little or no nexus to coal mining. However, OSMRE added temperature as a mandatory baseline data collection and monitoring parameter for both surface water and groundwater, and a requirement for the applicant to collect baseline (and monitoring) data for all parameters of concern, as determined by the regulatory authority, regardless of whether the regulations specifically identify those parameters.
- Form of streams: Under the final version of the Preferred Alternative, the applicant must provide a detailed description of stream channel characteristics for perennial and intermittent streams located within the proposed permit area. General descriptions are required for ephemeral stream channels located within the proposed permit area. OSMRE decided not to apply this requirement to streams within adjacent areas (as previously proposed under this Alternative) because it is only within the permit area that channel characteristics are likely to be altered by mining.
- Biological condition of streams: Under the final version of the Preferred Alternative, OSMRE has removed the requirement for measurement of the biological condition of ephemeral streams. For perennial streams, this Alternative requires use of a scientifically defensible bioassessment

protocol that will provide index values for both stream habitat and aquatic biota based on the reference condition. The protocol must be accepted by the agencies responsible for implementing the Clean Water Act and it must require identification of benthic macroinvertebrates to the genus level where possible, otherwise to the lowest practical taxonomic level. The same requirement applies to intermittent streams if scientifically defensible protocols have been developed for those streams. If no such protocols exist, the baseline data requires a description of the biology of each intermittent stream within the proposed permit area and each intermittent stream in the adjacent area that could be affected by the proposed operation.

- Wetlands: Under the final version of the Preferred Alternative, OSMRE has added a requirement that the permit applicant identify the extent and quality of wetlands adjoining all streams within the proposed permit area, and wetlands adjoining perennial and intermittent streams that occur in adjacent areas.
- Precipitation: The applicant is required to use continuous recording devices to record all precipitation and storm events to provide baseline data that is adequate to generate and calibrate a hydrologic model of the site. Under the final version of the Preferred Alternative, OSMRE is not adopting the proposed requirement that the regulatory authority extend the baseline data collection period if the Palmer Drought Severity Index for that period exceeded certain values. Historical data indicate that there are few 12-month periods in which the selected values would not exist for at least part of the time. Instead, the Preferred Alternative would require that the applicant identify the Palmer Drought Severity Index values for the period during which baseline data were collected. The regulatory authority then would have the discretion to determine whether and how long to extend the baseline data collection period under conditions of extreme drought or abnormally high precipitation.
- Geology: Requires collection of geologic data for the proposed permit and adjacent areas, with a focus on geological characteristics and properties that influence the hydrologic regime or that could alter the availability or quality of groundwater and surface water.

ES.5.1.1.2 Monitoring During Mining and Reclamation (Preferred Alternative)

As with the Preferred Alternative proposed in the DEIS, the Preferred Alternative continues to require monitoring of surface water and groundwater during mining and reclamation at least quarterly for the same parameters measured during baseline sampling at locations designated in the permit. As revised, the Preferred Alternative requires the applicant to monitor the biological condition of perennial streams and intermittent streams for which scientifically defensible bioassessment protocols exist annually until final bond release.

The Preferred Alternative now contains an additional requirement that the regulatory authority establish threshold values for water quality and quantity parameters that, when exceeded, as documented by monitoring, would result in an evaluation by the regulatory authority and the Clean Water Act authority to determine the reason for the exceedance. The Preferred Alternative continues to require that the permittee collect on-site precipitation measurements using self-recording rain gauges. Precipitation records must be adequate to generate and calibrate a hydrologic model of the site in the event the regulatory authority requires modeling.

Under the final Preferred Alternative, OSMRE has clarified that the regulatory authority must reevaluate the cumulative hydrologic impact assessment (CHIA) at intervals not to exceed three years. This evaluation must include a review of biological and water monitoring data from both this operation and all other coal mining operations within the cumulative impact area. The Preferred Alternative continues to require an inspection of the surface water runoff-control system following storm events that recur on a two-year or greater interval. The Preferred Alternative also continues to require the operator to submit a report after such an event that describes the performance of the hydraulic control structures, assesses and describes any potential material damage to the hydrologic balance, and addresses any remedial measures taken. In the Preferred Alternative, OSMRE has revised the requirement for how soon the regulatory authority must receive the report, from the previously proposed 48 hours to 30 days.

The Preferred Alternative continues to require that monitoring continue until final bond release. Under this Alternative, OSMRE added a requirement for restoration of the hydrologic function of mined-through perennial and intermittent streams before the regulatory authority may approve a Phase II bond release application. As proposed, the regulatory authority may not grant final Phase III bond release until the permittee demonstrates restoration of the ecological function of mined-through perennial and intermittent streams.

ES.5.1.1.3 Definition of Material Damage to the Hydrologic Balance Outside the Permit Area (Preferred Alternative)

The Preferred Alternative in the DEIS defined material damage to the hydrologic balance outside the permit area as any adverse impact from surface or underground mining operations, including subsidence, on the quantity or quality of surface water or groundwater, or on the biological condition of a perennial or intermittent stream, that would preclude attainment or continuance of any designated surface water use under sections 101(a) and 303(c) of the Clean Water Act or any existing or reasonably foreseeable use of surface water or groundwater outside the permit area. OSMRE has revised the Preferred Alternative definition of material damage to the hydrologic balance outside the permit area by removing all criteria and instead providing a list of factors that the regulatory authority, in consultation with the Clean Water Act authority, must consider in identifying material damage thresholds.

When selecting material damage thresholds, the revised Preferred Alternative requires that the regulatory authority, in consultation with the Clean Water Act authority as appropriate undertake a comprehensive evaluation that considers baseline data, the PHC determination, applicable water quality standards under the Clean Water Act, applicable state or tribal standards of surface water or groundwater, ambient water quality criteria developed under section 304(a) of the Clean Water Act, the biological requirements of species listed as threatened or endangered under the Endangered Species Act of 1973, and other pertinent information and considerations to identify the parameters for which thresholds are necessary. Thresholds may be either numeric or narrative, with the exception that, at the discretion of the Clean Water Act authority, numeric thresholds are required for relevant contaminants for which there are water quality criteria under the Clean Water Act. The intent of these changes is to ensure that the definition of this term does not foreclose the possibility of approving permits in watersheds with impaired streams, which could in turn drive mining into watersheds with higher quality streams.

ES.5.1.1.4 Evaluation Thresholds (Preferred Alternative)

The Preferred Alternative in the DEIS did not include a requirement for specific evaluation thresholds. Instead, the Preferred Alternative relied on existing regulations that require permit applicants proposing to conduct surface or underground coal mining under § 780.21(h) or § 784.14(g) respectively, to provide a plan of measures the applicant would take to avoid adverse potential adverse hydrologic consequences, including preventative and remedial measures. The Preferred Alternative in the DEIS also relied on existing requirements at 30 CFR 816.41(c)(2) and (e)(2) and 817.41(c)(2) and (e)(2) that state that if monitoring results demonstrate noncompliance with permit conditions or federal, state, or tribal water quality laws and regulations, the permittee must promptly notify the regulatory authority and then take all possible steps to minimize any adverse impact to the environment or public health and safety, and must immediately implement measures necessary to comply with permit conditions (30 CFR 773.17(e)).

In the Preferred Alternative, as revised, OSMRE has added a requirement that the permit include evaluation thresholds for critical water quality and quantity parameters as determined by the regulatory authority. An exceedance of an evaluation threshold, as documented by monitoring, would result in an evaluation by the regulatory authority and the Clean Water Act authority to determine the reason for the exceedance. If the evaluation determines that discharges from the mining operation were responsible for the exceedance and that exceedances are likely to reoccur in the absence of corrective action, the regulatory authority must issue a permit revision order requiring that the permittee reassess the PHC determination and the hydrologic reclamation plan and develop measures to prevent material damage to the hydrologic balance outside the permit area.

ES.5.1.2 Activities in or near Streams (Preferred Alternative)

ES.5.1.2.1 Stream Definitions (Preferred Alternative)

The Preferred Alternative as described in the DEIS redefined "perennial stream" in a manner that is substantively identical to the manner in which the U.S. Army Corps of Engineers (USACE) defines that term in Part F of the 2012 reissuance of the nationwide permits under section 404 of the Clean Water Act. See 77 FR 10184, 10288 (Feb. 21, 2012). In response to comments, OSMRE has revised the Preferred Alternative definitions of ephemeral, intermittent, and perennial streams to limit the scope of those terms to conveyances with channels that have a bed-and-bank configuration and an ordinary high water mark, which is consistent with the approach taken by the USACE in implementing section 404 of the Clean Water Act. This change means that our rules would no longer classify an ephemeral drainage that does not have a bed-and bank configuration and an ordinary high water mark as an ephemeral stream. In the final version of the Preferred Alternative, OSMRE clarifies that a stream with a bed that is always above the water table and with flows arising solely from snowmelt and precipitation events would be classified as ephemeral.

ES.5.1.3 Activities in or near Streams and Mining through Streams (Preferred Alternative)

In the DEIS, Alternative 8 (Preferred) would have prohibited mining activities in or through perennial and intermittent streams or on the surface of land within 100 feet of those streams unless the applicant makes certain demonstrations and the regulatory authority makes the corresponding findings listed below, that the proposed activity would not—

(1) Preclude attainment of the designated uses of that stream segment under section 101(a) or 303(c) of the Clean Water Act, 33 U.S.C. 1251(a) or 1313(c), before mining, or, if there are no designated uses, the premining uses of that stream segment; or

(2) Result in that stream segment not meeting the applicable anti-degradation requirements under section 303(c) of the Clean Water Act, 33 U.S.C. 1313(c), as adopted by a state or authorized tribe or as promulgated in a federal rulemaking under the Clean Water Act.

These requirements would apply to all mining activities except the construction of excess spoil fills and coal mine waste disposal facilities that cover perennial or intermittent streams (excess spoil fills and coal mine waste disposal facilities that extend into the buffer zone, but not the stream itself, are not exempt.)

As revised, Alternative 8 (Preferred) would prohibit mining activities in or through perennial and intermittent streams or on the surface of land within 100 feet of those streams unless the applicant makes the demonstrations and the regulatory authority makes the corresponding findings in Table ES.5-1.

Table ES.5-1.

Required Demonstrations for Activities in or within 100 feet of a Perennial or Intermittent Stream

1	2	3	4
When indicated in columns 2 through 4 of this table, your application must contain the demonstrations in column 1 if you propose to conduct surface mining activities in or through a perennial or intermittent stream or on the surface of land within 100 feet of a perennial or intermittent stream.	Any activity other than an activity listed in column 3 or column 4	Mining through or permanently diverting a stream	Construction of an excess spoil fill, coal mine waste refuse pile, or impounding structure that encroaches upon any part of a stream
(i) The proposed activity would not cause or contribute to a violation of applicable water quality standards adopted under the authority of section 303(c) of the Clean Water Act, 33 U.S.C. 1313(c), or other applicable state or tribal water quality standards.	Yes	Yes	Yes
(ii) The proposed activity would not cause material damage to the hydrologic balance outside the permit area.	Yes	Yes	Yes
(iii) The proposed activity would not result in conversion of the affected stream segment from perennial to ephemeral.	Yes	Yes	Not applicable

1	2	3	4
When indicated in columns 2 through 4 of this table, your application must contain the demonstrations in column 1 if you propose to conduct surface mining activities in or through a perennial or intermittent stream or on the surface of land within 100 feet of a perennial or intermittent stream.	Any activity other than an activity listed in column 3 or column 4	Mining through or permanently diverting a stream	Construction of an excess spoil fill, coal mine waste refuse pile, or impounding structure that encroaches upon any part of a stream
(iv) The proposed activity would not result in conversion of the affected stream segment from intermittent to ephemeral or from perennial to intermittent.	Yes	Yes, except as provided in paragraphs (e)(2) and (5) of this section	Not applicable
(v) There is no practicable alternative that would avoid mining through or diverting a perennial or intermittent stream.	Not applicable	Yes, except as provided in paragraph (e)(3) of this section	Yes
(vi) After evaluating all potential upland locations in the vicinity of the proposed operation, including abandoned mine lands and unreclaimed bond forfeiture sites, there is no practicable alternative that would avoid placement of excess spoil or coal mine waste in a perennial or intermittent stream.	Not applicable	Not applicable	Yes
(vii) The proposed operation has been designed to minimize the extent to which perennial or intermittent streams will be mined through, diverted, or covered by an excess spoil fill, a coal mine waste refuse pile, or a coal mine waste impounding structure.	Not applicable	Yes, except as provided in paragraphs (e)(3) and (5) of this section	Yes
(viii) The stream restoration techniques in the proposed reclamation plan are adequate to ensure restoration or improvement of the form, hydrologic function (including flow regime), streamside vegetation, and ecological function of the stream after you have mined through it, as required by § 816.57 of this chapter.	Not applicable	Yes, except as provided in paragraph (e)(5) of this section	Not applicable

1		2	3	4
When indicated in columns 2 through 4 of this table, your application must contain the demonstrations in column 1 if you propose to conduct surface mining activities in or through a perennial or intermittent stream or on the surface of land within 100 feet of a perennial or intermittent stream.		Any activity other than an activity listed in column 3 or column 4	Mining through or permanently diverting a stream	Construction of an excess spoil fill, coal mine waste refuse pile, or impounding structure that encroaches upon any part of a stream
(ix)	The proposed operation has been designed to minimize the amount of excess spoil or coal mine waste that the proposed operation will generate.	§ 780.35(b) of this part requires minimization of excess spoil	§ 780.35(b) of this part requires minimization of excess spoil	Yes
(x)	To the extent possible using the best technology currently available, the proposed operation has been designed to minimize adverse impacts on fish, wildlife, and related environmental values.	Yes	Yes	Yes
(xi)	The fish and wildlife enhancement plan prepared under § 780.16 of this part includes measures that would fully and permanently offset any long-term adverse impacts on fish, wildlife, and related environmental values within the footprint of each excess spoil fill, coal mine waste refuse pile, and coal mine waste impounding structure.	Not applicable	Not applicable	Yes
(xii)	Each excess spoil fill, coal mine waste refuse pile, and coal mine waste impounding structure has been designed in a manner that will not result in the formation of toxic mine drainage.	Not applicable	Not applicable	Yes
(xiii)	The revegetation plan prepared under § 780.12(g) of this part requires reforestation of each completed excess spoil fill if the land is forested at the time of application or if the land would revert to forest under conditions of natural succession.	Not applicable	Not applicable	Yes

Alternative 8 (Preferred) would require the applicant to demonstrate that (1) the operation has been designed to minimize, to the extent possible, the volume of excess spoil that the operation would generate and (2) the designed maximum cumulative volume of all proposed excess spoil fills is no larger than the

capacity needed to accommodate the anticipated cumulative volume of excess spoil that the operation would generate.

Under Alternative 8 (Preferred), the permittee must construct excess spoil fills in lifts not to exceed four feet in thickness. The use of end-dumping for final placement would be prohibited and the current regulation at 30 CFR 816.73 allowing construction of durable rock fills that rely upon end-dumping and the construction of underdrains by gravity segregation of the end-dumped material would be eliminated. This Alternative would require daily monitoring during excess spoil placement and that the quarterly inspection reports filed with the regulatory authority include the daily monitoring logs. Alternative 8 (Preferred) would prohibit the construction of excess spoil fills with flat decks on the top surface.

ES.5.1.4 Approximate Original Contour (AOC) and AOC Variances (Preferred Alternative)

ES.5.1.4.1 Surface Configuration (Preferred Alternative)

The Preferred Alternative is the same as Alternative 1, the No Action Alternative, with minor revisions to the definition of AOC to clarify its meaning, reflect state program amendment actions, and address implementation issues. Under the Preferred Alternative, AOC means that surface configuration achieved by backfilling and grading of the mined area so that the reclaimed area closely resembles the general surface configuration of the land within the permit area prior to any mining activities or related disturbances and blends into and complements the drainage pattern of the surrounding terrain. All highwalls and spoil piles must be eliminated to meet the terms of the definition, but that requirement does not prohibit the approval of terracing, the retention of access roads or the approval of permanent water impoundments. For purposes of this definition, the term “mined area” does not include excess spoil fills and coal refuse piles.

Alternative 8 (Preferred) also requires that the postmining drainage pattern of perennial, intermittent, and ephemeral stream channels be similar to the premining drainage pattern, unless the regulatory authority approves a different pattern to ensure stability; prevent or minimize downcutting of reconstructed stream channels; promote enhancement of fish and wildlife habitat; accommodate any anticipated temporary or permanent increase in surface runoff as a result of mining and reclamation; accommodate the construction of excess spoil fills, coal mine waste refuse piles, or coal mine waste impounding structures; replace a stream that was channelized or otherwise severely altered prior to submittal of the permit application with a more natural and ecologically sound drainage pattern or stream-channel configuration; or reclaim a previously mined area.

ES.5.1.4.2 AOC Variances (Preferred Alternative)

Alternative 8 (Preferred) would allow mountaintop removal mining operations and AOC variances for steep-slope mining operations under conditions generally similar to those in Alternative 1, the No Action Alternative. However, Alternative 8 (Preferred) would impose additional requirements to better protect streams, aquatic ecology, and biological communities. In addition, it would require that the permit include a condition prohibiting any bond release before substantial implementation of the approved postmining land use.

For approval of mountaintop removal mining operations, Alternative 8 (Preferred) would require the permit applicant to demonstrate that no damage would result to natural watercourses within the proposed permit and adjacent areas. The applicant can meet this requirement by making all of the following demonstrations:

- There would be no adverse changes in parameters of concern in discharges to surface water and groundwater;
- Flood hazards within the watershed containing the proposed permit area will be diminished by reduction of the size or frequency of peak-flow discharges from precipitation events or thaws.; and
- The total volume of flow during any season of the year would not vary from premining conditions; i.e., the seasonal flow regime would not change and there would be no increase in potential damage from flooding sufficient to adversely affect any designated use of surface water outside the proposed permit area under section 101(a) or 303(c) of the Clean Water Act, 33 U.S.C. 1251(a) or 1313(c), or, if there are no designated uses, any premining use of surface water outside the proposed permit area. Variations must also not adversely affect any premining use of groundwater outside the proposed permit area.
- The proposed operation would not result in any greater adverse impact to the aquatic and terrestrial ecology of the proposed permit and adjacent area than would occur if the area to be mined was restored to its approximate original contour.

In addition, the permittee must reforest the site with native species if the site was forested before submission of the permit application, unless reforestation would be inconsistent with the postmining land use. Finally, the permittee must install drains through the outcrop barrier to prevent saturation of the backfill.

For approval of steep-slope variances, Alternative 8 (Preferred) would, in addition to the requirements in the existing rules, require permit applicants to demonstrate that all of the following criteria are met:

- The operation, including any fish and wildlife enhancement measures, will result in fewer adverse impacts to the aquatic ecology of the cumulative impact area than would occur if the site were mined and restored to AOC;
- The variance would not result in construction of an excess spoil fill in an intermittent or perennial stream; and
- Any deviations from the premining surface configuration are necessary and appropriate to achieve the postmining land use.

In addition, the permittee must reforest the site with native species if the site was forested before submission of the permit application or would revert to forest under natural succession. This requirement would not apply to permanent impoundments, roads, and other impervious surfaces to be retained following mining and reclamation or to those portions of the permit area covered by the variance.

ES.5.1.5 Revegetation, Soils, Fish and Wildlife Protection and Enhancement (Preferred Alternative)

ES.5.1.5.1 Revegetation & Soils

Alternative 8 (Preferred) includes provisions similar to those of the No Action Alternative with respect to soil management and revegetation, but with a greater emphasis on restoration of the site's ability to support the uses it supported before any mining, regardless of the approved postmining land use. Alternative 8 (Preferred) also places greater emphasis on construction of a growing medium with an adequate root zone for deep-rooted species and on revegetation with native tree and plant species, especially reforestation of previously forested areas.

Like the No Action Alternative, Alternative 8 (Preferred) requires salvage and redistribution of all topsoil (the A and E soil horizons). However, it also requires salvage and redistribution of the B and C soil horizons (or other suitable overburden materials) to the extent necessary to achieve a growing medium with the optimal rooting depths required to restore premining land use capability or comply with revegetation requirements. Under the No Action Alternative, the regulatory authority has the discretion, but not necessarily the obligation, to require salvage and redistribution of the B and C soil horizons or other suitable overburden materials.

Alternative 8 (Preferred) allows use of selected overburden materials as substitutes for (or supplements to) either topsoil or subsoil or both only if the applicant demonstrates that either (1) the quality of the existing topsoil and subsoil is inferior to that of other overburden materials or (2) the quantity of the existing topsoil and subsoil is insufficient to provide the optimal rooting depth or meet other plant growth requirements. Alternative 8 (Preferred) differs slightly from the No Action Alternative in that the No Action Alternative allows the use of topsoil substitutes or supplements when the resulting soil medium will be equally or more suitable than the existing topsoil to sustain vegetation, while Alternative 2 allows their use only when the resulting soil medium will be more suitable to sustain vegetation.

Under Alternative 8 (Preferred), the permittee must salvage and redistribute all organic matter contained in or above the A soil horizon. Salvaging these materials would increase the moisture retention capability of the soil and provide a source of the seeds, plant propagules, mycorrhizae, and other soil flora and fauna needed to support and enhance reestablishment of locally adapted and genetically diverse plant communities as well as to improve soil productivity. The final version of Alternative 8 (Preferred) provides limited exceptions to the requirement for redistribution of salvaged organic material. The final version of Alternative 8 (Preferred) also requires that permit applications identify areas with substantial populations of invasive or noxious non-native species. The final version prohibits salvage and redistribution of organic materials from those areas. Instead, the operator must bury these materials at a depth sufficient to prevent regeneration.

Under Alternative 8 (Preferred), the permittee must reforest lands that were previously forested, or that would naturally revert to forest under conditions of natural succession, in a manner that would enhance recovery of the native forest ecosystem as expeditiously as possible. Prime farmland historically used for cropland is exempt from this requirement. The permittee must revegetate the entire reclaimed area (other than water areas and impervious surfaces like roads and buildings) using native species to restore or reestablish the plant communities native to the area unless a conflicting postmining land use is actually implemented before the end of the revegetation responsibility period.

ES.5.1.5.2 Fish and Wildlife Protection and Enhancement

Alternative 8 (Preferred) is similar to the No Action Alternative with respect to the protection of threatened and endangered species. At the DEIS stage, this Alternative would have included dispute resolution procedures in the regulations, codifying these procedures. In response to agency and public comment, OSMRE has removed this from the final version of the Preferred Alternative.[15] However, Alternative 8 (Preferred) would make it a requirement that the applicant demonstrate to the regulatory authority that the proposal is in compliance with the Endangered Species Act of 11973, 16 U.S.C. 1531 et seq. through one of the following mechanisms:

(1) Providing documentation that the proposed surface coal mining and reclamation operations within or adjacent to the permit area would have no effect on species listed or proposed for listing as threatened or endangered under the Endangered Species Act of 1973, 16 U.S.C. 1531 et seq., habitat occupied by those species, or on designated or proposed critical habitat, under that law; or

(2) Documenting compliance with a valid biological opinion that covers issuance of permits for surface coal mining operations and the conduct of those operations under the applicable regulatory program; or

(3) Providing documentation that interagency consultation under section 7 of the Endangered Species Act of 1973, 16 U.S.C. 1536, has been completed for the proposed operation; or

(4) Providing documentation that the proposed operation is covered under a permit issued pursuant to section 10 of the Endangered Species Act of 1973, 16 U.S.C. 1539.

Revised Alternative 8 (Preferred) requires that the applicant describe the steps that that applicant has taken or will take to comply with the Endangered Species Act of 1973, 16 U.S.C. 1531 et seq. It also provides that the regulatory authority may not approve the permit application before there is a demonstration of compliance with the Endangered Species Act of 1973, 16 U.S.C. 1531 et seq., through one of the mechanisms listed above.

Alternative 8 (Preferred) is similar to the No Action Alternative with respect to the fish and wildlife resource information and protection and enhancement plan required in the permit application. It also includes similar performance standards for protection of fish and wildlife. However, Alternative 8 (Preferred) requires that the permittee establish permanent streamside vegetative corridors at least 100 feet wide, comprised of native, non-invasive species, along the banks of restored or diverted ephemeral, intermittent or perennial stream channels.

In addition, fish and wildlife enhancement measures would be mandatory whenever the proposed operation would result in the long-term loss of native forest, loss of other native plant communities, or filling of a segment of a perennial or intermittent stream. The enhancement measures must be commensurate with the long-term adverse impact to the affected resources and they must be located in the same watershed as the proposed operation (or the nearest appropriate adjacent watershed if there are no opportunities for enhancement within the same watershed). Enhanced areas must be included within the

[15] OSMRE has undertaken formal Section 7 consultation with the U.S. FWS on the Preferred Alternative. The biological opinion, once issued, will be available on www.osmre.gov and on www.regulations.gov under the Stream Protection Rule docket. OSMRE is also coordinating with U.S. FWS to provide guidance to OSMRE, the U.S. FWS, and regulatory authorities for demonstrating compliance with the terms and conditions of the Incidental Take Statement that will accompany the biological opinion.

permit area.

At the DEIS stage, the Alternative 8 (Preferred) would have allowed the regulatory authority to prohibit mining of areas within the proposed permit area that are of such exceptional environmental value that any adverse mining-related impacts must be prohibited. In response to comments on the Proposed Rule, the final version of the Preferred Alternative does not include this authority. However, like the existing rules, this Alternative retains language intended to minimize adverse impacts to habitats of unusually high value to fish and wildlife.

ES.6 Comparison of all Alternatives Considered

In addition to the No Action Alternative and the Preferred Alternative, seven other Alternatives were analyzed in the FEIS. These Alternatives ranged from the most environmentally protective Alternative (Alternative 2) to Alternative 9, which would put the requirements of the 2008 SBZ rule back in place. Full descriptions of the Alternatives are contained in Chapter 2 of this FEIS. The following comparisons of the nine Alternatives by principal element provide the major similarities and differences between each of the Alternatives.

ES.7 Protection of the Hydrologic Balance Functional Group

ES.7.1.1 Baseline Data Collection and Analysis

ES.7.1.1.1 Biological Conditions

- The No Action Alternative (also Alternative 9) -- No requirement for baseline biological assessment;
- Alternative 2 (also 3, 4, 5, 6, and 8 (Preferred)) -- Baseline biological conditions assessment required; and
- Alternative 7 – Same as Alternative 2 when enhanced permitting requirements apply, otherwise same as the No Action Alternative.

ES.7.1.2 Hydrologic Conditions

ES.7.1.2.1 Water Quality

- The No Action Alternative (also Alternative 9) -- Limited water-quality sampling points and analytical constituents. At a minimum, the analytical suite for surface water and groundwater consists of the following: temperature, total suspended solids (only surface water), pH, specific conductance, total dissolved solids (TDS), total iron, and total manganese;
- Alternative 2 (also 3, 4, 5, and 6) -- Baseline water-quality data are required on all intermittent and perennial streams and a representative number of ephemeral streams. Twelve evenly spaced samples are required from a consecutive 12-month period. The analytical suite for surface water and groundwater consists of the following: temperature, total suspended solids (only surface water), aluminum, bicarbonate, sulfate, chloride, calcium, magnesium, sodium, potassium, (hot) acidity, alkalinity, pH, selenium, specific conductance, TDS, total iron, arsenic, zinc, copper, cadmium, ammonia, nitrogen, and total manganese;

- Alternative 7 – Same as Alternative 2 when enhanced permitting requirements apply, otherwise same as the No Action Alternative.
- Alternative 8 (Preferred) – Baseline water-quality data are required on all intermittent and perennial streams. Twelve evenly spaced samples are required from a consecutive 12-month period, or with regulatory authority approval on a quarterly basis for 24 consecutive months. The analytical suite for surface water must include both total and dissolved fractions of the parameters. The parameters for both ground and surface water include the following, at a minimum: temperature, total suspended solids (only surface water), bicarbonate, sulfate, chloride, calcium, magnesium, sodium, potassium, (hot) acidity, alkalinity, pH, selenium, specific conductance, TDS, total (surface water only) and dissolved iron, total (surface water only) and dissolved manganese. Does not specifically require analysis of ammonia, arsenic, cadmium, copper, nitrogen, aluminum or zinc.

ES.7.2.2 Surface Water Flow and Groundwater Levels

- The No Action Alternative (also Alternatives 3, 5, 8 (Preferred) and 9) -- Discrete stream flow and groundwater levels measurements required. Twelve evenly spaced samples required over a consecutive 12-month period;
- Alternative 2 (also 4 and 6) -- Continuous stream flow and groundwater levels measurements required; and
- Alternative 7 -- Same as Alternative 2 when enhanced permitting requirements apply, otherwise same as the No Action Alternative.

ES.7.1.2.3 Rainfall Measurements

- The No Action Alternative (also Alternative 9) -- No onsite rainfall measurements required;
- Alternative 2 (also 3, 4, 5, 6, and 8 (Preferred)) -- Continuous on-site rainfall measurement requirements; and
- Alternative 7 – Same as Alternative 2 when enhanced permitting requirements apply, otherwise same as the No Action Alternative.

ES.7.1.2.4 Stream Hydrologic Form and Ecological Function

- The No Action Alternative (also Alternative 9) -- No documentation required of stream hydrologic form and ecological function;
- Alternative 2 (also 3, 4, 5, 6, and 8 (Preferred)) --Documentation of stream hydrologic form and ecological function required; and
- Alternative 7 – Same as Alternative 2 when enhanced permitting requirements apply, otherwise same as the No Action Alternative.

ES.8 Monitoring During Mining and Reclamation

ES.8.1.1 Biological Monitoring

- The No Action Alternative (also Alternative 9) -- No requirements for monitoring of biological condition;
- Alternative 2 (also 3, 4, 5, 6, and 8 (Preferred)) --Annual monitoring of biological condition required; and
- Alternative 7 – Same as Alternative 2 when enhanced permitting requirements apply, otherwise same as the No Action Alternative.

ES.8.1.1.2 Water-Quality Monitoring

- The No Action Alternative (also Alternative 9) -- Monitoring for limited suite of analytes [temperature, total suspended solids (only surface water), pH, specific conductance, TDS, total iron, and total manganese] and the regulatory authority can release operator from monitoring before bond release;
- Alternative 2 (also 3, 4, 5, 6, and 8 (Preferred)) -- Quarterly monitoring until final bond; and
- Alternative 7 – Same as Alternative 2 when enhanced permitting requirements apply, otherwise same as the No Action Alternative.

ES.8.1.1.3 Rainfall Measurements

- The No Action Alternative (also Alternative 9) -- No requirement for on-site rainfall measurements;
- Alternative 2 (also 3, 4, 5, 6, and 8 (Preferred)) -- Continuous on-site rainfall measurements required; and
- Alternative 7 -- Same as Alternative 2 when enhanced permitting requirements apply, otherwise same as the No Action Alternative.

ES.8.1.1.4 Runoff Control Structures

- The No Action Alternative (also Alternative 9) -- Certification of drainage control structures not required;
- Alternative 2 (also 6) -- Inspect and certify surface runoff control structures by a professional engineer after every one-year return interval precipitation event;
- Alternative 3 (also 4, 5 and 8 (Preferred)) -- Inspect and certify surface runoff control structures by a professional engineer after every two-year return interval precipitation event; and
- Alternative 7 – Same as Alternative 2 when enhanced permitting requirements apply, otherwise same as the No Action Alternative.

ES.8.1.1.5 Regulatory Authority Hydrologic Data Review

- The No Action Alternative (also Alternative 9) -- No regularly scheduled hydrologic review required;
- Alternative 2 (also 3, 4, 5, and 6) -- Regulatory authority review of monitoring data at permit mid-term review and permit renewal;

- Alternative 7 – Same as Alternative 2 when enhanced permitting requirements apply, otherwise same as the No Action Alternative; and
- Alternative 8 (Preferred) – Regulatory authority review of monitoring data at three-year intervals.

ES.8.1.1.6 Definition of Material Damage to the Hydrologic Balance

- The No Action Alternative (also Alternatives 5, 6, 7 and 9) -- No national definition for material damage to the hydrologic balance. Regulatory authority discretion to determine material damage to the hydrologic balance criteria on case-by-case basis; and
- Alternative 2 (also 3 and 4) -- The term would be defined as any quantifiable adverse impact on the quality or quantity of surface water or groundwater or on the biological condition of intermittent and perennial streams that would preclude attainment or continuance of any designated surface-water use under sections 101(a) and 303(c) of the Clean Water Act or any existing or reasonably foreseeable use of surface water or groundwater outside the permit area. Includes areas overlying the underground workings of underground mines.
- Alternative 8 (Preferred) – Material damage to the hydrologic balance outside the permit area means an adverse impact, as determined in accordance with the rest of this definition, resulting from surface coal mining and reclamation operations, underground mining activities, or subsidence associated with underground mining activities, on the quality or quantity of surface water or groundwater, or on the biological condition of a perennial or intermittent stream. The determination of whether an adverse impact constitutes material damage to the hydrologic balance outside the permit area would be based on consideration of the baseline data and the following reasonably anticipated or actual effects of the operation:

    (1) Effects that cause or contribute to a violation of applicable state or tribal water quality standards or a state or federal water quality standard established for a surface water outside the permit area under section 101(a) or 303(c) of the Clean Water Act, 33 U.S.C. 1251(a) or 1313(c), or, for a surface water for which no water quality standard has been established, effects that cause or contribute to non-attainment of any premining use of surface water outside the permit area.
    (2) Effects that preclude a premining use of groundwater outside the permit area; or
    (3) Effects that result in a violation of the Endangered Species Act of 1973, 16 U.S.C. 1531 et seq.

ES.8.1.1.7 Evaluation Thresholds

- The No Action Alternative (also Alternatives 5, 6, and 9) -- No evaluation thresholds;
- Alternative 2 (also 3 and 4– Regulatory authority to develop evaluation thresholds that are less than the material damage to the hydrologic balance standards; and
- Alternative 7 – Same as Alternative 2 when enhanced permitting requirements apply, otherwise same as the No Action Alternative.
- Alternative 8 (Preferred) - Regulatory authority to develop evaluation thresholds for critical parameters in consultation with the Clean Water Act authority.

ES.9 Activities In or Near Streams Functional Group

ES.9.1.1 Stream Definitions

- The No Action Alternative (also Alternatives 3, 5, 6 and 9) -- No change in ephemeral, intermittent, and perennial stream definitions;
- Alternative 2 -- The definitions of intermittent, ephemeral, and perennial would be functionally replaced; all waterways defined as Waters of the U.S. under the CWA would be protected under this Alternative;
- Alternative 4 -- Streams defined based on flow and physical characteristics;
- Alternative 7 -- Existing definitions are not changed except that watershed size is not used as criteria to define intermittent streams; requires coordination with CWA authority; and
- Alternative 8 (Preferred) -- Stream definitions are defined in a way to limit the scope of those terms to conveyances with channels that have a bed-and-bank configuration and an ordinary high water mark, consistent with the approach taken by the USACE in implementing section 404 of the Clean Water Act.

ES.9.1.1.2 Activities in or near Streams, including Excess Spoil and Coal Refuse

- The No Action Alternative -- Prohibits mining activities through or within 100 feet of intermittent or perennial streams unless it can be demonstrated that the activity would not cause or contribute to the violation of applicable state or federal water quality standards and would not adversely affect the water quantity and quality or other environmental resources of the stream;
- Alternative 2 -- Prohibits surface mining activities in or within 100 feet of perennial streams. Prohibit surface mining activities in or within 100 feet of intermittent streams unless the applicant demonstrates that the activity would not: (1) preclude premining stream uses; (2) have more than a minimal adverse impact on the premining biological condition of the stream segment; or (3) cause material damage to the hydrologic balance outside the permit area. Requires a 100 foot forested streamside vegetative corridor for previously forested areas (or other native species for non-forested areas) adjacent to ephemeral or intermittent streams;
- Alternative 2 also prohibits placement of excess spoil within 100 feet of an intermittent stream (excess spoil placement is allowed in or near ephemeral streams). Under Alternative 2 disposal of coal mine waste in or within 100 feet of an intermittent or ephemeral stream is allowed;
- Alternative 3 (also 4 and 5) -- Prohibits surface mining activities in or within 100 feet of intermittent and perennial streams unless the applicant demonstrates that the activity would not: (1) preclude premining stream uses; (2) have more than a minimal adverse impact on the premining biological condition of the stream segment; or (3) cause material damage to the hydrologic balance outside the permit area;
- Alternative 6 --Prohibits mining activities within 100 feet of intermittent or perennial streams unless it can be demonstrated that: (1) the ecological function of the stream would be protected or restored; (2) placement of excess spoil fill or coal mine waste would not result in a discharge of "toxic mine drainage" and long-term adverse impacts to the environmental resources of the stream (within the footprint of the fill) would be offset in the same or adjacent watershed through fish and wildlife enhancement commensurate with the potential direct adverse impact to the stream; (3) other proposed mining activities within the stream buffer, but not within the stream

itself would not adversely affect the water quantity and quality or other environmental resources of the stream; (4) a 100-foot streamside vegetative corridor would be required along the entire reach (including ephemeral streams) of any restored stream;

- Alternative 7 -- Same as Alternative 2 when enhanced permitting requirements apply, otherwise same as the No Action Alternative;
- Alternative 8 (Preferred) – Prohibits mining activities within 100 feet of intermittent and perennial streams unless the applicant demonstrates that the proposed activity would meet specific criteria listed previously in Table ES.5-1; and
- Alternative 9 --Prohibits mining activities (other than construction of stream-channel diversions) within a perennial or intermittent stream unless the regulatory authority finds that avoiding disturbance of the stream is not reasonably possible.

Additionally,

- The No Action Alternative – Excess spoil minimization not expressly required by regulation;
- Alternative 2 (also 3, 4, 5, 6, 8 (Preferred) and 9) --The applicant must demonstrate that (1) the operation has been designed to minimize, to the extent possible, the volume of excess spoil that the operation would generate and (2) the designed maximum cumulative volume of all proposed excess spoil fills would be no larger than the capacity needed to accommodate the anticipated cumulative volume of excess spoil that the operation would generate; and
- Alternative 7 -- Same as Alternative 2 when enhanced permitting requirements apply, otherwise same as the No Action Alternative.

And also,

- The No Action Alternative (also 9) -- Durable rock fills may be constructed by end-dumping. Placement in streams is not expressly prohibited if all other applicable requirements are met;
- Alternative 2 (also 3, 4, 5, 6 and 8 (Preferred)) --The practice of “end-dumping” or creating a “durable rock fill” of fill material into streams is prohibited wherever a specific Alternative is applicable. In addition, daily monitoring and maintenance of daily log is required during fill construction; and
- Alternative 7 -- Same as Alternative 2 when enhanced permitting requirements apply, otherwise same as the No Action Alternative.

ES.9.1.1.3 Mining Through Streams

- The No Action Alternative -- Allows diversion of intermittent and perennial streams upon regulatory authority finding that the diversion would not adversely affect the water quantity and quality and related environmental resources of the stream;
- Alternative 2 (also 4) -- No mining activities allowed in or within 100 feet of a perennial stream. Mining allowed through all intermittent streams upon demonstration by the applicant that the reclamation plan would achieve complete restoration of the hydrologic form and ecological function of all perennial and intermittent streams in accordance with standards established by CWA permitting authority and baseline conditions; additional performance bond required for stream restoration. All ephemeral streams must be restored in form;

- Alternative 3 (also 5, and 6) -- Mining allowed through all streams upon demonstration by the applicant that the reclamation plan would achieve complete restoration of the hydrologic form and ecological function of all perennial and intermittent streams in accordance with standards established by CWA permitting authority and baseline conditions; additional performance bond required for stream restoration. Ephemeral streams restored in form to the extent required by geomorphic reclamation;
- Alternative 7 -- Same as Alternative 2 when enhanced permitting requirements apply, otherwise same as the No Action Alternative;
- Alternative 8 (Preferred) -- Requires restoration of both the hydrologic form and ecological function of intermittent and perennial streams that are mined through. Also requires establishment of postmining surface drainage pattern and stream-channel configuration that is similar to premining conditions, with certain exceptions; and
- Alternative 9 -- Requires that restored stream channels for perennial and intermittent streams be designed and constructed using natural channel design techniques to restore or approximate the premining characteristics of the original stream channel.

ES.10 AOC and AOC Variances Functional Group

ES.10.1.1 AOC Variances

ES.10.1.1.1 Mountaintop Removal Mining Operations

- The No Action Alternative (also 6, 7 and 9) – Achieve or support beneficial postmining land use; demonstrate equal or better land use. Assure investment in public facilities, and documentation of private financial capability to ensure completion. Requires demonstration that natural watercourses below lowest coal seam to be mined would not be damaged;
- Alternative 2 -- Prohibits all mountaintop removal mining operations (could require SMCRA amendment); and
- Alternative 3 (also 4 and 5) –Achieve or support beneficial postmining land use; demonstrate equal or better use. Requires implementation of the approved postmining land use prior to final bond release. Sufficient bond must be posted to ensure that, if the proposed postmining land use is not implemented, lands subject to the variance could be returned to approximate original contour. Requires assurance of investment in public facilities, and documentation of private financial capability to ensure completion. Requires demonstration that (1) no increase would occur in parameters of concern in discharges to surface or groundwater; (2) no change would occur in size or frequency of peak flow as compared to what would occur if the operator returned the site to approximate original contour; and (3) the total volume of flow during any season of the year would not vary (flooding potential cannot be altered). Requires demonstration that natural watercourses within the proposed permit and adjacent areas would not be damaged. If site was forested before permit application, then must return to forest and revegetate using native species except where inconsistent with the postmining land use.
- Alternative 8 (Preferred) – Same as Alternative 3 except that in the Preferred Alternative, the applicant is required to have substantially, and not fully, implemented the approved postmining land use prior to final bond release. In addition, OSMRE has removed the proposed requirement that the applicant post a bond in amount sufficient to ensure that, if the proposed postmining land

use is not implemented, lands subject to the variance could be returned to approximate original contour. All other demonstrations described above for Alternative 3 would still apply.

ES.10.1.1.2 AOC Variances for Steep-Slope Operations

- The No Action Alternative (also Alternatives 6, 7 and 9) -- Achieve/support beneficial postmining land use; demonstrate equal or better land use. Demonstrate that surface water flow in the watershed would be improved over premining conditions ***or*** conditions what would have existed had the area been returned to AOC. Total suspended solids or pollutants to surface and ground water must be reduced in a manner that improves existing uses or ecology, ***or*** that reduces flood hazards due to reduced peak flow. Total flow volume in every season must not vary so as to adversely affect ecology of surface water or existing or planned use of surface or ground water;
- Alternative 2 -- Prohibits all variances from requirement to return the mined area to its AOC (could require SMCRA amendment); and
- Alternative 3 (also 4 and 5) -- Must demonstrate that surface water flow in the watershed would be improved over premining conditions and conditions that would have existed had the areas been returned to AOC. Must demonstrate that the AOC variance would result in fewer impacts to aquatic ecology for the cumulative impact area than would occur if the site were returned to AOC. The AOC variance cannot result in any placement of excess spoil in an intermittent or perennial stream. The applicant must demonstrate that the proposed deviations from AOC are necessary and appropriate to achieve the postmining land use. The operator must post additional bond sufficient to ensure that, if the proposed postmining land use is not implemented, lands subject to the variance would be returned to AOC. If site was forested before permit application, then must return to forest and revegetate using native species except where inconsistent with the postmining land use.
- Alternative 8 (Preferred) – Same as Alternative 3 except that in the Preferred Alternative OSMRE has removed the requirement for the operator to post additional bond sufficient to ensure that lands approved for a variance from AOC can be returned to AOC if the proposed postmining land use is not implemented.

ES.10.1.2 Surface Configuration and Fills

ES.10.1.2.1 Definition of AOC

- The No Action Alternative (also Alternatives 6 and 9) -- Definition of AOC would not change, includes backfilling and restoring disturbed areas to *closely resemble* premining topography;
- Alternative 2 (also 3, 4, and 5) -- Definition of AOC same as the No Action Alternative with the additional requirement that surface configuration achieved by backfilling and grading of the mined area be documented by landform measurements and analyses conducted before, during, and after mining and reclamation; and
- Alternative 7 -- Same as Alternative 2 when enhanced permitting requirements apply, otherwise same as the No Action Alternative.
- Alternative 8 (Preferred) – AOC means that surface configuration achieved by backfilling and grading of the mined area so that the reclaimed area closely resembles the general surface configuration of the land within the permit area prior to any mining activities or related disturbances and blends into and complements the drainage pattern of the surrounding terrain.

All highwalls and spoil piles must be eliminated to meet the terms of the definition, but that requirement does not prohibit the approval of terracing, the retention of access roads or the approval of permanent water impoundments. For purposes of this definition, the term “mined area” does not include excess spoil fills and coal refuse piles.

ES.10.1.2.2 Digital Terrain Analysis

- The No Action Alternative (also Alternatives 6, 8 (Preferred) and 9)-- Digital terrain analysis not required, requires mine plans to address postmining land use but introduces no new specific requirements for terrain analysis;
- Alternative 2 (also 3, 4, and 5)-- Requires use of digital terrain models during premining and backfilling to confirm premining topography, and adherence to the reclamation plan for backfilling except that remining sites and contiguous permits 40 acres or less are exempt; and
- Alternative 7 -- Same as Alternative 2 when enhanced permitting requirements apply, otherwise same as the No Action Alternative.

ES.10.1.2.3 Permanent Impoundments and Final Elevations

- The No Action Alternative (also Alternative 3, 6, 8 (Preferred) and 9) -- No limits placed on final elevations. Still allows permanent impoundments, including final-cut impoundments provided they do not conflict with achieving AOC and they meet the postmining land use requirements. No requirements to use landforming principles during reclamation.
- Alternative 2 (also 4) -- Allowable deviation in the elevation of the backfilled and graded area postmining in comparison to the premining elevation based on the lowest coal seam mined. The allowable deviation in the postmining elevation could be no more than ±20 percent of the difference between the premining surface elevation and the premining bottom elevation of that lowest coal seam, with allowances for slope stability and minor shifts in the location of premining features. Allows exceedance of 20 percent tolerance to minimize excess spoil generation. In addition, tolerance requirement does not apply to that portion of the permit where steep-slope contour mining is conducted. Requires use of landforming principles (geomorphic reclamation). Still allows permanent impoundments, including final-cut impoundments provided they do not conflict with achieving AOC and they meet the postmining land use requirements;
- Alternative 5 – Same as the No Action Alternative except that it requires return of as much as spoil material to the mined area as possible (including transport of spoil above the original contour), and that it prohibits flat decks on excess spoil fills and coal refuse facilities; and
- Alternative 7 – Same as Alternative 2 when enhanced permitting requirements (other than steep slope conditions) apply, otherwise same as the No Action Alternative. This Alternative does not require compliance with the ±20 percent tolerance because stability and equipment constraints make it impracticable to impose this requirement on contour mining on steep slopes (defined as slopes greater than 20 degrees).

ES.10.1.3 Revegetation, Topsoil, and Fish and Wildlife Functional Group

ES.10.1.3.1 Revegetation

- The No Action Alternative (also Alternatives 6 and 9) -- Vegetative cover in accordance with the approved permit and reclamation plan, comprised of species native to the area, or of introduced species where desirable and necessary to achieve the approved postmining land use;
- Alternative 2 (also 3, 4, and 5) -- Requires that all reclaimed lands be revegetated with native species unless the postmining land use is actually implemented before the end of the revegetation responsibility period;
- Alternative 7 -- Same as Alternative 2 when enhanced permitting requirements apply, otherwise same as the No Action Alternative.
- Alternative 8 (Preferred) – Requires the use of native pollinator-friendly plants and planting arrangements that promote the establishment of pollinator-friendly habitat when practicable. The revegetation plan must create a diverse permanent vegetative cover that is consistent with native plant communities, and the species used must themselves be native with limited exceptions for temporary ground cover and certain postmining land uses.

ES.10.1.3.2 Topsoil management

- The No Action Alternative (also Alternatives 6 and 9) -- Requires salvage and redistribution of all topsoil (A and E soil horizons) or the top 6 inches of soil material if less than that thickness of topsoil is present. Salvage and redistribution of the B and C soil horizons is at the discretion of the regulatory authority (except on prime farmland, where it is mandatory). Selected overburden materials may be substituted for, or used as a supplement to topsoil if the operator demonstrates to the regulatory authority that: (1) the resulting soil medium is equal to, or more suitable for sustaining vegetation than, the existing topsoil; and (2) the resulting soil medium is the best available in the permit area to support revegetation;
- Alternatives 2 (also 3, 4, 5 and 8 (Preferred)) -- Requires salvage and redistribution of all topsoil (A and E soil horizons). Also requires salvage and redistribution of the B and C soil horizons (or other suitable overburden materials) to the extent necessary to achieve a growing medium with the optimal rooting depths required to restore premining land use capability or comply with revegetation requirements. Allows use of selected overburden materials as substitutes for (or supplements to) either topsoil or subsoil or both if the operator demonstrates that either (1) the quality of the existing topsoil and subsoil is inferior to that of other overburden materials or (2) the quantity of the existing topsoil and subsoil is insufficient to provide the optimal rooting depth or meet other plant growth requirements. In the latter case, all existing topsoil and favorable subsoil must be salvaged and redistributed. The operator also must demonstrate that the resulting soil medium would be more suitable than the existing topsoil and subsoil to sustain vegetation and that the selected overburden materials are the best available within the permit area for that purpose. The operator would have to redistribute soils in a manner that limits compaction, and provides optimal rooting depth to support the approved plan for revegetation and reforestation; and
- Alternative 7 -- Same as Alternative 2 when enhanced permitting requirements apply, otherwise same as the No Action Alternative.

ES.10.1.3.3 Salvage and Redistribution of Organic Materials

- The No Action Alternative (also Alternatives 6 and 9) -- Does not require salvage and redistribution or reuse of organic materials (duff, other organic litter, and vegetative materials such as tree tops, small logs and root balls) above the A soil horizon;
- Alternative 2 (also 4) -- Requires salvage and redistribution or reuse of ***all*** vegetative organic materials above the A soil horizon to promote reestablishment of locally adapted and genetically diverse native vegetation and soil flora and fauna and to enhance fish and wildlife habitats. Prohibits burning or burying of vegetation or other organic materials;
- Alternatives 3 (also 5) -- Requires salvage and redistribution of materials from native vegetation only (not from all vegetation) above the A soil horizon root balls in accordance with an approved plan developed by a qualified ecologist or similar expert who would determine the amounts needed to promote reestablishment of native vegetation and soil flora and fauna. Prohibits burning of above ground debris from native vegetation. Organic materials not needed for the approved plan may be used to construct fish and wildlife enhancement features;
- Alternative 7 -- Same as Alternative 2 when enhanced permitting requirements apply, otherwise same as the No Action Alternative; and
- Alternative 8 (Preferred) – Same as Alternative 3 except that it creates a limited exception to the requirement for salvage and redistribution or other use of organic matter. The Preferred Alternative also requires that organic matter from invasive species be buried rather than salvaged and redistributed.

ES.10.1.3.4 Reforestation

- The No Action Alternative (also Alternatives 6 and 9) -- Lands that have returned to forest through natural succession classified as "undeveloped" are not required to be reforested;
- Alternative 2 (also 3, 4, 5 and 8 (Preferred)) -- Requires reforestation of previously forested areas and of lands that would revert to forest under conditions of natural succession (except for prime farmland historically used for cropland) in a manner that would enhance recovery of the native forest ecosystem as expeditiously as possible; and
- Alternative 7 -- Same as Alternative 2 when enhanced permitting requirements apply, otherwise same as the No Action Alternative.

ES.10.1.3.5 Fish and Wildlife Protection and Enhancement

ES.10.1.3.5.1 Enhancement of Fish and Wildlife

- The No Action Alternative (also Alternative 9) -- Achieve enhancement of fish and wildlife resources where practicable. Surface mining activities must enhance where practicable, or restore, habitats of unusually high value for fish and wildlife;
- Alternative 2--Enhancement required if mitigation required pursuant to the CWA. CWA mitigation incorporated as a condition of the SMCRA permit. Bond release on the SMCRA permit would be conditioned on successful mitigation as determined by the regulatory authority and the agency implementing the CWA. This option may require an amendment of SMCRA;
- Alternative 3 (also 4, 5, and 6) -- Enhancement measures would be mandatory whenever the proposed operation would result in the long-term loss of native forest, loss of other native plant

communities, or filling of a segment of a perennial or intermittent stream (but not ephemeral streams). Resource enhancement must be: (1) commensurate with long-term adverse impact to affected resources; and (2) be located in the same or nearest adjacent watershed as the proposed operation if there are no opportunities for enhancement within the same watershed, and be on permitted area. Mining of certain areas within the permit area with exceptional environmental value may be prohibited by regulatory authority;

- Alternative 7 – Same as Alternative 3 when enhanced permitting requirements apply, otherwise same as the No Action Alternative; and
- Alternative 8 (Preferred) -- Same as Alternative 3 except that it does not include provision for prohibiting mining on areas of exceptional environmental value within the permit area.

ES.10.1.3.5.2 Endangered and Threatened Species Protection

- The No Action Alternative (also Alternatives 6 and 9) -- No surface mining activity can be conducted which is likely to jeopardize the continued existence of endangered or threatened species listed by the Secretary or which is likely to result in the destruction or adverse modification of designated critical habitat of such species in violation of the Endangered Species Act of 1973, as amended (16 U.S.C. 1531 *et seq.)*;
- Alternative 2 (also 3, 4, and 5) -- Same as Alternatives 1 and 6, in addition would (1) codify the dispute resolution provisions of the biological opinion concerning protection of threatened and endangered species and (2) add a provision to the regulations expressly requiring that the fish and wildlife protection and enhancement plan in the permit application include any species-specific protection and enhancement plans developed in accordance with the Endangered Species Act and any biological opinions implementing that law; and
- Alternative 7 – Same as Alternative 2 where enhanced permitting conditions apply, otherwise same as the No Action Alternative.
- Alternative 8 (Preferred) – The "adjacent area" includes those areas outside the proposed or actual permit area where surface coal mining operations or underground mining activities may affect a species listed or proposed for listing as endangered or threatened under that Act or designated or proposed critical habitat under that Act. Requires that the applicant document that the proposed operation would have no effect on species listed or proposed for listing as threatened or endangered or on designated or proposed critical habitat; or documentation of consultation on impacts and planned compliance with terms and conditions resulting from consultation. Does not codify the dispute resolution procedures but instead addresses them through the SPR biological opinion and the ESA MOU between OSMRE and the U.S. FWS.

ES.10.1.3.5.3 Streamside Vegetative Corridors

- The No Action Alternative (also Alternative 9) -- The operator must avoid disturbances to, enhance where practicable, restore, or replace, wetlands, and riparian vegetation along rivers and streams and bordering ponds and lakes;
- Alternative 2 (also 5, 6 and 8 (Preferred)) -- Requires creation of a 100-foot streamside vegetative corridor, comprised of native non-invasive species, to enhance restoration of the ecological function of ephemeral, intermittent, or perennial streams. The streamside vegetative corridor must be established along the entire reach of any stream restored or permanently diverted;

- Alternative 3 (also 4) -- Requires establishment of a 300-foot streamside vegetative corridor comprised of native woody species along restored or permanently diverted intermittent and perennial streams, if the land would naturally revert to forest under natural succession (not required if this would conflict with the approved postmining land use); and
- Alternative 7 – Same as Alternative 2 when enhanced permitting requirements apply, otherwise same as the No Action Alternative.

ES.11 Alternatives Considered but not Carried Forward

Three other distinct Alternatives were also considered, but OSMRE ultimately determined that they did not adequately meet the purpose and need and therefore did not carry them forward for further analysis in the FEIS. These Alternatives included an Alternative that would prohibit mining activities (including placement of excess spoil) in or near streams and mining through all streams and that would limit backfilling elevation to a maximum ±10 percent elevation deviation from the original elevation was considered. The results of the preliminary analysis indicated that this threshold was not realistic and OSMRE instead incorporated a ±20 percent elevation threshold into Alternatives 2, 4 and 7.

Another Alternative that would absolutely prohibit all surface coal mining and reclamation activities, including fill placement and coal mine waste, in or within 100 feet of all streams, including ephemeral streams was also considered. The results of the preliminary analysis indicated that implementation of this Alternative would result in a significant reduction in coal recovery in five of the seven coal-producing regions. OSMRE determined that the impacts to coal production from this Alternative were so substantial that they ran counter to the mandate under SMCRA 102(f) to balance the need for energy with the protection of the environment. While the prohibition would provide maximum protection for streams, it would result in an unacceptable impact on the nation's energy production via coal. For this reason, OSMRE determined that this Alternative did not fall within the range of reasonable Alternatives that could achieve the purpose of this proposed action, and dismissed this Alternative from further consideration.

Finally, an Alternative that would define material damage to the hydrologic balance outside the permit area based on a percentage of the watershed impacted by any one coal mining operation was considered. Once that percentage of the watershed had been impacted by coal mining activities, no additional mining could be permitted in those watersheds. Although it would prohibit further impacts in already impacted watersheds, this Alternative would greatly restrict the ability to mine coal in areas of the country that produce a sizeable percentage of the Nation's coal. The preliminary analysis indicated that this Alternative would significantly affect the ability to mine coal in three of the highest coal-producing counties in West Virginia and over half of currently mined watersheds in the Powder River Basin. Additionally, this Alternative would impose these impacts on coal production based on an acreage threshold that has not been scientifically determined to be a suitable nationwide basis for determining the likelihood or extent of material damage to the hydrologic balance. For these reasons, OSMRE determined that this Alternative was not scientifically justifiable, and did not meet the purpose of the proposed action.

ES.12 Impacts of the Alternatives

The FEIS examined each of the Alternatives carried forward, including the No Action Alternative, to determine the potential for each Alternative to impact resources within the human environment. The resources addressed in the EIS include the following:

- Mineral Resources and Mining;
- Physical Resources (including water resources; topography, geology and soils; air quality, greenhouse gas emissions and climate change);
- Biological Resources;
- Social, Cultural, and Economic Resources (including socioeconomic conditions; land use; utilities; infrastructure; historic and archaeological resources, visual resources; noise; recreation; and public health and safety); and
- Environmental Justice.

The effects of each Alternative on these resources were analyzed within the seven primary coal-bearing regions of the United States.

Under the No Action Alternative, coal mining would continue to be conducted under existing regulations and all impacts associated with mining under these regulations would continue.

ES.12.1.1 Summarized Impacts of the Alternatives

Impacts of the Action Alternatives would generally include adverse effects on socio-economic resources and positive effects on the other resource categories. The EIS defines categories of impacts using classes ranging from “Major Adverse” through “Negligible” to “Major Beneficial” to assist the reader in putting the impacts and results into context. These impacts are determined by comparing anticipated effects of an Action Alternative with the anticipated effects of the No Action Alternative (the baseline), for the study period (2020 to 2040). In general, Alternative 2 has the most strongly adverse impacts, which are anticipated for socioeconomic conditions, as well as the most strongly beneficial impacts, which occur for most other resources, when compared to impacts of the No Action Alternative. Alternative 9 shows Negligible impacts when compared to impacts of the No Action Alternative. Remaining Action Alternatives exhibit the same pattern of impacts as Alternative 2, but with varying degrees of adverse effects on socioeconomic conditions and benefits to natural resources. The following sections summarize the results of the analysis by resource in more detail.

ES.12.1.1.1 Water Resources

Under the No Action Alternative, mining practices would remain unchanged and no further regulations or corrective measures in addition to those already in place would be implemented. Consequently, the impact of surface and underground mining operations would continue to produce adverse effects on water resources outside the permit area. Some examples of the impacts of mining include, but are not limited to, reduced stream and groundwater pH from acid mine drainage; elevated concentrations of iron, aluminum, manganese, and sulfate in surface water; increased sedimentation in the water column; flow alteration and stream elimination as a result of mining through streams and spoil management practices; drawdown of groundwater levels; and degradation of groundwater through increased concentrations of sulfate, iron, and other pollutants (see Subsection 4.2.1.1).

Consistent with the intent of the regulations to reduce adverse impacts of mining activities on perennial and intermittent streams, the Action Alternatives (except Alternative 9) would result in benefits to water resources relative to the No Action Alternative at the national scale. In particular, the analysis finds that Action Alternatives would result in Major Beneficial impacts to water resources under Alternatives 2, 3, 4, and 8 (Preferred) at the national scale. Moderate Beneficial impacts to water resources would be expected under Alternatives 6 and 7, with Minor Beneficial impacts under Alternative 5 at the national scale. Alternative 9 is anticipated to be functionally similar to the No Action Alternative and is anticipated to result in Negligible effects on water resources.

On a regional scale, Major Beneficial impacts are anticipated in the Appalachian Basin and Illinois Basin under Alternatives 2, 3, 4, and 8 (Preferred). Moderate Beneficial impacts are anticipated in the Appalachian Basin for Alternatives 5, 6, and 7, in the Illinois Basin for Alternatives 6 and 7, and in the Colorado Plateau, Gulf Coast, and Northern Rocky Mountains and Great Plains regions for Alternatives 2, 3, 4, 6, 7, and 8 (Preferred). Other effects on water resources are anticipated to be Negligible at the regional scale when compared to the No Action Alternative.

ES.12.1.1.2 Biological Resources

Under the No Action Alternative, no further regulations or corrective measures in addition to those already in place would be implemented. Therefore, ongoing trends in biological resources would continue. The annual quantity of coal demanded and associated production is anticipated to be approximately 10 percent lower in 2040 than in 2020, even without implementation of the Alternatives (i.e., under the No Action Alternative). This reduction in production would reduce adverse impacts of ongoing coal mining activities on biological resources under the No Action Alternative.

Action Alternatives are generally anticipated to benefit biological resources at the national scale when compared to the No Action Alternative, with Alternatives 2, 3, 4, 7, and 8 (Preferred) providing Moderate Beneficial impacts, and Alternatives 5 and 6 providing Minor Beneficial impacts at a national scale. Alternative 9 is anticipated to be functionally similar to the No Action Alternative and is anticipated to result in Negligible effects on biological resources.

On a regional scale, and similarly to water resources, Major Beneficial impacts are anticipated in the Appalachian Basin and the Illinois Basin under Alternatives 2, 3, 4, and 8 (Preferred). Major Beneficial impacts are also anticipated in the Appalachian Basin under Alternative 5. Moderate Beneficial impacts are anticipated in the Colorado Plateau, Gulf Coast, and Northern Rocky Mountains and Great Plains regions under Alternatives 2, 3, 4, 7, and 8 (Preferred). Moderate Beneficial impacts are also anticipated in the Appalachian Basin and the Illinois Basin under Alternative 7. Other effects on biological resources are anticipated to be Minor Beneficial or Negligible at the regional scale when compared to the No Action Alternative.

ES.12.1.1.3 Topography, Geology, and Soils

Under the No Action Alternative, no further regulations or corrective measures in addition to those already in place would be implemented. Therefore, ongoing trends in geology, soils, and topography would continue. The annual quantity of coal demanded and associated production is anticipated to be approximately 10 percent lower in 2040 than in 2020, even without implementation of the Alternatives (i.e., under the No Action Alternative). This reduction in production would reduce adverse impacts of ongoing geology, soils, and topography under the No Action Alternative.

Action Alternatives are generally anticipated to benefit topography, geology, and soils when compared to the No Action Alternative, with Minor Beneficial impacts anticipated for Alternatives 2, 3, 4, 5, 7, and 8 (Preferred). Alternatives 6 and 9 are anticipated to result in Negligible effects on topography, geology, and soils at a national scale.

On a regional scale, Moderate Beneficial impacts are anticipated in the Appalachian Basin under Alternatives 2, 4, 5, 7, and 8 (Preferred). Other effects on topography, geology, and soils resources are anticipated to be Minor Beneficial or Negligible at the regional scale when compared to the No Action Alternative.

ES.12.1.1.4 Air Quality, Greenhouse Gas Emissions, and Climate Change

Under the No Action Alternative, no further regulations or corrective measures in addition to those already in place would be implemented. Therefore, ongoing trends in air quality, greenhouse gas emission, and climate change would continue. The annual quantity of coal demanded and associated production is anticipated to be approximately 10 percent lower in 2040 than in 2020, even without implementation of the Alternatives (i.e., under the No Action Alternative). This reduction in production would reduce adverse impacts of air impacts associated with coal mining activities under the No Action Alternative.

While, none of the Action Alternatives explicitly targets air quality resources, implementation of the elements of the Action Alternatives may have both beneficial and adverse effects on air quality and greenhouse gas emissions. The predominant effect of the rule on air quality and greenhouse gas emissions that is quantified in this EIS is the reduction in carbon dioxide (CO_2) emissions associated with the overall reduction in coal activity due to increased costs of coal production. Even accounting for increased energy generation from substitute sources (primarily natural gas), the Action Alternatives would generate a net reduction in greenhouse gas emissions over the timeframe of the analysis. The monetary value of this benefit reflects the anticipated effect of marginal reductions in emissions on a wide range of climate-related impacts, such as agricultural productivity, human health, and property damage from flooding. Additionally, the Action Alternatives may increase the terrestrial carbon sequestration potential of the landscape during and post-mining activities due to the reforestation and streamside vegetative corridor requirements of the Action Alternatives (except for Alternative 9), further generating reductions in climate-related damages. On the other hand, the Action Alternatives may also increase the use of equipment and vehicles to haul materials and therefore increase greenhouse gas emissions from these sources.

In contrast to the other categories of environmental and economic impacts evaluated in this analysis, the benefits of reduced greenhouse gas emissions represent worldwide climate-related damages, independent of the geographic source of the emissions. This analysis accordingly considers the magnitude of these benefits, finding that the effects are beneficial across all Action Alternatives.

ES.12.1.1.5 Socioeconomic Conditions

The annual quantity of coal demanded and associated production is anticipated to be approximately 10 percent lower in 2040 than in 2020, even without implementation of the Alternatives (i.e., under the No Action Alternative). In particular, the Colorado Plateau, Appalachian Basin, and Northern Rocky Mountain and Great Plains regions are forecasted to have the largest production decreases in coal production, respectively. This reduction in production would be expected to have adverse impacts on localized socioeconomics conditions, to the extent that reductions in coal production also reduce coal mining employment and associated income. In 2014, coal mining accounted for 0.06 percent of national employment and 0.1 percent of national income (U.S. Census Bureau, 2014; U.S. EIA, 2016a). EIA estimates that 2014 coal industry employment was approximately 75,000 employees (U.S. EIA, 2016a). This analysis projects that coal industry employment will decrease by over 7,000 full-time equivalents (FTEs) under baseline conditions from 2020 to 2040. This decrease in employment demand over the analysis period in the No Action Alternative is consistent with the projected declining demand for U.S. coal from retiring coal-fired power plants and is expected to occur primarily in the Appalachian Basin, the Illinois Basin, and the Northern Rocky Mountains and Great Plains regions.

At the national scale, Alternative 2 is anticipated to result in Moderate Adverse impacts on socioeconomic conditions including, in particular, employment and severance taxes when compared to the No Action Alternative. Alternatives 3, 4, 5, 6, 7, and 8 (Preferred) are anticipated to result in Minor Adverse impacts on socioeconomic conditions, including employment, and severance taxes at the national scale. Alternative 9 is anticipated to be functionally similar to the No Action Alternative and is anticipated to result in Negligible effects on socioeconomic conditions.

To the extent that impacts of the Action Alternatives are concentrated in a particular community, these communities may experience a reduced quality of life to the extent that the Action Alternatives result in reduced mining activity. In addition, coal companies may have a philanthropic presence in communities; reduced mining could adversely affect these philanthropic activities. Depending on the severity of the observed changes, declining quality of life in coal-dependent communities could lead to population declines in those communities.

At a regional scale, Major Adverse impacts on socioeconomic conditions, including employment, are anticipated in the Appalachian Basin under Alternative 2. Moderate Adverse impacts on socioeconomic conditions are anticipated in the Appalachian Basin under Alternatives 3, 4, 5, 7, and 8 (Preferred). Impacts to other regions to socioeconomic conditions are anticipated to be Minor Adverse or Negligible across Alternatives at the regional scale when compared to the No Action Alternative. The following summary of expected effects helps to illustrate anticipated adverse impacts:

- Under Alternative 2, annual impacts to production-related employment are expected to range from a reduction in demand for 854 FTEs to a reduction of 28 across all regions, with an average reduction in annual demand of 270 FTEs.[16] Annual impacts to industry implementation-related

[16] The range of annual impacts to employment represents the minimum and maximum effect in any year in the study period. The average effect is the average annual effect on employment of the Alternative over the 21 year study period.

employment are expected to range from a gain of 525 FTEs to a gain of 686 across all regions, with an average increase in annual demand of 620 FTEs;

- Under Alternative 3, annual impacts to production-related employment are expected to range from a reduction in demand for 654 FTEs to a reduction of two across all regions, with an average reduction in annual demand of 178 FTEs. Annual impacts to industry implementation-related employment are expected to range from a gain of 360 FTEs to a gain of 460 across all regions, with an average increase in annual demand of 419 FTEs;
- Under Alternative 4, annual impacts to production-related employment are expected to range from a reduction in demand for 579 FTEs to a reduction of 11 across all regions, with an average reduction in annual demand of 154 FTEs. Annual impacts to industry implementation-related employment are expected to range from a gain of 88 FTEs to a gain of 124 across all regions, with an average increase in annual demand of 105 FTEs;
- Under Alternative 5, annual impacts to production-related employment are expected to range from a reduction in demand for 388 FTEs to a reduction of five across all regions, with an average reduction in annual demand of 99 FTEs. Annual impacts to industry implementation-related employment are expected to range from a gain of 164 FTEs to a gain of 212 across all regions, with an average increase in annual demand of 193 FTEs;
- Under Alternative 6, annual impacts to production-related employment are expected to range from a reduction in demand for 335 FTEs to a reduction of seven across all regions, with an average reduction in annual demand of 86 FTEs. Annual impacts to industry implementation-related employment are expected to range from a gain of 227 FTEs to a gain of 315 across all regions, with an average increase in annual demand of 272 FTEs;
- Under Alternative 7, annual impacts to production-related employment are expected to range from a reduction in demand for 580 FTEs to a gain of one across all regions, with an average reduction in annual demand of 169 FTEs. Annual impacts to industry implementation-related employment are expected to range from a gain of 215 FTEs to a gain of 275 across all regions, with an average increase in annual demand of 252 FTEs;
- Under Alternative 8 (Preferred), annual impacts to production-related employment are expected to range from a reduction in demand for 511 FTEs to a reduction of three across all regions, with an average reduction in annual demand of 124 FTEs. Annual impacts to industry implementation-related employment are expected to range from a gain of 240 FTEs to a gain of 309 across all regions, with an average increase in annual demand of 280 FTEs; and
- Under Alternative 9, no changes in either production-related or industry implementation-related annual employment are expected.

ES.12.1.1.6 Land Use, Utilities, Infrastructure, Visual Resources, and Noise

Under the No Action Alternative, no further regulations or corrective measures in addition to those already in place would be implemented. Therefore, ongoing trends in land use, utilities, infrastructure, visual resources, and noise would continue. The annual quantity of coal demanded and associated production is anticipated to be approximately 10 percent lower in 2040 than in 2020, even without implementation of the Alternatives (i.e., under the No Action Alternative). This reduction in production would reduce adverse impacts of ongoing coal mining activities on land uses under the No Action Alternative.

Reduced coal production would reduce adverse impacts to land use, reduce demands on utilities, and infrastructure, reduce adverse impacts to visual resources, and reduce noise in coal mining regions that would have otherwise occurred under the No Action Alternative. Alternative 2 is anticipated to result in Minor Beneficial results to land use, utilities, infrastructure, visual resources, and noise at the national scale when compared to the No Action Alternative. Other Alternatives are anticipated to result in Negligible impacts at the national scale.

At a regional scale, Moderate Beneficial impacts to land use, utilities, infrastructure, visual resources, and noise are anticipated in the Appalachian Basin under Alternative 2, 3, 4, 5, 7, and 8 (Preferred). Other effects on land use, utilities, infrastructure, visual resources, and noise are anticipated to be Minor Beneficial or Negligible at the regional scale when compared to the No Action Alternative.

ES.12.1.1.7 Public Health and Safety

Water and air quality are primary drivers of public health changes in coal mining regions. Arsenic, selenium, and sulfates are drinking water contaminants found to be elevated near mining regions. Under the No Action Alternative, no further regulations or corrective measures in addition to those already in place would be implemented. Therefore, ongoing public health and safety trends would continue. The annual quantity of coal demanded and associated production is anticipated to be approximately 10 percent lower in 2040 than in 2020, even without implementation of the Alternatives (i.e., under the No Action Alternative). This reduction in production would reduce adverse impacts of ongoing coal mining activities on water resources under the No Action Alternative.

At the national scale, Alternatives 2, 3, 4, and 8 (Preferred) are anticipated to result in Major Beneficial impacts to public health and safety when compared to the No Action Alternative. Alternatives 6 and 7 are anticipated to result in Moderate Beneficial impacts to public health and safety. Alternative 5 is anticipated to result in Minor Beneficial impacts to public health and safety at the national scale. Alternative 9 is anticipated to be functionally similar to the No Action Alternative and is anticipated to result in Negligible effects on public health and safety.

At a regional scale, Major Beneficial impacts are anticipated in the Appalachian Basin and Illinois Basin regions under Alternatives 2, 3, 4, and 8 (Preferred). Major Beneficial impacts are also anticipated in the Appalachian Basin under Alternative 7. Moderate Beneficial impacts are expected in the Colorado Plateau, Gulf Coast, and Northern Rocky Mountains and Great Plains regions under Alternatives 2, 3, 4, 6, 7, and 8 (Preferred). Moderate Beneficial impacts are also anticipated in the Appalachian Basin for Alternatives 5 and 6, and in the Illinois Basin for Alternatives 6 and 7. Other effects on public health and safety are anticipated to be Minor Beneficial or Negligible at the regional scale when compared to the No Action Alternative.

ES.12.1.1.8 Archaeology, Paleontology, and Cultural Resources

Under the No Action Alternative, no further regulations or corrective measures in addition to those already in place would be implemented. Therefore, ongoing trends in archaeology, paleontology and cultural resources would continue. For example, adverse effects to cultural resources that occur as part of development activities would continue under the No Action. Under the No Action Alternative, a fairly stringent set of regulations are in place which attempt to avert and mitigate impacts to these resources where they occur.

Nationally, all Action Alternatives are expected to have Negligible impacts on Archaeology, Paleontology, and Cultural Resources. At a regional level, Negligible impacts are expected in all regions under all Alternatives. To the extent that any particular rule element reduces the extent of ground disturbance associated with mining, it would also reduce the disturbance of cultural resources located within that area. Therefore, cultural resources may benefit from some or all of the rule elements.

ES.12.1.1.9 Recreation

Recreational activities, including hunting, wildlife viewing, trail use, boating, and fishing, may occur on both public and private lands within the study area. Public lands, including federal, state, and locally managed lands, are often popular destinations for recreators due to the relatively natural and undeveloped quality of those lands. In addition, private lands are also used for recreation. Under the No Action Alternative, no further regulations or corrective measures in addition to those already in place would be implemented. Therefore, ongoing trends in recreation would continue. The annual quantity of coal demanded and associated production is anticipated to be approximately 10 percent lower in 2040 than in 2020, even without implementation of the Alternatives (i.e., under the No Action Alternative). This reduction in production would reduce adverse impacts of ongoing coal mining activities on recreational activities under the No Action Alternative.

At the national scale, Alternative 2 is anticipated to result in Moderate Beneficial impacts to recreational activities when compared to the No Action Alternative. Alternatives 3, 4, 5, 6, 7, and 8 (Preferred) are anticipated to result in Minor Beneficial impacts to recreation. Alternative 9 is anticipated to be functionally similar to the No Action Alternative and is anticipated to result in Negligible effects on recreational activities.

At a regional scale, Major Beneficial impacts are anticipated in the Appalachian Basin under Alternative 2. Moderate Beneficial impacts are anticipated in the Appalachian Basin region under Alternatives 3, 4, 5, 7, and 8 (Preferred) and in the Colorado Plateau region under Alternatives 2, 3, 4, 7, and 8 (Preferred). Other effects on to recreational activities are anticipated to be Minor Beneficial or Negligible at the regional scale when compared to the No Action Alternative.

ES.12.1.1.10 Environmental Justice

Environmental justice communities are those that meet the defined environmental justice criteria for minority, low-income, and American Indian populations. The environmental justice evaluation discusses the potential impacts of the Action Alternatives on these populations, including impacts on socioeconomic resources, public health and safety, biological resources, water resources, air quality, topography, land use, and recreation.

The affected area for this analysis is large and spans a variety of demographic conditions. In total, the affected area intersects with 286 counties in 24 states. The analysis was conducted at a county level to determine if any of the 286 counties contain populations that meet environmental justice criteria. Indian tribes are considered as a distinct category in the minority population environmental justice analysis.

Under the No Action Alternative, no further regulations or corrective measures in addition to those already in place would be implemented. Therefore, ongoing trends in the evaluated resources would continue. The annual quantity of coal demanded and associated production is anticipated to be approximately 10 percent lower in 2040 than in 2020, even without implementation of the Alternatives (i.e., under the No Action Alternative).

Of the 286 counties in the study area, there are 190 counties that have populations that meet the previously specified low income and/or the minority population environmental justice thresholds. Of these 190 counties, 60 percent of them are in the Appalachian Basin. Of those counties in the Appalachian Basin, four have been identified as minority communities, 103 as low income communities, and nine as both low income and minority environmental justice communities. The minority communities identified as potentially affected environmental justice populations in this region are as follows: Black or African American; American Indian and Alaskan Native; Asian, Native Hawaiian or Other Pacific Islander; Hispanic Origin; and Other.

There were six counties in the Colorado Plateau identified as potentially affected low income populations and four counties identified as both low income and minority environmental justice communities. Minority populations included American Indian and Alaskan Native. In the Gulf Coast region, three counties had populations that met the criteria for environmental justice low income and minority populations, 11 counties were identified as only low income communities, and one county was identified as a minority community (Black or African American, American Indian and Alaskan Native, and Hispanic Origin).

In the Illinois Basin, 28 counties met the criteria for low income populations and three counties met environmental justice thresholds for both low-income and minority populations (Black or African American; and American Indian and Alaskan Native). In the Northern Rocky Mountains and Great Plains region, three counties were identified as minority communities, six as low income communities, and four as both low income and minority environmental justice communities. The minority communities identified as potentially affected environmental justice populations in this region are as follows: American Indian and Alaskan Native; Hispanic Origin; and Other. In the Northwest, one county was identified as a low income environmental justice community. In the Western Interior, one county was identified as both low income community and minority population. Six counties met environmental justice low income population thresholds only and two counties met minority population thresholds only. Three counties identified for minority populations met environmental justice criteria for American Indian and Alaskan Native minority populations. One of the counties also has minority populations of Asian, Native Hawaiian or Other Pacific Islander and Other that meet environmental justice criteria.

Mining occurs in close proximity to or on a number of tribal reservations. The Northern Cheyenne Indian Reservation is situated in both Big Horn and Rosebud Counties in Montana where five active surface mines exist. In addition, the Crow Indian Reservation covers nearly 65 percent of Big Horn County. San Juan County overlaps both the Navajo Nation Reservation and the Ute Mountain Reservation where one active surface mine and one active underground mine exist. The Zuni Reservation is located primarily in McKinley County where two active surface mines exist. McKinley County also overlaps with the Navajo Nation Reservation. Navajo County in Arizona is comprised of the Navajo Nation Reservation, the Fort Apache Reservation, and the Hopi Reservation where one active surface mine exists.

Of particular note are mines located on (not just near) tribal land. For example, the Navajo Mine and the Kayenta Mine are operated on the Navajo Nation lands and produce about 15 million tons of coal annually (U.S. EIA, 2012c). An additional coal mine, the Absaloka Mine, is located on the Crow Reservation in Montana.

At the regional scale, adverse impacts to socioeconomic resources associated with environmental justice communities are expected to occur as follows:

- Under Alternatives 2, 3, 6, 7 and 8 (Preferred): the Appalachian Basin, Illinois Basin, and Northern Rocky Mountains and Great Plains are expected to incur adverse socioeconomic effects; Negligible effects are expected for all other regions. In the Appalachian Basin, 103 counties have populations that meet the criteria for low-income environmental justice communities and four for minority populations, with nine counties falling into both categories. In the Illinois Basin, four counties have an American Indian and Alaskan Native environmental justice population. In seven counties in the Northern Rocky Mountains and Great Plains region there are three environmental justice minority populations: Asian, Native Hawaiian, Pacific Islander, or Other; Hispanic Origin; and Other. Negligible effects on socioeconomic conditions are expected for all other regions.
- Under Alternative 4: the Appalachian Basin and Illinois Basin are expected to incur Moderate and Minor Adverse socioeconomic effects. In the Appalachian Basin, 103 counties have populations that meet the criteria for low-income environmental justice communities and four for minority populations, with nine counties falling into both categories. In the Illinois Basin, four counties have an American Indian and Alaskan Native environmental justice population. The Northern Rocky Mountains and Great Plains region is expected to experience Minor Beneficial socioeconomic effects. Negligible effects on socioeconomic conditions are expected for all other regions.
- Under Alternative 5: the Appalachian Basin is expected to incur Moderate Adverse Socioeconomic effects. In the Appalachian Basin, 103 counties have populations that meet the criteria for low-income environmental justice communities, four meet the criteria for minority populations, and nine counties fall into both categories. Minor Adverse socioeconomic effects are expected in the Northern Rocky Mountains and Great Plains region, and there are three environmental justice minority populations in that region (as mentioned previously). Negligible effects on socioeconomic conditions are expected for all other regions.
- Under Alternative 9: Negligible effects on socioeconomic conditions are expected for all regions.

At the regional scale, impacts to resources other than socioeconomics for environmental justice communities are expected to be Negligible or beneficial.

ES.12.2.1 Summarized Impacts of the No Action Alternative

Impacts of the No Action Alternative are discussed for each resource in the EIS. The categories used above describe a result, i.e. a predicted beneficial or adverse effect that is different upon implementation of the Alternative being considered in relation to the effects that are expected to occur under the No Action Alternative. A determination of impacts of the No Action Alternative is therefore “No Effect” under this analytical framework (as the No Action Alternative is compared to itself). The FEIS provides detailed qualitative discussions of the impacts of mining under the current regulations especially as documented in scientific research and through the experience of the regulatory authorities.

ES.12.2.1.1 Summarized Benefits of the Preferred Alternative

All of the Action Alternatives (excluding Alternative 9) would have beneficial, long-term effects on resources, except for socioeconomic resources, to varying degrees by Alternative and region. Alternative 8 (Preferred), throughout the planning process and as revised since the DEIS, incorporates measure to minimize impacts to socioeconomic resources and would have a number of important benefits in comparison to the No Action Alternative. Implementation of the Preferred Alternative would do the following:

- Improve permitting processes and make it easier for the regulatory authority to determine whether mine plans are designed in accordance with the regulatory program. It would also improve assessment of the mine operation's compliance with the approved permit. Permits contain specific protective measures developed through interagency coordination; ensuring compliance with these conditions is critical to protecting the environment.
- Result in earlier detection of adverse impacts to ground and surface water outside the permit area. Earlier detection would allow for earlier correction to conditions that could impact aquatic wildlife and people.
- Limit activities in or near intermittent and perennial streams and reduce the number and length of intermittent and perennial stream segments disturbed by mining. Streams provide habitat, drinking water and recreational space.
- Minimize disturbance and adverse impacts to perennial and intermittent stream segments of high environmental value. Stream segments with high environmental value include those that support sensitive species or unique attributes that deserve greater protection.
- Grant clear authority to the regulatory agency to require that surface coal mining operations promote enhancement of fish, wildlife, and related environmental values wherever and whenever practicable. Enhancement of habitats to offset impacts to habitats disturbed during mining would help to ensure that wildlife have sufficient resources to meet their life cycle needs.
- Improve reforestation on sites disturbed by coal mining. This would improve the ability of the landscape to filter contaminants from runoff before the runoff reaches the stream.
- Increase use of native species on sites disturbed by coal mining. Native plant species require less maintenance because they are better adapted to the environment and require less water and fertilization to thrive long-term. They resist damage from freezing, drought, common diseases, and herbivores. They also may fill specific roles in the ecosystem and provide higher forage value to wildlife.
- Increase the extent of forested riparian areas on mine sites. Forested riparian areas enhance streams because they trap sediments before they reach the stream. They connect fragmented habitat and create wildlife movement corridors. They aid stream ecological health by shading the water to help keep cold water streams cold and by providing leaf litter in the streams, which serves as food source for macroinvertebrates and later in the food chain for fish.

Specific to water resources, the Preferred Alternative would provide Major Beneficial impacts in the coal regions of the Appalachian and Illinois Basins. Specifically:

- Major benefits are anticipated in the Appalachian Basin:
- Four fewer stream miles would be filled annually;
- Improved mining practices would lead to improved stream quality in approximately 174 stream miles annually and improved groundwater;
- Percentage of groundwater usage for private consumption is the highest of the regions, suggesting this region would benefit most from improved groundwater protection; and
- Major benefits would occur in the Illinois Basin:
- Downstream water quality would be improved for 33 stream miles annually;
- Ephemeral stream restoration would occur for 7 stream miles annually;
- For Colorado Plateau, Gulf Coast, and Northern Rocky Mountains and Great Plains, regional benefits would be moderate:
- Four to 29 stream miles would be improved annually;
- Two to six ephemeral stream miles would be restored annually;
- Groundwater protection would be improved; two to three percent of households in this region rely on private groundwater supplies.

While this summary of the impacts of the Preferred Alternative is informative, it does not highlight the impacts that would occur over the long-term. Tables ES.12-1 and ES.12-2 provide a quantitative summary of the benefits to streams and forests over the twenty-one year study period for the analysis (2020 through 2040).

Table ES.12-2.
Results of the Preferred Alternative: Annual Stream Impacts (Miles)

Coal Region	Downstream Improved (Miles Per Year)	Downstream Preserved (Miles Per Year)	Not Filled (Miles Per Year)	Restored (Miles Per Year)
Appalachian Basin	174	0	4	1
Colorado Plateau	4	0	0	2
Gulf Coast	29	0	0	6
Illinois Basin	33	0	0	7
Northern Rocky Mountains and Great Plains	16	0	0	5
Northwest	1	0	0	0
Western Interior	5	0	0	1
Total Per Year	**263 miles**	**0 mile**	**4 miles**	**22 miles**
Total Over The 21- Year Study Period (2020 to 2040)	**5,520 miles**	**0 miles**	**88 miles**	**462 miles**

Notes: Downstream water quality improved (miles): Streams that experience water quality improvements with the SPR.
Downstream stream miles preserved: Streams that do not experience water quality impacts due to reduced mining activity.
Stream miles not filled: Streams not filled due to SPR.
Stream miles restored: Mined through streams that are restored due the SPR.
Totals may not sum due to rounding.

ES.12.2.1.2 Cumulative Impacts

The potential for the rule to have cumulative effects with other actions that might affect the same resources in the past, present or reasonably foreseeable future was also analyzed. After determining a resource-specific spatial and temporal boundary, information on other regulatory actions that would interact with the Action Alternatives was gathered, as well as other non-regulatory actions that would affect the same resources.

The diverse set of affected resources, combined with the broad geographic and temporal scope of the SPR, makes cumulative impact analysis highly challenging. A large set of past, present, and reasonably foreseeable future actions could interact with the Alternatives. These include:

- Regulatory actions directly related to mining and surface (e.g., stream) water quality;
- Rules that affect coal-fired power plants that could affect coal demand;
- Overall trends in the coal mining industry and energy markets;
- Other trends that affect resources in the study area and that may alter the cumulative impacts of the proposed actions; and
- Other secondary regulatory actions.

Table ES.12-3.
Results of the Preferred Alternative: Annual Forest Impacts (Acres)

Coal Region	Improved (Acres Per Year)	Preserved (Acres Per Year)
Appalachian Basin	1,313	7
Colorado Plateau	274	0
Gulf Coast	397	0
Illinois Basin	257	1
Northern Rocky Mountains and Great Plains	78	0
Northwest	0	0
Western Interior	166	0
Total Per Year	**2,486 acres**	**8 acres**
Total Over The 21- Year Study Period (2020 to 2040)	**52,211 acres**	**163 acres**

Notes: Improved Acres – Land that will benefit from improved forest land cover under the SPR because it would otherwise have been put in grassland, pastureland or an Alternative post mining land use, or would have been reforested under the baseline but the Alternative prescribes better practices to ensure healthier forest postmining.
Preserved Acres – Forest area that is left uncut due to changes in coal mining activity.
Totals may not sum due to rounding.

The diverse set of affected resources, combined with the broad geographic and temporal scope of the SPR, makes cumulative impact analysis highly challenging. Indeed, simply identifying the full suite of past, present, and future actions affecting water resources in coal mining areas in the U.S. is not feasible. For example, dozens, if not hundreds, of federal, state, and local laws and regulations could be perceived as being relevant to protecting the quality of water resources in streams affected by mining. Furthermore, an array of individual projects (e.g., dam construction, dredging), permitting decisions, and economic trends could further influence water quality. Identifying and accounting for all of these factors is not practical, and prediction of cumulative impacts based on such an approach would be speculative. Because it is practically infeasible to characterize every potentially relevant cumulative action in all coal-producing areas in the U.S., the analysis focuses on identifying the primary actions – particularly those that may combine with the Alternatives to produce noteworthy cumulative effects. This approach is consistent with CEQ guidance, which states that "a cumulative effects analysis should 'count what counts,' not produce superficial analyses of a long laundry list of issues that have little relevance to the effects of the proposed action on eventual decisions" (CEQ, 1997).

Under the No Action Alternative, a wide variety of past, present, and reasonably foreseeable future actions are anticipated to affect the same natural resources affected by the Action Alternatives. These include other regulatory actions related to coal mining and surface water quality, such as other existing SMCRA provisions, the Clean Water Act, actions that regulate coal combustion and coal-fired power plants, as well as local and regional initiatives. These actions also include non-regulatory trends, such as the ongoing trend in the coal market and coal industry overall, other land uses, such as forestry, agriculture, and development patterns. For most natural resources, the overall cumulative trend across the study area is difficult to discern because there are often actions with negative impacts on a resource (e.g., residential development on biological resources) as well as positive impacts (e.g., watershed restoration activities).

For most natural resources, implementation of one of the Action Alternatives would reduce impacts of coal mining on natural resources that would have occurred under the No Action Alternative (other than for socioeconomics, as discussed below). This is especially true when the Action Alternatives are considered in combination with other actions of similar intent not related to the current action (e.g., river conservation initiatives, etc.). Thus, for resources other than socioeconomics, Action Alternatives (except for Alternative 9) are anticipated to either have beneficial or a countervailing cumulative effect, depending on the underlying trends occurring for a particular resource. For example, the overall cumulative trend in water resources across the study area is difficult to discern when considering other cumulative actions with negative impacts (e.g., agriculture) as well as those with positive effects (e.g., river conservation initiatives). The Action Alternatives (except for Alternative 9) are anticipated to result in direct or indirect benefits to water resources. Thus, when the Action Alternatives are considered in combination with other actions and trends, the Alternatives are expected to result in either a net increase in beneficial impacts or a net reduction in adverse impacts to the resource (countervailing). Alternative 9 is anticipated to have a neutral cumulative effect.

The Action Alternatives are expected to produce Minor to Major Adverse impacts to socioeconomics, depending on the region and Alternative. These adverse impacts are primarily related to long-term adverse impacts to coal mining industry employment and the often small and rural communities that depend upon industry employment as well as other services. These effects would primarily occur in the Appalachian Basin, the Illinois Basin, and the Northern Rocky Mountains and Great Plains regions. The analysis also anticipates some reduction in severance and other tax collections over time related to reduced coal production. While these impacts are forecasted for all the Action Alternatives (except Alternative 9), they are most prevalent under Alternative 2.

The cumulative effects analysis considers direct and indirect socioeconomic impacts of Action Alternatives in combination with various other trends and actions. Other relevant cumulative actions include regulations with a direct effect on coal mining, as well as actions and trends that are likely to affect the demand for coal over time. For instance, established mining safety rules may continue to affect the profitability of mining while rules on greenhouse gas emissions from coal-fired power plants may encourage a transition away from coal to substitute fuels. These changes are occurring in the context of other energy sector trends such as decreasing natural gas prices resulting from growth in domestic production. On balance, the coal mining industry faces economic and regulatory challenges in the domestic market.

In 2014, coal mining accounted for 0.06 percent of national employment and 0.1 percent of national income (U.S. Census Bureau, 2014; U.S. EIA, 2016a). Additionally, a shift toward the more labor-intensive underground mining in the Appalachian Basin region, combined with an overall depletion of the most readily accessed surface reserves, has led to an offsetting increase in coal mining employment in recent years. For context, EIA estimates that 2014 coal industry employment was approximately 75,000 employees (U.S. EIA, 2016a). This analysis projects that coal industry employment will decrease by over 7,000 FTEs under baseline conditions from 2020 to 2040. This decrease in employment demand that is expected to occur independent of the Proposed Rule is consistent with the declining demand for U.S. coal from retiring coal-fired power plants and is expected to occur primarily in the Appalachian Basin, the Illinois Basin, and the Northern Rocky Mountains and Great Plains regions.

While the socioeconomic implications of the Action Alternatives are minor, they would be added to existing and anticipated adverse conditions in the coal mining industry. Therefore, the cumulative impact of the Action Alternatives (excluding Alternative 9), in combination with other actions and trends, is classified as negative. Alternative 9 is anticipated to have a neutral cumulative effect.

Chapter 1. Purpose of and Need for the Federal Action

1.0 Introduction

1.0.1 Proposed Action

The Office of Surface Mining Reclamation and Enforcement (OSMRE) is considering revising the regulations implementing the Surface Mining Control and Reclamation Act of 1977 (SMCRA) (30 U.S.C. §§ 1201-1328). These regulations are found in Parts 700 through 999 of Title 30 of the Code of Federal Regulations (CFR).

The proposed action seeks to revise the regulations to provide a better balance between the Nation's need for coal as an essential energy source with the need to prevent or mitigate adverse environmental effects of present and future surface coal mining operations. The proposed action applies to both surface and underground mines.

This Environmental Impact Statement (EIS) evaluates several Alternatives. Each Action Alternative considered in detail is made up of various regulatory components (hereafter referred to as elements), to achieve some or all of the following objectives:

- Providing for the collection of more comprehensive environmental baseline data for proposed coal mining operations;
- Defining "material damage to the hydrologic balance outside the permit area;"
- Establishing more protective standards for mining activities in or near streams (including mining through streams);
- Providing for more comprehensive monitoring of groundwater and surface water;
- Improving the effectiveness of monitoring by providing for periodic review and analysis of all monitoring results;
- Revising excess spoil disposal and postmining surface configuration requirements to minimize adverse impacts on streams;
- Revising the provisions for approval of variances and exceptions from approximate original contour restoration requirements to more completely implement the statute;
- Revising the definitions of ephemeral, intermittent stream and perennial streams to be more consistent with the corresponding definitions used by the U.S. Army Corps of Engineers (USACE) for purposes of implementing Section 404 of the Clean Water Act;
- Providing for coordination with Clean Water Act permitting activities to the extent practicable;
- Improving soil salvage and redistribution standards to ensure construction of an appropriate root zone on the reclaimed area;
- Providing that revegetation success standards be established in a manner that documents restoration of premining capability;

- Providing for the increased use of native species;
- Promoting reforestation and fish and wildlife protection and enhancement; and
- Updating measures to protect threatened and endangered species and designated critical habitat under the Endangered Species Act of 1973.

OSMRE is also proposing a number of changes that would improve the consistency, accuracy, implementation, and ease of use of existing regulations. These changes do not require evaluation in this FEIS because of their administrative nature. They include:

- More detailed requirements for preparation of the determination of the probable hydrologic consequences of the proposed operation (the PHC determination) and the Cumulative Hydrologic Impact Assessment (CHIA);
- Improved coordination between the SMCRA regulatory authority and the agencies responsible for implementing the Clean Water Act (33 U.S.C. §§ 1251-1387);
- Incorporating into regulation the policy requirement that appropriate and adequate financial assurance be posted to guarantee treatment of long-term discharges, and otherwise updating performance bond and bond release requirements; and
- Reorganizing, restructuring, and rewriting regulations in accordance with Executive Order 12114 on using Plain Language in Government Writing and Section 501(b) of SMCRA.

This EIS has been prepared in accordance with the National Environmental Policy Act (NEPA) (42 U.S.C. § 4321 *et seq.*) and the implementing regulations of the Council on Environmental Quality (CEQ) (40 CFR Part 1500-1508), and the Department of the Interior (43 CFR Part 46).

1.0.2 Organization of this Document

This EIS is organized into nine chapters:

Chapter 1 describes the steps taken by OSMRE to comply with NEPA for this proposed federal action. It also describes the process used to identify the affected public and agency concerns and to define the issues and Alternatives that required detailed examination in this EIS (scoping). In addition, Chapter 1 provides a summary of comments received during the scoping process. Finally, Chapter 1 describes the purpose of and need for the proposed federal action.

Chapter 2 describes the nine Alternatives that were examined in detail, including the No Action Alternative (current regulations) and the Preferred Action Alternative. This chapter also describes several additional Alternatives that OSMRE considered but did not carry forward for detailed analysis. This chapter also describes the process used in developing the Alternatives examined in this EIS.

Chapter 3 describes the affected environment—i.e., the general environmental conditions of the seven coal-producing regions in the United States where 95 percent of total U.S. coal production occurs and is anticipated to occur in the future. Those regions are the Appalachian Basin, the Colorado Plateau, the Gulf Coast, the Illinois Basin, the Northern Rocky Mountains and Great Plains, the Northwest, and the Western Interior.

Chapter 4 analyzes the environmental consequences of each of the Alternatives analyzed in detail. This chapter also includes a description of the scope and impact of existing regulations (including regulations other than the implementing regulations for SMCRA) as part of the discussion of the No Action Alternative.

Chapter 5 describes the consultation and coordination that OSMRE has undertaken as part of the EIS development process.

Chapter 6 lists preparers of and contributors to this EIS.

Chapter 7 lists the references cited in this EIS.

Chapter 8 lists acronyms used in this EIS.

Chapter 9 provides a glossary of terms used in this EIS.

The appendices, which provide additional information and support for the discussion in this EIS, are located in a separate volume.

1.0.3 Background - The 1979, 1983, and 2008 Stream Buffer Zone Rules

SMCRA was enacted into law on August 3, 1977. Some of the stated purposes of the Act are:

- To establish a national program to protect society and the environment from the adverse effects of surface coal mining operations;
- To assure that surface mining operations are not conducted where reclamation as required by the Act is not feasible;
- To assure that reclamation occurs as contemporaneously as possible with surface coal mining operations;
- To strike a balance between protection of the environment and agricultural productivity and the need for coal as an essential source of energy;
- To assist the States in developing and implementing regulatory and abandoned mine land reclamation programs to achieve the purposes of the Act;
- To promote reclamation of areas mined before the enactment of SMCRA;
- To provide appropriate procedures for public participation in the development, revision, and enforcement of regulations, standards, reclamation plans, and regulatory programs under SMCRA.

The Act sets forth minimum performance standards for environmental protection and public health and safety which apply to surface coal mining and reclamation operations, including the surface effects of underground coal mining operations. Persons who propose to conduct surface coal mining and reclamation must apply for permits that meet the requirements of the applicable regulatory program. After the regulatory authority approves a permit application, the applicant must post a performance bond to guarantee completion of the approved reclamation plan. Upon receipt of a suitable bond, the regulatory authority will issue the permit.

The Act provides that any state may obtain primary jurisdiction over the regulation of surface coal mining and reclamation operations on non-federal and non-Indian lands within its borders if it submits and receives approval of a regulatory program under the Act. Indian tribes may also obtain primary jurisdiction over the regulation of surface coal mining and reclamation operations on land under the jurisdiction of the Indian tribe. A state or tribal program becomes effective after review and approval by the Secretary of the Interior. Coal mining is currently occurring in 25 states, and on lands of the Navajo, Crow and Hopi nations. To date, all but two of the states have achieved primacy; i.e. approval to serve as the regulatory authority on non-federal and non-Indian lands. As of the date of this EIS, no tribal nation has achieved primacy. States with primacy are eligible to enter into a cooperative agreement with the Secretary of the Department of the Interior to regulate mining on federal lands within their borders. Most states with mineable coal on federal lands have entered into such cooperative agreements. OSMRE has a limited enforcement role in a state with an approved program. This role includes (1) conducting such inspections as are necessary to evaluate the administration of state programs, (2) conducting inspections where a state, after notification from OSMRE of “any information” of a violation, fails to respond appropriately within ten days, (3) issuance of a cessation order when an OSMRE inspector finds a situation that presents an imminent danger to public health or safety or imminent danger of significant environmental harm, and (4) substitution of federal enforcement of a state program when a state is not effectively implementing, administering, or enforcing its approved program. OSMRE retains direct regulatory authority over coal mining on Indian lands and in states without primacy. Only one of the states without primacy (Tennessee) currently produces coal.

OSMRE’s first permanent program performance standards, as published on March 13, 1979, included stream buffer zone (SBZ) rules at 30 CFR 816.57 (for surface mining operations) and 817.57 (for underground mining operations). Except for stream-channel diversions, those rules provided that no surface area within 100 feet of a perennial stream or a stream with a biological community may be disturbed by surface operations or facilities unless the regulatory authority finds that the original stream channel would be restored and that, during and after mining, the activities would not adversely affect the water quantity and quality of the stream segment within 100 feet of those activities.

The 1979 rules also defined “intermittent stream” in two ways. One method relied on hydrological criteria, while the other method classified all streams that drain a watershed of one square mile or larger as intermittent even if those streams do not meet the hydrological criteria for an intermittent stream. A stream meeting either of those criteria qualified as intermittent; the stream did not need to meet both criteria. This definition did not impact the 1979 stream buffer zone rule, but it proved to be relevant to implementation of subsequent stream buffer zone rules.

In 1983, OSMRE revised the stream buffer zone rules to delete the requirement that the original stream channel be restored. The 1983 rule replaced the biological community criterion for determining which non-perennial streams must be protected with a requirement for protection of all intermittent streams. Finally, the rule specified that the regulatory authority may authorize mining activities through or within 100 feet of a perennial or intermittent stream only after finding that the proposed activities would not cause or contribute to a violation of applicable state or federal water quality standards and would not adversely affect the water quality or quantity or other environmental resources of the stream.

On December 12, 2008, OSMRE published a revised SBZ rule that replaced the findings in the 1983 rule with a requirement that permittees avoid conducting mining activities in perennial and intermittent streams unless the regulatory authority finds that avoiding disturbance of the stream is not reasonably possible. The prohibition did not apply to mining through streams, for which the standard for approval was that the stream-channel diversion be located and designed to minimize adverse impacts on fish, wildlife, and related environmental values to the extent possible, using the best technology currently available. The 2008 rule also prohibited mining activities on the surface of land within 100 feet of perennial and intermittent streams unless (1) they are part of mining activities (such as the construction of excess spoil fills, coal mine waste disposal facilities, sedimentation pond embankments, or bridge abutments) that the regulatory authority has approved to take place in the pertinent stream segment itself, (2) the regulatory authority finds that avoidance is not reasonably possible, or (3) the regulatory authority finds that the prohibition is not needed to meet fish and wildlife and hydrologic balance protection requirements.

The 2008 rule required that permittees (1) design and conduct their operations to minimize the volume of excess spoil generated by mining operations and (2) design and construct fills to be no larger than needed to accommodate the anticipated volume of excess spoil to be generated. As part of the excess spoil minimization requirement, the rule required that mining operations return the excavated overburden to the mined-out area to the extent possible, after taking into consideration applicable regulations concerning restoration of approximate original contour, safety, stability, and environmental protection, as well as the needs of the postmining land use.

The 2008 rule also provided that, to minimize adverse impacts on fish, wildlife, and related environmental values, the operation must be designed to avoid constructing excess spoil fills, refuse piles, or slurry impoundments in perennial and intermittent streams to the extent possible. When avoidance was not possible, the rule required that the permit application identify a range of reasonable alternatives for disposal and placement of the excess spoil or coal mine waste, evaluate their environmental impacts, and select the Alternative with the least overall adverse impact on fish, wildlife, and related environmental values. The rule established criteria for determining whether a potential Alternative is reasonably possible; as part of those criteria, it stated that an Alternative generally may be considered unreasonable if its cost is substantially greater than the costs normally associated with this type of project.

Shortly after publication of the 2008 rule, ten environmental organizations challenged the validity of the rule. *See Coal River Mountain Watch v. Salazar*, No. 08-2212 (D.D.C., filed Dec. 22, 2008) and *National Parks Conservation Ass'n v. Salazar*, No. 09-115 (D.D.C., filed Jan. 16, 2009). Because of the litigation, OSMRE never requested that states with primacy amend their programs. Thus, the 2008 SBZ rule took effect only in states with federal regulatory programs (of which only Tennessee has active coal mining) and on Indian lands.

On November 30, 2009, OSMRE published an Advance Notice of Proposed Rulemaking (ANPR) seeking public comment on how current regulations should be revised to reduce "the harmful environmental consequences of surface coal mining operations in Appalachia, while ensuring that future mining remains consistent with federal law" (OSMRE, 2009). The ANPR confirmed that "[t]he Secretary of the Interior remains committed to reducing the adverse impacts of Appalachian surface coal mining operations on streams." The ANPR also indicated that OSMRE would consider whether "revisions to other OSMRE regulations, including approximate original contour (AOC) requirements, are needed to better protect the environment and the public from the impacts of Appalachian surface coal mining." Further, the ANPR solicited comments "identifying significant issues, studies, and specific alternatives that we should consider in the [Supplementary Environmental Impact Statement (EIS)] for this rulemaking initiative" (74 FR 62664-62668, Nov. 30, 2009). OSMRE received approximately 32,750 comments during the 30-day comment period on various issues related to stream protection.

On February 20, 2014, the U.S. District Court for the District of Columbia issued an order that vacated the 2008 SBZ rule, which had the effect of reinstating the pre-2008 version of the vacated rules. *See Nat'l Parks Conservation Ass'n v. Jewell*, 2014 U.S. Dist. LEXIS 152383, at *31-*34 (D.D.C. Feb. 20, 2014). On December 22, 2014, OSMRE formally removed the provisions of the vacated 2008 rule from the Code of Federal Regulations and reinstated the prior regulations (79 FR 76227-76233).

1.0.3.1 Previous Environmental Impact Statements Related to Stream Protection

After the passage of SMCRA on August 3, 1977, the Secretary of the Interior, through OSMRE, developed regulations for both the initial and permanent regulatory programs required by SMCRA (30 U.S.C. 1211(c)(2)). OSMRE prepared a programmatic environmental impact statement (OSMRE EIS-1) that analyzed the environmental consequences of Alternatives for the permanent program regulations. OSMRE published OSMRE EIS-1 as final in January 1979. The permanent program regulations were published as a Final Rule on March 13, 1979 (44 FR 15313, Mar. 13, 1979).

In 1981, OSMRE identified a need for changes to the March 1979 regulations. OSMRE analyzed the effects of the Proposed Rule changes on the environment in EIS-1 Supplement, released in January 1983.

Beginning in 2003, OSMRE initiated a rulemaking to revise regulatory requirements for placement of excess spoil generated during mining, and to revise the stream buffer zone rule. OSMRE prepared an EIS to support this rulemaking and announced the availability of the Final EIS in the *Federal Register* on October 24, 2008 (73 FR 63510, Oct. 24, 2008).

CEQ's regulations implementing NEPA encourage agencies to incorporate information by referring to information already presented in other documents to reduce unnecessary repetition (40 CFR 1502.21). Therefore, when applicable and appropriate, OSMRE relies on and references analyses in the following EIS documents:

- U.S. Department of the Interior, Office of Surface Mining Reclamation and Enforcement. Excess Spoil Minimization--Stream Buffer Zones, Proposed Revisions to the Permanent Program Regulations Implementing the Surface Mining Control and Reclamation Act of 1977 Concerning the Creation and Disposal of Excess Spoil and Coal Mine Waste and Stream Buffer Zones. Final Environmental Impact Statement OSMRE-EIS-34, Sept. 2008.[17]

[17] The validity of this EIS was challenged in *Coal River Mountain Watch et al. v. Jewell*, No. 08-2212 (D.D.C., filed Dec. 22, 2008). However, after the court vacated the rule that was the subject of this EIS in *Nat'l Parks Conservation Ass'n v. Jewell*, 2014 U.S. Dist. LEXIS 152383, at *34 (D.D.C. Feb. 20, 2014), the court held that the NEPA challenge was moot. *See Coal River Mountain Watch et al. v. Jewell*, No. 08-2212, Memorandum Decision at 2 (D.D.C., Feb. 20, 2014). The DEIS and FEIS for this rulemaking use information from this document to discuss aspects of the purpose and need (see sections 1.0.4 and 1.1.3), the history of the environmental analyses for the 2008 rule (see section 3.0.3), and aspects of the affected environment such as soils, topography and biological resources (see sections 3.3, 3.4 and 3.8) and trends of mining under existing regulations (see section 4.2.2 and section 4.2.3).

- U.S. Environmental Protection Agency, Mountaintop Mining/Valley Fills in Appalachia, Draft Programmatic Environmental Impact Statement (MTM-VF DPEIS), EPA 9-03-R-00013, EPA Region 3, June 2003 and Final Programmatic Environmental Impact Statement (MTM-VF FPEIS), October 2005.[18]

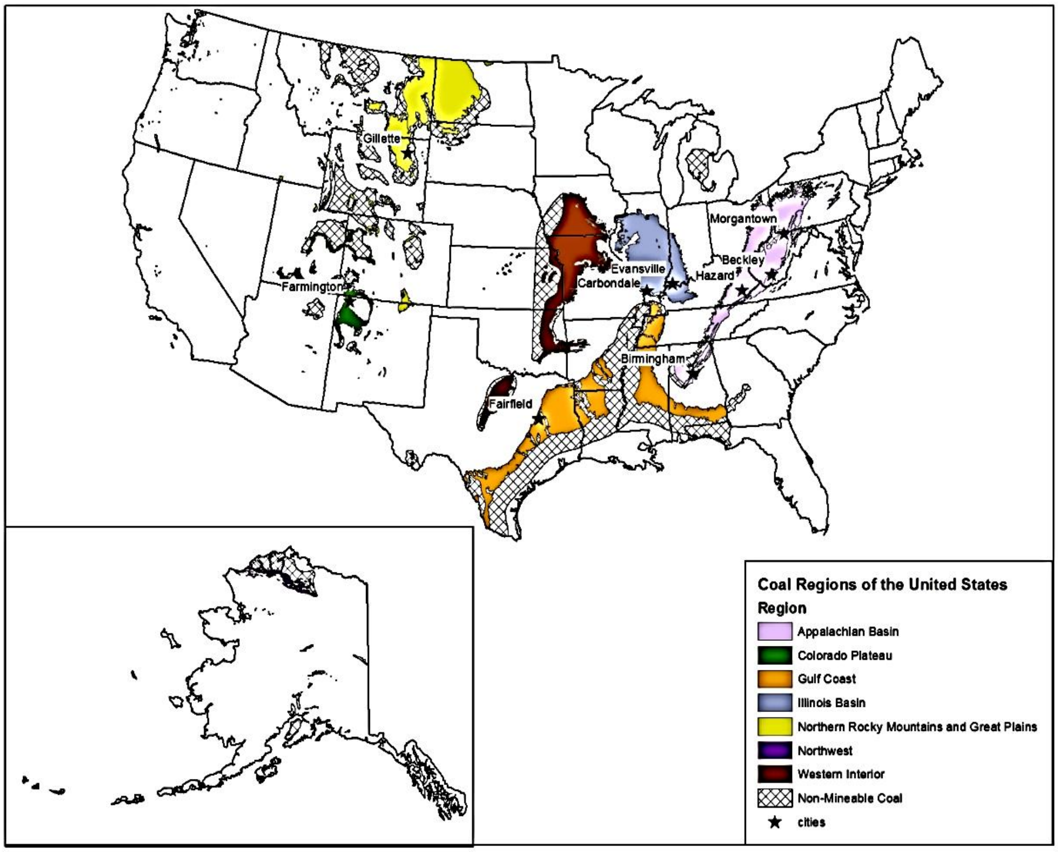
1.0.3.2 Public Participation in Development of this DEIS

OSMRE published the first Notice of Intent (NOI) to prepare an EIS under Section 102(2)(C) of the NEPA in the *Federal Register* on April 30, 2010 (75 FR 22723). OSMRE also posted that notice on the bureau's website. OSMRE invited comments and suggestions on the scope of the analysis, including the eleven principal elements of the contemplated action. OSMRE received 25 written comments during this initial scoping period.

On June 18, 2010, OSMRE published a second NOI to announce that nine open house format scoping meetings would be held to collect information on the proposed Alternatives and elements under consideration in the rulemaking, and to extend the comment period (75 FR 34666). The second NOI invited comments on possible Alternatives based on eleven principal rule elements. During the additional 45-day public scoping period, OSMRE held open houses in Carbondale, IL; Evansville, IN; Birmingham, AL; Fairfield, TX; Hazard, KY; Beckley, WV; Morgantown, WV; Farmington, NM; and Gillette, WY. These nine cities are located in or near the major coal-producing regions of the U.S. and are accessible to the majority of the population living in those regions (Figure 1.0-1). Approximately 400 people attended the open houses and provided almost 450 written and oral comments. In addition, 20,126 comments were received via electronic and hard copy submissions outside of the open houses.

[18] Information from this document is used within the discussion of topography in section 3.4, for the discussion of wetlands in section 3.9, for the discussion of stream fills in section 4.2.1.4, and within the discussion of downstream effects within the documented impacts of mining under the no action alternative in section 4.2.2.1.

Figure 1.0-1. Map of Coal Regions and Scoping Open-House Locations Used in EIS Development



Source: Coal fields layer obtained from *USGS National Atlas*. To prepare this figure OSMRE modified the coal fields data to distinguish mineable versus non-mineable coal by region.

1.0.3.3 Issues Identified Through Public Involvement

1.0.3.3.1 Comments from EIS Scoping

Some of the comments received during scoping were related to Alternatives that OSMRE might consider in both the Proposed Rulemaking and within the analysis of the DEIS. Most commenters provided specific comments regarding each of the principal elements and possible Alternatives set out in the June 18, 2010 NOI. Of these comments, some recommended clarifications to existing rules as opposed to a new rulemaking, made suggestions pertaining to specific elements or Alternatives within the Proposed Rulemaking, or raised new issues or rule elements for consideration.

Comments generally fell into two categories: (1) comments in support of rule revisions that would provide greater environmental protection for streams and other natural resources; and (2) comments that support the adequacy of the existing regulations.

Some commenters favoring greater environmental protections advocated interpretation of the 1983 SBZ rule as an absolute prohibition on stream impacts. This group of comments often described the 1983 SBZ rule as a bright-line prohibition against any adverse impacts within the stream buffer zone. Other comments suggested that OSMRE should assess the effects of an Alternative that would ban surface mining of coal entirely.

OSMRE incorporated most of the comments described above regarding Alternatives into the development of the Alternatives analyzed. The suggestion to include an Alternative that would ban surface coal mining entirely was not incorporated because that Alternative is not authorized under SMCRA and would not meet the purpose and need for the proposed action.

1.0.3.3.2 Comments in Response to the Advance Notice of Proposed Rulemaking

Additional substantive comments were received on the ANPR. Some of these comments highlighted the impacts of surface coal mining and current regulatory shortcomings regarding streams:

- Large surface mines in the interior coal basins of the U.S. typically impact numerous streams during the mining process. There is a need for consistent, scientifically viable methods of evaluating the premining condition of these streams, as well as the impacts of mining on them.
- Plans for stream protection and restoration should provide for consistent application of best practices nationwide to assure restoration of form and function as well as maintenance of streams' ecological value. Measurements of success should be uniformly applied.
- When possible, stream restoration plans should provide for enhancements as part of the reclamation process.
- After reclamation, changes in the water table near re-established stream channels may result in loss of intermittent or perennial streams or conversion to ephemeral streams.

Other commenters opposed changes to current rules and asserted that additional regulation would impair mining operations, increase costs, endanger jobs at a time of high unemployment, and provide little, if any, additional protection for the environment. Some comments questioned the authority of OSMRE under SMCRA to adopt certain measures under consideration. Others asserted that OSMRE had failed to articulate a need for new regulations so soon after adopting the 2008 SBZ Rule.

Although some commenters emphasized the need for nationwide stream protection regulations, other commenters, especially those from the coal-producing regions of the Midwest and the West, questioned the need to promulgate a nationwide Stream Protection Rule, arguing that there is no evidence of adverse impacts on streams outside Appalachia. These commenters also argued that because of regional differences, many elements under consideration would be inapplicable, cumbersome, costly, or impractical to apply outside Appalachia.

Comments received in response to the ANPR and impacts of operating under the existing regulations were incorporated into the analysis of the DEIS where appropriate. In addition, they were also incorporated into the Proposed Rule language as appropriate.

1.0.3.3.3 Comments on the DEIS and the Proposed Rule

On July 16, 2015, OSMRE announced that the Proposed Rule, Draft Environmental Impact Statement (DEIS), and Draft Regulatory Impact Analysis (RIA) were available for review at www.regulations.gov, on our web site (www.osmre.gov), and at selected OSMRE offices. On July 17, 2015, OSMRE published a notice in the Federal Register announcing the availability of the DEIS for the Proposed Rule. See 80

FR 42535-42536. The notice reiterated that the DEIS was available for review at www.regulations.gov, www.osmre.gov, and the OSMRE offices listed in the notice. The comment period for the DEIS was originally scheduled to close on September 15, 2015. On July 27, 2015, OSMRE published the Proposed Stream Protection Rule in the Federal Register. See 80 FR 44436-44698. That document reiterated that the Proposed Rule, DEIS, and Draft RIA were available for review at www.regulations.gov, www.osmre.gov, and the OSMRE offices listed in the notice. The comment period for the Proposed Rule and Draft RIA was originally scheduled to close on September 25, 2015. In response to requests for additional time to review and prepare comments on all three documents, OSMRE extended the comment period for the Proposed Rule, DEIS, and Draft RIA through October 26, 2015. See 80 FR 54590-54591 (Sept. 10, 2015).

During the public comment period, OSMRE held six public hearings on the Proposed Rule and DEIS in Golden, Colorado (September 1, 2015); Lexington, Kentucky (September 3, 2015); St. Charles, Missouri (September 10, 2015); Pittsburgh, Pennsylvania (September 10, 2015); Big Stone Gap, Virginia (September 15, 2015); and Charleston, West Virginia (September 17, 2015). In addition to the testimony offered at the hearings and meetings, OSMRE received approximately 94,000 written or electronic comments on the Proposed Rule. Responses to comments on the DEIS are included in Appendix K of this FEIS. Responses to comments on the Proposed Rule are provided in the preamble to the Final Rule.

1.0.4 Scope of Analysis

This EIS evaluates a range of Alternatives related to stream protection and the conservation of fish, wildlife and related environmental values, including a No Action Alternative, under which the current federal regulations would be unchanged. OSMRE carefully considered all issues raised during the scoping and public outreach process associated with this action when developing the Alternatives.

OSMRE analyzed the effects of each Alternative on the seven most productive coal-bearing regions of the United States (Figure 1.0-1 above). Some coal regions have a more extensive mining history than others, leading to variable data availability across the seven regions. In addition, environmental impacts are disparate across the regions, largely due to historical trends in coal production. Data tend to be more readily available in regions with an extensive mining history and legacy coal mining impacts. In some instances, when data are limited, OSMRE relies on reasonable assumptions to evaluate the relative impacts of different Alternatives (see Chapter 4).

In analyzing the Alternatives, OSMRE relied on reports included in previous EISs and considered studies published since preparation of the 2008 EIS (see Chapter 7 for a complete list of references). OSMRE also obtained updated factual information relevant to stream protection from OSMRE field offices and state regulatory agencies. In addition, OSMRE conducted one new study for this EIS in cooperation with the U.S. Environmental Protection Agency (U.S. EPA) (Pond et al. 2014). The study examined biological community composition downstream from reclaimed valley fills. This was a follow-up to a 2008 study (Pond et al. 2008). More details are provided in Chapter 4 Section 4.2.2.

1.1 Need for the Federal Action

The need for this federal action is to improve implementation of SMCRA to ensure protection of the hydrologic balance, and reduce impacts of surface coal mining operations on streams, fish, wildlife, and related environmental values. In considering this need, OSMRE has identified several subcomponents of our regulations that could be improved.

- First, there is a need to define "material damage to the hydrologic balance outside the permit area" and ensure that each permit identifies the point at which adverse mining impacts on groundwater and surface water (both of which provide stream flow) reach an unacceptable level; that is, the point at which they would cause material damage to the hydrologic balance outside the permit area.
- Second, there is a need to collect adequate premining data about the site of the proposed mining operation and adjacent areas to establish a comprehensive baseline against which the impacts of mining can be compared.
- Third, there is a need for effective, comprehensive monitoring of groundwater and surface water both during and after mining and reclamation to provide timely documentation of the impacts of mining and to enable prompt detection of any adverse trends and implementation of corrective measures before it is either too late to take remedial measures or exceedingly costly to do so.
- Fourth, there is a need to ensure protection or restoration of perennial and intermittent streams and related resources including fish and wildlife, especially headwater streams that are critical to maintaining the ecological health and productivity of downstream waters.
- Fifth, there is a need to ensure the use of objective standards in making important regulatory and operational decisions with a potential impact on perennial and intermittent streams.
- Sixth, there is a need to ensure that permittees and regulatory authorities make use of advances in information, technology, science, and methods related to surface and groundwater hydrology, surface-runoff management, stream restoration, soils, and revegetation, all of which relate directly or indirectly to protection of water resources and the ability of mined land to support the uses that it was capable of supporting before mining.

After evaluating the comments received on the ANPR, OSMRE identified a need for a comprehensive rulemaking to better protect streams nationwide. Refinement of existing regulations is needed to more completely implement SMCRA's permitting requirements and performance standards and provide regulatory clarity to operators and stakeholders while better achieving the purposes of SMCRA as set forth in section 102 of the Act. In particular, to more completely realize the purposes in paragraphs (a), (c), (d), and (f) of that section, which include establishing a nationwide program to protect society and the environment from the adverse effects of surface coal mining operations and assuring that surface coal mining operations are conducted in an environmentally protective manner and are not conducted where reclamation is not feasible. Furthermore, the this action is needed to addresses court decisions and strike the appropriate balance between environmental protection, agricultural productivity and the Nation's need for coal as an essential source of energy, while providing greater regulatory certainty to the mining industry.

1.1.1 Need for Regulatory Improvements

Section 201(c)(2) of SMCRA requires that the Secretary of the Interior, acting through OSMRE, "publish and promulgate such rules and regulations as may be necessary to carry out the purposes and provisions of this Act." In section 101(c) of SMCRA, Congress found that:

> many surface coal mining operations result in disturbances of surface areas that burden and adversely affect commerce and the public welfare by … polluting the water, by destroying fish and wildlife habitats, by impairing natural beauty, … and by counteracting governmental programs and efforts to conserve soil, water, and other natural resources.

The federal action analyzed in this EIS will better prevent or remediate the adverse impacts that Congress described when it made this finding. Despite the enactment of SMCRA and the promulgation of federal regulations implementing the statute, surface coal mining operations continue to have negative effects on streams, fish, and wildlife. These conditions are documented in the literature surveys and studies discussed in Chapter 4. Further evidence is available through several decades of observing the impacts of coal mining operations. These documented and observed problems have prompted OSMRE to consider whether it should take a different approach in the regulations implementing the following SMCRA provisions related to stream protection:

- Section 510(b)(3) of SMCRA in effect requires that each surface coal mining operation be designed to prevent material damage to the hydrologic balance outside the permit area. Current regulations intentionally do not define the extent of damage that is allowable and how much damage constitutes "material damage," an approach that was intended to afford regulatory authorities flexibility in making determinations on a case-by-case basis (48 FR 43973, Sept. 26, 1983).
- Section 515(b)(2) of SMCRA requires that mined land be restored to a condition capable of supporting the uses that it was capable of supporting prior to mining. Alternatively, it allows mined land to be restored to a condition capable of supporting higher or better uses of which there is reasonable likelihood, provided certain conditions are met. Existing rules and permitting practices have focused primarily on the land's suitability for a single approved postmining land use, which may or may not be implemented. OSMRE believes it is essential to ensure that land be restored to a condition in which it is capable of supporting all uses that it was capable of supporting before mining, unless the approved postmining land use is implemented before final bond release.
- Section 515(b)(10) of SMCRA requires that mining operations minimize disturbances to the prevailing hydrologic balance at the mine site and in associated offsite areas. It also requires that mining operations minimize disturbances to the quality of water in surface water and groundwater systems both during and after surface coal mining operations and during reclamation. As discussed in more detail in Chapter 2, OSMRE is evaluating a number of options to provide the most effective implementation of this statutory requirement, including regulatory options for avoidance of acid and toxic drainage from mine sites. OSMRE also seeks the most effective regulation of excess spoil fill construction because of the potential effects of those fills on the hydrologic balance, water quality, and aquatic life.
- Sections 515(b)(19) and 516(b)(6) of SMCRA require the operator to establish a diverse, effective, permanent vegetative cover of the same seasonal variety native to the area on all

regraded areas and other lands affected by mining. However, many previously forested areas have been reclaimed with heavily compacted soils that reduce site productivity and the ability of the site to support productive forests. These sites are commonly revegetated as grasslands with scrub trees, and vegetation that is not representative of native premining vegetation. OSMRE is considering Alternatives that would implement these SMCRA provisions more effectively.

- Sections 515(b)(24) and 516(b)(11) of SMCRA require, subject to certain limitations, that surface coal mining and reclamation operations minimize disturbances and adverse impacts on fish, wildlife, and related environmental values. These provisions also require operations to "achieve enhancement of such resources where practicable." Reconstructed streams, however, often neither look nor function the way they did before mining. The emphasis has been primarily upon creating a channel sufficient to convey postmining flows, while minimizing channel erosion and sediment loading. Until recent years, there has been relatively little attention paid to the impact of mining on water quality and hence aquatic life in reconstructed streams and in streams downstream of the mining operation. Particularly in Appalachia, streams may no longer support the benthic and other aquatic communities that they did before mining. Additionally, efforts to enhance fish, wildlife, and related environmental values have not been evenly implemented as part of state reclamation programs, despite the presence of that requirement in both the statute and the regulations.
- OSMRE's current rules at 30 CFR 816.73 allow excess spoil fills to be constructed by end-dumping. With end-dumping, operators push or dump rock overburden over the side of the mountain to cascade into the valley below, with the larger rocks rolling to the bottom of the valley to form the underdrain. Based on several decades' experience implementing the existing rules, OSMRE is reexamining the extent to which this technique accords with a number of SMCRA requirements. For instance, some end-dumping may not comply with Section 515(b)(22)(A) of SMCRA which provides that all excess spoil material resulting from surface coal mining operations must be "transported and placed in a controlled manner in position for concurrent compaction and in such a way to assure mass stability and to prevent mass movement." End-dumping, moreover, can result in elevated dissolved ion concentrations in water leaving the site and significant increases in concentrations of total dissolved solids (TDS) in receiving streams, both of which may adversely affect fish and wildlife in contravention of Section 515(b)(24) of SMCRA. Further, construction of end-dumped rock fills can result in inconsistent development of the underdrains required under Section 515(b)(2) of SMCRA, leading to structural instability of the fill.
- Section 515(b)(3) requires, with certain exceptions, that mined land be restored to AOC. Restoration of mined land to a surface configuration that includes convex and concave terrain patterns and landforms typical of the premining surface configuration could more effectively meet this requirement. The existing rules governing AOC restoration are general, subjective, and lacking in specificity. Too often, this has resulted in postmining surface configurations that are significantly flatter than the premining configuration; that lack many of the landform features found prior to mining; and that have significantly altered drainage patterns and stream characteristics and functions. OSMRE has identified a number of instances where the regulatory authority overlooked inadequate contour restoration until late in the process (at which point correcting the problem would be overly expensive or cause unacceptable disruption of stabilized

conditions). OSMRE is evaluating Alternatives to address this problem including additional mapping and reporting regarding compliance with contour restoration.

1.1.2 Need for Adequate Data

To effectively evaluate the impacts of a mining operation and to ensure implementation of SMCRA's requirements, the regulatory authority must have both sufficient baseline data and sufficient data about ongoing changes to stream-related resources and biota. Adequate data about the conditions before the mining activity are critical to ascertaining the extent and cause of any changes that do occur after mining is underway; this information in turn is critical to correcting problems if and when they occur. To ensure that the necessary corrections can be made to prevent and mitigate damage, the regulations must specify the types of information that need to be collected, and the locations, timing, and frequency of information collection. As discussed above, Section 510(b)(3) of SMCRA requires that each surface coal mining operation be designed to prevent material damage to the hydrologic balance outside the permit area. Section 515(b)(10) of SMCRA requires, in essence, that surface coal mining and reclamation operations "minimize the disturbances to the prevailing hydrologic balance at the mine site and in associated offsite areas and to the quality and quantity of water in surface and ground water systems both during and after surface coal mining operations and during reclamation." For underground mining, Section 516(b)(9) of SMCRA requires operations to minimize disturbances to the prevailing hydrologic balance at the mine site and associated offsite areas, and to ensure the quantity of water. Sections 515(b)(24) and 516(b)(11) of SMCRA require, subject to certain limitations, that surface coal mining and reclamation operations minimize disturbances and adverse impacts on fish, wildlife, and related environmental values; and also require operations to "achieve enhancement of such resources where practicable."

As discussed previously, studies indicate that environmental degradation is still occurring despite the current requirements within the implementing regulations of SMCRA. OSMRE has determined that this research indicates that effective evaluation of trends and impacts on groundwater, surface water, and stream-related resources and biota would require additional monitoring of data beyond what is currently required by existing regulations. Additional water quality parameters must be monitored both in the baseline condition and within any effluent leaving mine sites. Similarly, existing regulations do not provide for collection of baseline data sufficient to determine the biological condition of streams. Consequently, characteristics of the aquatic community in the stream are not well documented in SMCRA permit files. This impedes regulators' ability to assess whether an operation is adequately minimizing adverse impacts on fish, wildlife, and related environmental values, as required by Sections 515(b)(24) and 516(b)(11) of SMCRA. More complete and accurate baseline information is needed to improve regulators' ability to determine whether mine plans are designed in accordance with SMCRA, and whether operations are being conducted in accordance with mining plans. For example, better baseline data would facilitate a more thorough CHIA, would help set objective and measurable material damage standards, and would help identify and address hydrologic problems that may arise after permit issuance.

Additional monitoring data are also needed to provide sufficient warning when water impacts are approaching thresholds where evaluations should occur to prevent further damage. This change would help operators and regulators evaluate the potential for the operation to result in material damage to the hydrologic balance.

1.1.3 Need for Adequate Objective Standards

To effectively implement SMCRA's requirements related to stream protection, regulations must allow permittees and operators, as well as regulatory authorities, to effectively evaluate compliance and limit or prevent adverse impacts, as appropriate.

The regulatory standards must provide an objective threshold with clear and predictable standards for preventing "material damage to the hydrologic balance outside the permit area," as required by Section 510(b)(3) of SMCRA. That section requires that each surface coal mining operation be designed to prevent material damage to the hydrologic balance outside the permit area. However, neither OSMRE nor most states have defined this term. A clear federal definition and federal minimum standards or criteria against which to measure whether material damage has occurred is needed to provide a basis for oversight of state implementation of this statutory requirement.

As noted above, based on observed changes, OSMRE believes that existing permitting and performance standards implementing Section 515(b)(10) of SMCRA may be inadequate to minimize disturbances to the prevailing hydrologic balance at the mine site and to the quality of water in surface and ground water systems. More specific, more clearly defined and objective standards would improve implementation of this statutory requirement.

1.1.4 Need to Apply Current Information, Technology, and Methods

This federal action is also designed to incorporate significant advances in scientific knowledge that have occurred since OSMRE's permanent program regulations were adopted in 1979 and then substantially amended, starting in 1983.

First, new information exists on the adverse impacts that coal mining can cause to water resources and stream biota. As discussed in more detail in Chapter 4, there are many recent publications of studies and literature surveys that evaluate the impacts of surface coal mining and reclamation operations on water quantity and quality, as well as related biological resources.

Second, since OSMRE's earlier rulemakings, there have been significant improvements in technologies and methods for prediction, prevention, mitigation, and reclamation of coal mining impacts on hydrology, streams, fish, wildlife, and related resources. As discussed in more detail in Chapter 4, OSMRE has identified major improvements in technology and methods related to identifying, quantifying, mapping, and modeling mining operations and their impacts on the environment. Examples of such improvements are discussed below.

Advances in identification and prediction of impacts on stream resources. Since the 2008 SBZ rule, there have been significant improvements in analysis of the impacts of mining on stream resources. For instance, coal mining-related regulatory programs have traditionally focused on acid mine drainage and sediment loads as the sources of potential problems. However, as described in Chapter 4 of this EIS, the fracturing of overburden as part of the mining process results in significant increases in conductivity and TDS in streams below many surface mines, particularly below excess spoil fills. Those changes can have significant toxic effects on streams, leading to a loss of sensitive aquatic organisms even when downstream habitats are otherwise intact. Emerging science indicates that problems can include golden alga blooms and adverse impacts to fish and wildlife from the discharge or formation of chemical constituents not considered in past rulemaking efforts. Further, data now indicate that some pollutants, such as selenium, may bio-accumulate. Accumulation of pollutants in biological systems over time may adversely affect biota and human health. In addition, new studies indicate that toxic discharges may continue for decades even after reclamation of the site has otherwise been successful according to current requirements for restoration of the land itself.

Landform elements such as ridges, valleys, hill slopes, and streams can now be measured quantitatively in a way not feasible until recently. Permit reviewers can now use computers and sophisticated software to process huge amounts of elevation data acquired from stereo satellite and airborne images, lidar, and radar to produce much more accurate maps and models of surface configuration than was possible a few short years ago. This information may allow state regulators to determine the total volume of earth that a mining operation has displaced or will displace, based on the position of the coal seams and volume of overburden relative to the premining topography. These data can also be used to plan for restoration of smaller-scale features that blend into the surrounding topography within a watershed. By contrast, reclamation practices under existing regulations often rely on construction of uniformly sized and spaced structures and features.

Advances in reclamation techniques. Emerging science now provides much better information on effective reclamation practices related to stream protection. During the last decade, the scientific community has made great strides in developing geomorphic reclamation strategies that reduce erosion and improve water quality. These improvements are not reflected in current regulations. More traditional approaches to restoration of AOC have created large reclaimed acreages that resemble landscapes of agricultural fields, urban recreational parks, or construction fill sites such as large dam embankments, spillways, or waterway diversions. Modern Global Positioning System (GPS)-enabled equipment can incorporate the use of geomorphic principles in reclamation design, and can provide a closer approximation of the highly dissected and randomly spaced and sized drainage patterns of an undisturbed landscape. The Los Angeles abrasion test (a standard test method for determining resistance to degradation) and the sodium or magnesium sulfate soundness test (which distinguishes between rocks based on their susceptibility to weathering) can be used to assess the appropriateness of material used in fills. Hydrologic modeling programs such as the USACE Hydrologic Engineering Center, Hydrologic Modeling System (HEC-HMS) can predict with greater accuracy the flow pattern and volume of runoff that would occur under different rainfall scenarios at defined locations. Use of programs such as the Civil Software Design, LLC Sediment, Erosion, Discharge by Computer Aided Design (SEDCAD) program can more effectively design and evaluate erosion and sediment control systems. Such improvements in reclamation may significantly improve restoration of ephemeral streams, protection of water quality in perennial and intermittent streams, and long-term landscape stability.

Advances in reforestation techniques have been shown to decrease the detrimental effects of storm runoff. Science now indicates that high nutrient loads can have negative, cumulative impacts downstream, but that streamside buffer zones can reduce those nutrient loads and associated impacts. OSMRE experience over the past thirty years indicates that extensive herbaceous ground cover on reclaimed areas can inhibit the establishment and growth of trees and shrubs. The dense herbaceous ground covers historically used to control erosion compete with newly planted trees and tree seedlings for soil nutrients, water, and sunlight, and provide habitat for rodents and other animals that damage tree seedlings and young trees.

1.2 Purpose of the Federal Action

Our primary purpose in considering this rulemaking is to strike a better balance between "protection of the environment and agricultural productivity and the Nation's needs for coal as an essential source of energy." Specifically, our purpose is to minimize the adverse impacts of surface coal mining operations on surface water, groundwater, and site productivity, with particular emphasis on protecting or restoring streams, aquatic ecosystems, streamside habitats and vegetative corridors, native vegetation, and the ability of mined land to support the uses that it was capable of supporting before mining. The proposed action reflects our experience during the more than three decades since adoption of the existing regulations, as well as advances in scientific knowledge and mining and reclamation techniques during that time. In addition, as proposed, OSMRE revised and reorganized the regulations for clarity, to make them more user-friendly, to remove obsolete and redundant provisions, and to implement plain language principles.

Chapter 2. Description of All Alternatives Including the No Action Alternative

2.0 Introduction

This chapter of the Final Environmental Impact Statement (EIS) introduces and describes the eight Action Alternatives that the Office of Surface Mining Reclamation and Enforcement (OSMRE) is considering in its Proposed Stream Protection Rule (SPR). It also discusses the No Action Alternative, which reflects current applicable regulations, policies and practices.

In addition, this chapter identifies and describes the eleven principal elements for evaluation (factors for analysis) within each of the nine Alternatives that OSMRE is considering. For ease of discussion and analysis, OSMRE has organized these eleven principal elements into the following four "functional groups" under each of the Alternatives. These functional groups recognize common or related characteristics that address an overarching rulemaking topic or concern:

- Protection of the Hydrologic Balance;
- Activities in or near Streams;
- Approximate Original Contour (AOC) and AOC Variances; and
- Revegetation, Topsoil, and Fish and Wildlife Protection and Enhancement.

Table 2.1-1 summarizes the principal elements using these four functional groups. Grouping certain elements together helps to illustrate their relationship and makes the impact analysis clearer and easier to follow. For example, when discussed together, it is easier to draw the connection between *establishing* a baseline for surface water and groundwater characteristics, *monitoring ongoing changes* from the baseline condition during mining and reclamation and *establishing evaluation thresholds*[19] to prevent environmental damage. Further, the functional grouping demonstrates how these elements relate to protection of the hydrologic balance.

2.1 Development of the Alternatives

OSMRE identified the need for improved stream protection through internal analysis and external scoping and public outreach activities. Public concerns ranged from support for an outright ban on certain coal mining practices to maintaining the current regulations (the No Action Alternative) and providing time to implement the regulatory changes adopted in the 2008 Stream Buffer Zone (SBZ) rule. Some participants focused on environmental issues, while others expressed concerns about the potential costs and impacts

[19] Evaluation thresholds were referred to as "corrective action thresholds" in the DEIS and Proposed Rule. Evaluation thresholds are numeric values lower than the material damage thresholds for the corresponding parameters

from any Proposed Rulemaking on the coal mining industry, employment, affected regulatory authorities, and local, regional, and national economies.

Table 2.1-1.
Organization of 11 Principal Elements (Factors for Analysis) into Functional Groups

Functional Groups	Protection of the Hydrologic Balance	Activities in or near Streams	AOC and AOC Variances	Revegetation, Topsoil, and Fish and Wildlife Protection and Enhancement
Factors for Analysis (Principal Elements)	Baseline data collection and analysis	Stream definitions	Surface configuration	Revegetation, topsoil management, and reforestation
Factors for Analysis (Principal Elements)	Monitoring during mining and reclamation	Activities in or near streams, including disposal of excess spoil and coal mine waste	AOC variances	Fish and wildlife protection and enhancement
Factors for Analysis (Principal Elements)	Definition of material damage to the hydrologic balance outside the permit area	Mining through streams	---	---
Factors for Analysis (Principal Elements)	Evaluation thresholds	---	---	---

OSMRE published the first Notice of Intent (NOI) to conduct scoping for this DEIS in the *Federal Register* on April 30, 2010 (75 FR 22723, Apr. 30, 2010). OSMRE invited comments and suggestions on the scope of the analysis, including the principal elements of the contemplated action. OSMRE received 25 written comments during this initial scoping period. On June 18, 2010, OSMRE published a second NOI announcing nine additional scoping “open houses” to provide information on the proposed Alternatives and elements under consideration in the rulemaking and to accept public comments (75 FR 34666, Jun. 18, 2010). The second NOI invited comments on possible Alternatives, based on 11 principal elements.

As part of the scoping process, OSMRE held open houses in Carbondale, IL; Evansville, IN; Birmingham, AL; Fairfield, TX; Hazard, KY; Beckley, WV; Morgantown, WV; Farmington, NM; and Gillette, WY. OSMRE selected these locations based on proximity to the major coal-producing regions of the U.S. and accessibility to the majority of the population living in those regions (Figure 1.0-1). Approximately 400 people attended the open houses and provided 450 written and oral comments. In addition, OSMRE received over 20,000 comments via electronic and hard copy submissions outside the open houses.

In developing a reasonable range of Alternatives, OSMRE also considered responses to an Advance Notice of Proposed Rulemaking (ANPR) published on November 30, 2009, which sought public comment on how OSMRE should revise current regulations to reduce “the harmful environmental consequences of surface coal mining operations in Appalachia, while ensuring that future mining remains consistent with Federal law” (74 FR 62664-62668, November 30, 2009). The ANPR also indicated that OSMRE would consider whether “revisions to other OSMRE regulations, including AOC requirements, are needed to better protect the environment and the public from the impacts of Appalachian surface coal mining." OSMRE received approximately 32,750 comments during the 30-day comment period on various issues, including those related to stream protection.

As a result of interagency discussions, internal reviews, and consideration of the comments received in response to the ANPR and during the extensive DEIS scoping process, OSMRE revised the principal rulemaking elements. In the process, OSMRE also identified the need for application of consistent, scientifically viable methods for evaluating the biological condition of streams, and for restoring their form and ecological function after mining. Section 1.0.1 provides a complete list of rulemaking elements that OSMRE considered.

OSMRE continued to refine the Alternatives based on preliminary input from the state and federal cooperating agencies, and later based on federal interagency review of the Preferred Alternative facilitated through the Office of Information and Regulatory Affairs (OIRA). OIRA is part of the Office of Management and Budget (OMB), which is an agency within the Executive Office of the President. The OMB is tasked per Executive Order 12866, "Regulatory Planning and Review," with the review of federal agency draft and proposed final regulatory actions.

2.2 Overview of the Alternatives and Chapter Organization

This chapter (Chapter 2) describes Alternatives that OSMRE considered with respect to the eleven principal elements outlined in the two NOIs, with modifications based on comments received and analysis of the Alternatives. Section 2.3 provides a brief description of the eleven elements. Section 2.4 describes the nine Alternatives in detail, organized by Alternative. Section 2.5 reverses that approach by grouping the Alternatives under the principal elements to assist the reader in identifying the Alternatives that address a particular concern. Finally, Section 2.6 describes Alternatives and elements that OSMRE considered, but subsequently dismissed without further analysis. OSMRE dismissed these Alternatives for several reasons, including that they: (1) were not reasonable; (2) did not meet the purpose and need of the proposed federal action as described in Chapter 1 of this FEIS; and/or (3) were outside the scope of the Proposed Rulemaking.

2.3 Range of Analysis for Each of the Eleven Principal Elements

In the NOIs, OSMRE published a list of eleven principal issues (elements) to be analyzed for the Stream Protection Rulemaking initiative. Initially, these eleven elements included baseline data requirements; a definition of material damage to the hydrologic balance outside the permit area; restrictions on activities in, near, or through streams; monitoring requirements; evaluation thresholds; surface configuration; variances to approximate original contour restoration requirements; enhanced reforestation activities; permit coordination among agencies; financial assurances for long-term treatment of postmining discharges; and stream definitions.

OSMRE revised the list of principal elements after further analysis and in light of the comments received during scoping. For example, OSMRE analyzes "mining through streams" and "activities that occur in or near streams" as separate principal elements because OSMRE believes these two categories of mining activities are significantly different. Mining *through* streams typically means that operators would excavate coal deposits beneath the streambed. In this situation, the operator would either permanently divert the stream channel or reconstruct it in its original location after mining. Mining *in or near* streams refers to activities that take place within a stream or its buffer zone. These activities may sometimes cover the stream but never include removal of the streambed to extract coal. Examples of activities that may occur in or near streams include construction of sedimentation ponds, water treatment facilities, excess spoil fills or coal mine waste disposal facilities, and stream crossings.

OSMRE also added fish and wildlife protection and enhancement as a principal element and expanded the enhanced reforestation element to include revegetation, reforestation, and soil management.

2.4 Description of Alternatives

This section describes each of the nine Alternatives according to the four functional groups discussed above. As noted earlier, each functional group combines elements that have similar or interrelated attributes.

2.4.1 Alternative 1 (No Action Alternative)

Alternative 1, the No Action Alternative, consists of current regulatory requirements, policies, and practices under the Surface Mining Control and Reclamation Act (SMCRA), the Clean Water Act (CWA), and other federal and state laws that are relevant to this federal action. For reasons of brevity, this discussion describes only the requirements for surface coal mining operations. However, in most instances, analogous requirements apply to underground mining operations. If OSMRE were to select this Alternative, existing rules under SMCRA would not change.

2.4.1.1 Protection of the Hydrologic Balance

2.4.1.1.1 Baseline Data Collection and Analysis

Under the current regulations, the applicant for a mining permit is required to submit, at a minimum, the following baseline information, and any additional hydrologic or geologic information required by the regulatory authority.[20]

Groundwater: Under 30 CFR 780.21, the applicant must submit data for existing wells, springs, and other groundwater resources within or adjacent to the proposed permit area. These data characterize the quality and quantity of groundwater and provide information on usage sufficient to demonstrate seasonal variation. Information on water quality must include total dissolved solids or specific conductance, pH, total iron, and total manganese. Groundwater quantity information must include approximate rates of discharge or usage, as well as depth to the water in the coal seam, each water-bearing stratum above the coal seam, and each potentially affected stratum below the coal seam.

Surface water: Under 30 CFR 780.21, the applicant must submit information on surface water quality and quantity sufficient to demonstrate seasonal variation and water usage. At a minimum, water-quality information must include baseline information on total suspended solids, total dissolved solids or specific

[20] Unless otherwise specifically stated, the term "regulatory authority" as used in this FEIS refers to the SMCRA regulatory authority.

conductance, pH, total iron, and total manganese. The applicant must provide additional information on baseline acidity and alkalinity if there is a potential for acidic drainage from the proposed mining operation. Water quantity information must contain information on seasonal flow rates.

Geology: Under 30 CFR 780.22, the permit application must describe the geology of the proposed permit area and the adjacent area down to and including the deeper of either (1) the stratum immediately below the lowest coal seam to be mined or (2) any aquifer below that seam that could be adversely affected by mining. The description must include the areal and structural geology of the proposed permit area and the adjacent area. The description must also address other parameters that influence the required reclamation and the occurrence, availability, movement, quantity, and quality of potentially impacted surface water and groundwater. The geologic information must also include analyses of samples collected from test borings, drill cores, or samples from rock outcrops from the permit area. This requirement includes lithologic characterization and chemical analysis of strata and the coal seam for acid-forming or toxic-forming materials (including total sulfur, pyritic sulfur, and alkalinity-producing materials). The regulatory authority may waive analysis for alkalinity-producing materials and pyritic sulfur if sufficient data exists to document that the data is not needed.

2.4.1.1.2 Monitoring During Mining and Reclamation

The current regulations at 30 CFR 780.21(i) and (j) and 816.41(c) and (e) require monitoring of the quantity and quality of surface water and groundwater. The monitoring plan must include parameters related to the suitability of the water for current and approved postmining land uses, the hydrologic reclamation plan, and (for surface water) the effluent limitations in 40 CFR Part 434. At a minimum, pH, total iron, total manganese, total dissolved solids (TDS) or specific conductance, water levels (for groundwater), flow (for surface water), and total suspended solids (TSS) (for surface water) must be monitored every three months until final bond release. The permittee must monitor point-source discharges in accordance with their National Pollutant Discharge Elimination System (NPDES) permit. The monitoring plan must identify the monitoring locations, but the regulations do not establish criteria for the number or placement of monitoring locations.

The regulatory authority may modify or waive the monitoring requirements at any time if the permittee demonstrates that monitoring, in whole or in part, is no longer necessary to achieve the purposes set forth in the monitoring plan; that the operation has minimized disturbance to the hydrologic balance within the permit area and prevented material damage to the hydrologic balance outside the permit area; that water quality and quantity are suitable to support the approved postmining land uses; and that the water rights of other users have been protected or adequately replaced. However, all effluent limitations and conditions must comply with NPDES permit issued for your operation by the appropriate authority under the Clean Water Act, 33 U.S.C. 1251 et seq. In addition, the regulatory authority may not modify or waive NPDES monitoring requirements.

2.4.1.1.3 Definition of Material Damage to the Hydrologic Balance Outside the Permit Area

The current regulations do not define material damage to the hydrologic balance outside the permit area. However, the preamble to existing 30 CFR 780.21(g) and 784.14(f) states that “because the gauges for measuring material damage may vary from area to area and from operation to operation,” OSMRE has not established fixed criteria, except for those established under §§ 816.42 and 817.42 related to compliance with water quality standards and effluent limitations (48 FR 43973, Sept. 26, 1983). OSMRE further noted in the preamble to the existing rules that each regulatory authority should establish criteria to measure material damage to the hydrologic balance for purposes of cumulative hydrologic impact assessments (48 FR 43973, Sept. 26, 1983).

2.4.1.1.4 Evaluation Thresholds

The current regulations contain no requirement for specific evaluation thresholds. However, permit applicants proposing to conduct surface or underground coal mining are required under § 780.21(h) or § 784.14(g) respectively, to provide a plan of measures the applicant would take to avoid adverse potential adverse hydrologic consequences, including preventative and remedial measures. Under 30 CFR 816.41(c)(2) and (e)(2) and 817.41(c)(2) and (e)(2), if monitoring results demonstrate noncompliance with permit conditions or federal, state, or tribal water quality laws and regulations, the permittee must promptly notify the regulatory authority. The applicant must then take all possible steps to minimize any adverse impact to the environment or public health and safety, and must immediately implement measures necessary to comply with permit condition (30 CFR 773.17(e)).

2.4.1.2 Activities in or Near Streams

2.4.1.2.1 Stream Definitions

The current regulatory definitions of perennial, intermittent, and ephemeral streams utilize hydrologic characteristics and watershed size to define these waters (30 CFR 701.5). The current definitions do not include biological or chemical characteristics.

- Under the current regulations, a perennial stream is a stream or part of a stream that flows continuously during all of the calendar year because of groundwater discharge or surface runoff.
- An intermittent stream is (1) a stream or reach of a stream that drains a watershed of at least one square mile, or (2) a stream or reach of a stream that is below the local water table for at least some part of the year, and obtains flow from both surface runoff and groundwater discharge.
- An ephemeral stream is a stream that flows only in direct response to precipitation in the immediate watershed or in response to the melting of a cover of snow and ice, and which has a channel bottom that is always above the local water table.

The definition in the second bullet has sometimes been incorrectly interpreted as if the “or” was an “and;” i.e., the one-square-mile criterion has sometimes been applied as a threshold for all intermittent streams, when, in fact, a stream in a smaller watershed that meets the second criterion is an intermittent stream regardless of the size of its watershed.

2.4.1.2.2 Activities in or near Streams (Including Excess Spoil Fills and Coal Mine Waste Disposal Facilities)

The 1983 SBZ rule, 30 CFR 816.57, which is now back in effect after the court vacated the 2008 rule,[21] provides that mining activities may not disturb land within 100 feet of a perennial or an intermittent

[21] See 79 FR 76227-76233 (Dec. 22, 2014).

stream unless the regulatory authority specifically authorizes activities closer to, or through, such a stream. The regulatory authority may authorize such activities only after finding that the proposed activities would not cause or contribute to a violation of applicable federal or state water quality standards under the Clean Water Act and would not adversely affect the water quantity and quality or other environmental resources of the stream.

The 1983 SBZ rule does not specifically mention placement of excess spoil and coal mine waste in or within 100 feet of streams, but OSMRE and most state regulatory authorities generally have applied the 1983 SBZ rule in a manner that allows the construction of excess spoil fills, refuse piles, slurry impoundments, and sedimentation ponds in all types of streams and their buffer zones.

The existing regulations at 30 CFR 816.71 through 816.74 require that excess spoil fills be constructed by controlled placement of the excess spoil in lifts no greater than four feet thick, except that durable rock fills may be constructed by end-dumping, which is intended to result in the formation of underdrains by gravity segregation.

In general, only surface coal mining operations in steep-slope terrain generate excess spoil. Although not expressly required by regulation, most states with mining operations in steep-slope terrain have adopted policies intended to minimize the generation of excess spoil and thus reduce the need for (and size of) excess spoil fills, which in turn would reduce the length of stream covered by those fills. In addition, the agencies administering the Clean Water Act have implemented policies that have sharply reduced both the number of excess spoil fills and the length of stream covered by those fills. Furthermore, the regulations in 40 CFR Part 230 for implementation of section 404(b)(1) of the Clean Water Act require an analysis of all practicable alternatives to placement of fill material in waters of the United States, which would include most streams. Under those regulations, the applicant must select the alternative with the least adverse effect on the aquatic ecosystem and mitigate any remaining adverse impacts on the aquatic environment.

2.4.1.2.3 Mining Through Streams

The 1983 version of the stream-channel diversion rules at 30 CFR 816.43 is now back in effect following the court decision vacating the 2008 SBZ rule. Under 30 CFR 816.43(b)(1), the regulatory authority may approve diversion of perennial or intermittent streams within the permit area only after making the finding related to stream buffer zones in 30 CFR 816.57 that the diversion would not adversely affect the water quantity and quality and related environmental resources of the stream. Under 30 CFR 816.43(a), the applicant must design the diversion to minimize adverse impacts to the hydrologic balance within the permit and adjacent areas, prevent material damage to the hydrologic balance outside the permit area, and to assure the safety of the public. In addition, the applicant must design, locate, construct, maintain, and use the diversion to prevent, to the extent possible using the best technology currently available, additional contributions of suspended solids to streamflow outside the permit area.

Under 30 CFR 816.43(b)(4), both the design and construction of stream-channel diversions for perennial and intermittent streams must be certified by a qualified registered professional engineer as meeting applicable performance standards and any design criteria established by the regulatory authority. Under 30 CFR 816.43(a)(3), the design for restored stream channels for perennial and intermittent streams (or permanent diversion channels for those streams) must restore or approximate the premining characteristics of the original stream channel, including the natural riparian vegetation. Under 30 CFR 816.43(b)(2), the design capacity for both temporary and permanent stream-channel diversions must at least equal the capacity of the unmodified stream channel immediately upstream and downstream of the diversion.

2.4.1.3 AOC and AOC Variances

2.4.1.3.1 Surface Configuration

Under existing 30 CFR 780.18(b)(3), each permit application must include a plan for backfilling, soil stabilization, and compacting and grading. Contour maps or cross-sections must show the anticipated final surface configuration. The performance standards at 30 CFR 816.102, 816.104, 816.105, 816.106, and 816.107 require that disturbed areas be backfilled and regraded to closely resemble the premining surface configuration, with exceptions for thin and thick overburden situations, previously mined areas, and certain other circumstances. The regulations allow permanent impoundments, including final-cut impoundments, provided they do not otherwise create conflicts with achieving AOC and they meet the design, construction, maintenance, postmining land use, and other requirements in 30 CFR 800.40(c)(2), 816.49(b), and 816.133.

2.4.1.3.2 AOC Variances

The current regulations provide for the approval of permits for mountaintop removal mining operations, which are exempt from AOC restoration requirements if the postmining land use and postmining surface topography requirements of paragraphs (3) and (4) of section 515(c) of SMCRA are met. The regulations also provide for the approval of AOC variances for steep-slope mining operations under certain conditions.

As described in 30 CFR 785.14(b), mountaintop removal mining operations are surface mining activities in which the mining operation removes an entire coal seam or seams running through the upper fraction of a mountain, ridge or hill by removing substantially all of the overburden off the bench and creating a level plateau or gently rolling contour, with no highwalls remaining. To obtain a permit for mountaintop removal mining operations, the proposed postmining land use must be a commercial, industrial, residential, agricultural, or public facility land use. The regulatory authority must find that the proposed postmining land use meets all requirements for alternative postmining land uses and is an equal or better economic or public use of the land compared to its premining use. The permit application must include specific plans for the proposed postmining land use, including assurance of investment in public facilities and documentation of private financial capability to ensure completion. The current regulations do not require implementation of the approved postmining land use prior to final bond release.

Under 30 CFR 824.11(a)(9), the regulatory authority may approve a permit for a mountaintop removal mining operation only upon a demonstration that there would be no damage to natural watercourses below the lowest coal seam to be mined. The regulations do not define the term “no damage.” Natural watercourses above the lowest coal seam mined are not protected from damage.

Under 30 CFR 824.11(a)(6), the permittee must leave an outcrop barrier in place at the toe of the lowest coal seam mined to ensure stability.

As defined in 30 CFR 701.5, steep slopes are any slope of more than 20° or a lesser slope designated by the regulatory authority after consideration of soil, climate, and other characteristics of a region or State. To obtain an AOC variance for steep-slope mining operations under 30 CFR 785.16, the proposed postmining land use must be of an industrial, commercial, residential, or public (including recreational facilities) nature. It also must meet the requirements in 30 CFR 816.133 for approval of alternative postmining land uses, which, among other things, means that the postmining use must be an equal or better economic or public use. The applicant must demonstrate that the proposed operation will improve the watershed when compared to either premining conditions or the conditions that would exist if the applicant restored the area to AOC after mining. The regulatory authority can concur that the operation would improve the watershed only if the operation would reduce the amount of total suspended solids or other pollutants discharged from the permit area to surface water or groundwater *or* reduce the flood hazards within the watershed by a reduction of the peak-flow discharge from precipitation events or thaws. In both cases, the total volume of flow from the proposed permit area during every season of the year must not vary in a way that adversely affects the ecology of any surface water or any existing or planned use of surface water or groundwater.

2.4.1.4 Revegetation, Topsoil, and Fish and Wildlife Protection and Enhancement

2.4.1.4.1 Revegetation, Reforestation and Topsoil Management

Under 30 CFR 816.133(a), the permittee must restore all disturbed areas to a condition in which they are capable of supporting the uses that they were capable of supporting before any mining or higher or better uses.

Under 30 CFR 816.22, the permittee must salvage and redistribute all topsoil (the A and E soil horizons), unless alternative overburden materials are approved as being equal to or better than the existing available topsoil to support vegetation. The permittee also must demonstrate that the selected overburden materials they propose to use as topsoil substitutes and supplements are the best available material within the permit area. Paragraph (e) of 30 CFR 816.22 provides that the regulatory authority may require salvage and redistribution of the subsoil (the B and C soil horizons) or other underlying strata if it finds that those layers are necessary to comply with the revegetation performance standards in 30 CFR 816.111 through 816.116.

Paragraph (d) of 30 CFR 816.22 requires that the permittee redistribute topsoil and topsoil substitutes and supplements in a manner that achieves an approximately uniform, stable thickness when consistent with the approved postmining land use, contours, and surface water drainage systems. Soil thickness may vary to the extent necessary to meet the specific revegetation goals identified in the permit. The permittee also must redistribute soil materials in a manner that prevents excess compaction and protects the materials from wind and water erosion before and after seeding and planting.

Under 30 CFR 816.116, revegetation success standards must be based upon the effectiveness of the vegetation to support the approved postmining land use, the extent of ground cover compared to the cover provided by the natural vegetation of the area, and the general requirements of 30 CFR 816.111. These general requirements provide that the vegetative cover must be diverse, effective, and permanent; comprised of species native to the area (with certain exceptions); at least equal in extent of cover to the natural vegetation of the area; capable of stabilizing the soil surface from erosion; compatible with the postmining land use; have the same seasonal characteristics of growth as the original vegetation; be capable of self-regeneration and plant succession; be compatible with the plant and animal species of the area; and meet the requirements of state and federal laws and regulations concerning seeds, poisonous and noxious plants, and introduced species. The regulations provide limited exceptions to some of these requirements for agricultural crops and for plantings used to establish temporary cover.

2.4.1.4.2 Fish and Wildlife Protection and Enhancement

Under 30 CFR 780.16(a), each permit application must include fish and wildlife resource information for the proposed permit area and the adjacent area. The regulatory authority must determine the scope and level of detail of that information in consultation with state and federal agencies with responsibility for fish and wildlife. Paragraph (b) of 30 CFR 780.16 requires that the permit application also include a fish and wildlife protection and enhancement plan. Paragraph (c) of 30 CFR 780.16 requires that the regulatory authority provide the fish and wildlife resource information and the fish and wildlife protection and enhancement plan to the U.S. Fish and Wildlife Service (U.S. FWS) upon request.

Under the current regulations at 30 CFR 816.97(a), the mine operator must, to the extent possible using the best technology currently available (BTCA), minimize disturbances and adverse impacts to fish, wildlife, and related environmental values and enhance such resources where practicable.

Under 30 CFR 816.97(b), surface mining activities must not jeopardize the continued existence of endangered or threatened species or result in the destruction or adverse modification of designated critical habitats of such species in violation of the Endangered Species Act of 1973 (16 U.S.C. §§1531 to 1599). On September 24, 1996, the U.S. FWS issued a biological opinion (BO) and conference report to OSMRE (1996 BO) on the continuation and approval and conduct of surface coal mining and reclamation operations under state and federal regulatory programs adopted pursuant SMCRA where such operations may adversely affect species listed as threatened or endangered or designated critical habitat under the ESA. The 1996 BO explains how this requirement is designed to be implemented; it also provides an incidental take statement. The BO states that the regulatory authority must "implement and require compliance with any species-specific protective measures developed by the USFWS field office and the regulatory authority (with the involvement, as appropriate, of the permittee and OSM[RE])." The BO further provides that, "[w]henever the regulatory authority decides not to implement one or more of the species-specific measures recommended by the USFWS, it must provide a written explanation to the USFWS. If the USFWS field office concurs with the regulatory authority's action, it would provide a concurrence letter as soon as possible. However, if the USFWS does not concur, the issue must be elevated through the chain of command of the regulatory authority, the USFWS, and (to the extent appropriate) OSM[RE] for resolution." OSMRE and the U.S. FWS are coordinating on a MOU, the "ESA MOU" as it was referred to in the Executive Summary, to provide guidance to OSMRE, the U.S. FWS, and the regulatory authorities for demonstrating compliance with the terms and conditions of the Incidental Take Statement accompanying the 1996 biological opinion, which provides incidental take coverage for any take resulting from a proposed coal mining and reclamation operation. The ESA MOU, while still in development as of publication of this document, is part of the current regulatory environment because it adds no new requirements but instead merely provides guidance on existing ones.

Under 30 CFR 816.97(f), the permittee must avoid disturbances to wetlands and riparian vegetation along rivers and streams and bordering ponds and lakes; permittees must enhance where practicable, restore, or replace these resources. Likewise, surface mining activities must also avoid disturbances to habitats of unusually high value for fish and wildlife; these resources must be restored or enhanced where practicable.

Where fish and wildlife habitat is to be a postmining land use, 30 CFR 816.97(g) requires that the plant species to be used on reclaimed areas be selected based upon their proven nutritional value for fish or wildlife, their use as cover for fish or wildlife, and their ability to support and enhance fish or wildlife habitat after bond release. Paragraph (g) also requires that the plants selected be grouped and distributed in a manner that optimizes edge effect, cover, and other benefits to fish and wildlife.

The remaining paragraphs of 30 CFR 816.97 identify assorted other measures that permittees must implement during and after mining to minimize damage to fish and wildlife resources and their habitats or to ensure that all postmining land uses provide some fish and wildlife habitat or travel corridors to the extent practicable.

2.4.2 Alternative 2

Alternative 2 would result in the most significant changes to permit requirements and mining operations under SMCRA. Under Alternative 2, and all the Action Alternatives to follow, the proposed regulatory changes pertain to SMCRA only; implementation of any of the proposed Alternatives below would not affect compliance with any other federal, state or tribal laws.

Alternative 2 would change water monitoring and reporting requirements before and during mining operations and during reclamation. The regulatory authority would be required to coordinate with Clean Water Act implementing agencies to harmonize baseline data collection and monitoring requirements to the extent consistent with each agency's statutory authority and responsibilities. This Alternative would prohibit mining operations in or through perennial streams; it also would prohibit the placement of excess spoil in intermittent or perennial streams. In addition, it would prohibit all variances from AOC, which could require amendment of SMCRA. Proposed modifications under Alternative 2 are characterized below.

2.4.2.1 Protection of the Hydrologic Balance

2.4.2.1.1 Baseline Data Collection and Analysis

Alternative 2 differs from the No Action Alternative by establishing minimum sample collection intervals and by expanding the suite of parameters for which permittees must analyze all water samples. It also requires documentation of the biological condition of perennial and intermittent streams and the sediment load of the watershed, as well as precipitation.

Under this Alternative, the applicant must collect and submit the following baseline data during the application process:

- Surface water: The applicant must sample all potentially affected perennial and intermittent streams and a representative number of ephemeral streams within the proposed permit and adjacent areas a minimum of 12 times, with the samples evenly spaced over a 12-month period.

The applicant must collect samples for a suite of parameters to include temperature, bicarbonate, sulfate, chloride, calcium, magnesium, sodium, potassium, hot acidity, alkalinity, pH, selenium, specific conductance (or total dissolved solids (TDS)), total iron, total manganese, total suspended solids, arsenic, zinc, copper, cadmium, ammonia, nitrogen, and any additional parameters for which effluent limitations have been established under the NPDES in accordance with section 402 of the Clean Water Act. The applicant must collect continuous streamflow data and must collect stream sediment load data for each watershed.

- Groundwater: The applicant must measure groundwater levels continuously throughout baseline monitoring. The applicant must sample groundwater in perched and regional aquifers at the same frequency and for the same water-quality parameters as surface water (with the exception of total suspended solids). In addition, the baseline monitoring must include static water levels and other quantitative measurements of the aquifer capacity, discharge, and seasonal variation.
- Biological condition of streams: Requires use of comprehensive, multi-assemblage, scientifically defensible bioassessment protocols to document the biological condition of all perennial and intermittent streams and a representative number of ephemeral streams within the proposed permit and adjacent areas over multiple seasons (at a minimum spring, summer, and fall). Requires identification of aquatic biota to the genus taxonomic level.
- Precipitation: Requires use of continuous recording devices to record all precipitation and storm events, including precipitation amounts and the duration of each storm event, not just monthly totals.
- Form and function of streams: Requires documentation of the hydrologic form and ecological function of all perennial and intermittent streams in the proposed permit and adjacent areas.
- Geology: Requires collection of geologic data for the proposed permit and adjacent areas, with a focus on geological characteristics and properties that influence the hydrologic regime or could alter the availability or quality of groundwater and surface water.

2.4.2.1.2 Monitoring During Mining and Reclamation

Under Alternative 2, monitoring of surface water and groundwater during mining and reclamation must occur at least quarterly. The permittee must analyze each sample for the same parameters measured during baseline sampling. The permittee must monitor groundwater and surface water at locations designated in the permit.

The permittee must monitor the biological condition of streams annually until the data demonstrate full restoration of the premining biological condition of the stream.

The permittee must review all monitoring data annually to identify adverse trends and sample analyses that approach evaluation thresholds.

The permittee must collect on-site precipitation measurements using self-recording rain gages. The regulatory authority would review the monitoring data midway through the permit term and during permit renewal cycles. The surface water runoff control plan for designing and monitoring the control structures requires an inspection following a one-year or greater recurrence-interval storm event. The permittee must then submit to the regulatory authority within 48 hours a report prepared by a certified professional engineer. The report must describe the performance of the hydraulic control structures, assess and describe any potential material damage to the hydrologic balance, and address any remedial measures taken.

Monitoring must continue until final bond release. The regulatory authority may not release the bond until monitoring results document that there are no adverse trends that could result in material damage to the hydrologic balance outside the permit area.

2.4.2.1.3 Definition of Material Damage to the Hydrologic Balance Outside the Permit Area

Section 510(b)(3) of SMCRA provides that the regulatory authority may not approve a permit for surface coal mining operations unless it first finds that the proposed operation has been designed to prevent material damage to the hydrologic balance outside the permit area. However, neither SMCRA nor the current regulations implementing SMCRA define the term "material damage to the hydrologic balance outside the permit area."

Alternative 2 would define material damage to the hydrologic balance outside the permit area as any adverse impact from surface or underground mining operations on the quantity or quality of surface water or groundwater, or on the biological condition of a perennial or intermittent stream, that would preclude attainment or continuance of any designated surface water use under sections 101(a) and 303(c) of the Clean Water Act or any existing or reasonably foreseeable use of surface water or groundwater outside the permit area.

This definition would also apply to adverse impacts from subsidence and to other adverse impacts resulting from underground mining operations (e.g., permanent dewatering of a stream by mining through a fracture zone) that result in material damage to the hydrologic balance. Thus, the definition would not be limited to the impacts from surface mining activities or the impacts of activities conducted on the surface of land (i.e., where surface facilities are located) in connection with an underground coal mine.

2.4.2.1.4 Evaluation Thresholds

Under Alternative 2, the regulatory authority must establish permit-specific or regional evaluation thresholds for key water-quality parameters based on baseline data and the cumulative hydrologic impact assessment (CHIA). These thresholds would define the point at which environmental degradation would become so significant that the permittee must take evaluation to prevent the operation from causing material damage to the hydrologic balance outside the permit area.

The permittee must conduct a water-quality trend analysis of the monitoring data on a quarterly basis. If the analysis of the monitoring data indicates that trends in values for any surface water or groundwater parameter or analyte have reached the evaluation threshold specified in the permit, the permittee must notify the regulatory authority and evaluate the conditions that caused the threshold parameter to be met or exceeded. If the permittee finds, and the regulatory authority agrees, that the increase was due to the permittee's mining activity, the permittee must develop and implement corrective measures to prevent environmental degradation (i.e., material damage to the hydrologic balance outside the permit area as defined under Alternative 2). Evaluation plans are subject to regulatory authority approval.

The requirement to take evaluation would not apply if the permittee demonstrates, and the regulatory authority concurs in writing, that the adverse values or trends for the parameters of concern are not the result of the permittee's mining operation.

2.4.2.2 Activities in or Near Streams

2.4.2.2.1 Stream Definitions

Instead of using the definitions of streams in the current SMCRA regulations, Alternative 2 would use "waters of the United States" as defined and interpreted under 40 CFR section 230.3(s) and CWA section 404(b)(1). This Alternative would protect all waters defined as "waters of the United States". The definition of an intermittent stream would no longer include the one-square-mile watershed criterion.

2.4.2.2.2 Activities in or near Streams (Including Excess Spoil Fills and Coal Mine Waste Disposal Facilities)

Alternative 2 would prohibit all mining activities in or within 100 feet of perennial streams. It would also prohibit the construction of excess spoil fills in or within 100 feet of intermittent streams. However, it would allow the construction of excess spoil fills in or within 100 feet of ephemeral streams, and the construction of coal mine waste disposal facilities in or within 100 feet of intermittent or ephemeral streams, provided the operation meets certain conditions. Furthermore, this Alternative would allow the regulatory authority to approve operations that propose to mine through intermittent or ephemeral streams, provided the operation meets certain conditions.

Under this Alternative, an applicant for a permit that proposes to conduct any other type of mining activities in or within 100 feet of an intermittent or ephemeral stream must demonstrate that the proposed activity will not cause material damage to the hydrologic balance outside the permit area. That is, the applicant must demonstrate that the proposed activity would not preclude attainment or maintenance of an existing or reasonably foreseeable designated use of the affected stream segment under section 101(a) or section 303(c) of the Clean Water Act after reclamation and that it will not result in conversion of an intermittent stream segment to an ephemeral stream segment. The applicant must demonstrate that the operation would not have more than a minimal adverse effect on the biological condition of the affected stream segment after reclamation.

Alternative 2 requires that applicants design proposed mining operations to minimize the amount of excess spoil generated. It also requires that the permittee design excess spoil fills and coal mine waste disposal facilities to minimize their footprints. Both requirements are intended to reduce the length of stream that the operation will cover.

Each applicant proposing to place excess spoil in or near an ephemeral stream or to place coal mine waste in or near an intermittent or ephemeral stream must identify and analyze a range of reasonable operational alternatives. The applicant must select the alternative that would have the least adverse impact of all reasonable operational alternatives on fish, wildlife, and related environmental values.

Alternative 2 would require development and implementation of fish and wildlife enhancement measures in compliance with any Clean Water Act mitigation plan as a condition of the SMCRA permit.

Under Alternative 2, the permittee must construct any excess spoil fills in lifts not to exceed four feet in thickness. The current regulation at 30 CFR 816.73 allowing construction of durable rock fills that rely upon end-dumping and the construction of underdrains by gravity segregation of the end-dumped material would be eliminated. This Alternative requires daily monitoring during excess spoil placement. It would revise the existing rules to require that the quarterly inspection reports filed with the regulatory authority include the daily monitoring logs.

Under Alternative 2, the regulatory authority would no longer allow construction of excess spoil fills and coal waste disposal facilities with flat decks on top. The final surface configuration must resemble the surrounding terrain.

Alternative 2 provides that, to the extent that stability considerations allow, the permittee must construct excess spoil fills with aquitards as a barrier to groundwater infiltration, and in a manner that facilitates stream construction. Placement of a layer of lower-permeability spoil or other material near the surface but below the root zone for trees and shrubs could provide the subsurface flow needed to restore flow in intermittent and ephemeral stream segments.

2.4.2.2.3 Mining Through Streams

Alternative 2 prohibits all mining activities in or within 100 feet of perennial streams. Mining through an intermittent stream would be allowed if the hydrologic form and ecological function of the stream can and will be restored. The regulatory authority would consider a stream to be restored in function when its postmining biological condition is comparable to its premining biological condition and in accordance with specific standards established by the Clean Water Act permitting authority. The regulatory authority could permit mining through an ephemeral stream only if the applicant could and would restore the hydrological form of the stream.

To obtain a permit to mine through or divert an intermittent stream, the applicant must demonstrate that the operational design would minimize the length of stream disturbed. The applicant also must demonstrate that the hydrologic form and ecological function of the stream segment can and would be fully restored. With respect to ephemeral streams, the applicant would only need to restore the hydrologic form of the stream segment. The bond posted for the permit must specifically include the cost of restoration of both the form and function of intermittent streams and the hydrologic form of ephemeral streams. Alternative 2 requires the use of natural-channel design techniques when constructing restored stream channels or permanent stream-channel diversions. The reclamation plan must provide for the establishment or preservation of a permanent streamside vegetative corridor,[22] comprised of native non-

[22] In responding to comments on the Proposed Rule, OSMRE has changed the term “riparian corridor” to “streamside vegetative corridor” to alleviate the concern that water-loving plants were required in the 100-foot corridor to either side of the stream even in conditions where water loving plants would not otherwise naturally occur. For the sake of clarity OSMRE has changed this term where used in the other alternatives as well as the preferred.

invasive species (or other native species for non-forested areas), at least 100 feet in width along both banks of the entire reach of restored or permanently diverted ephemeral or intermittent stream channels.

Alternative 2 would require the design and construction of all permanent stream-channel diversions, all temporary stream-channel diversions in use for two or more years, and all restored stream channels to adhere to natural-channel design techniques. Permanent stream-channel diversions and restored intermittent stream channels must approximate the premining characteristics of the original stream channel, including the natural riparian vegetation and the natural hydrological characteristics of the original stream. Finally, Alternative 2 would require that the hydraulic capacity of all temporary and permanent stream-channel diversions be at least equal to the hydraulic capacity of the unmodified stream channel immediately upstream of the diversion and no greater than the hydraulic capacity of the unmodified stream channel immediately downstream of the diversion.

2.4.2.3 AOC and AOC Variances

2.4.2.3.1 Surface Configuration

Alternative 2 would require the use of landforming principles, when consistent with stability and postmining land use considerations, to establish a postmining surface configuration within specific tolerances from the premining surface configuration. Landforming is a design and grading technique that attempts to replicate the appearance of the natural terrain and provide a cost-effective, attractive, and environmentally compatible way to construct slopes and other landforms that are stable and that blend in with the natural surroundings. Use of these principles would ensure restoration of dendritic ephemeral drainages and result in a more varied, natural-looking topography. Alternative 2 would require that the applicant use digital terrain modeling to document and restore the premining surface configuration. It also would require use of digital terrain modeling during backfilling and grading and upon completion of final grading to document restoration of the approved final surface configuration.

Under this Alternative, the regulatory authority would determine the allowable deviation in the elevation of the backfilled and graded area postmining in comparison to the premining elevation based on the lowest coal seam mined. The allowable deviation in the postmining elevation could be no more than ±20 percent of the difference between the premining surface elevation and the premining bottom elevation of that lowest coal seam, with allowances for slope stability and minor shifts in the location of premining features. This tolerance would apply only to those portions of the mine site that are subject to the AOC restoration requirement; e.g., the tolerance would not apply to excess spoil fills or coal mine waste disposal facilities.

AOC restoration requirements for steep-slope mining permits would allow the placement of what would otherwise be excess spoil on the mined-out area to heights in excess of the premining elevation if safety and stability requirements were met, and if the final surface configuration would be compatible with the surrounding terrain and consistent with natural premining landforms. This exemption would allow the permittee to exceed premining elevations and otherwise applicable tolerances to achieve the desired topography and would minimize the need to place excess spoil in streams.

Compliance with the ±20 percent tolerance is not practicable in contour mining on steep slopes (defined as slopes greater than 20 degrees) because of stability and equipment constraints. Therefore, the ±20 percent tolerance requirement does not apply to that portion of a contour mine permit where steep-slope mining is conducted. The tolerance and digital terrain modeling requirements also would not apply to remining sites, permits 40 acres or smaller in size, or operations that qualify for the thin overburden standards of 30 CFR 816.104.

This Alternative would allow permanent impoundments, including final-cut impoundments, provided they would not otherwise create conflicts with achieving AOC and they met the approved postmining land use. This Alternative would encourage the construction of aquitards within the backfill to act as a barrier to groundwater infiltration and to facilitate stream construction. Placement of a layer of lower-permeability spoil or other material near the surface but below the root zone for trees and shrubs could provide the subsurface flow needed to restore flow in intermittent and ephemeral stream segments.

Alternative 2 would prohibit flat decks on excess spoil fills and coal waste disposal facilities.

2.4.2.3.2 AOC Exceptions

Alternative 2 would eliminate all exceptions from the requirement to return the mined area to its approximate original contour. Thus, Alternative 2 would preclude both mountaintop removal mining operations and AOC variances for steep-slope mining operations. Implementing this Alternative could require an amendment to SMCRA.

2.4.2.4 Revegetation, Topsoil, and Fish and Wildlife Protection and Enhancement

2.4.2.4.1 Revegetation, Reforestation and Topsoil Management

Alternative 2 includes provisions similar to those of the No Action Alternative with respect to soil management and revegetation, but with a greater emphasis on restoration of the site's ability to support the uses it supported before any mining, regardless of the approved postmining land use. Alternative 2 also places greater emphasis on construction of a growing medium with an adequate root zone for deep-rooted species and on revegetation with native tree and plant species, especially reforestation of previously forested areas.

Like the No Action Alternative, Alternative 2 requires salvage and redistribution of all topsoil (the A and E soil horizons). However, it also requires salvage and redistribution of the B and C soil horizons (or other suitable overburden materials) to the extent necessary to achieve a growing medium with the optimal rooting depths required to restore premining land use capability or comply with revegetation requirements. Under the No Action Alternative, the regulatory authority has the discretion, but not necessarily the obligation, to require salvage and redistribution of the B and C soil horizons or other suitable overburden materials.

Alternative 2 allows use of selected overburden materials as substitutes for (or supplements to) either topsoil or subsoil or both only if the applicant demonstrates that either (1) the quality of the existing topsoil and subsoil is inferior to that of other overburden materials or (2) the quantity of the existing topsoil and subsoil is insufficient to provide the optimal rooting depth or meet other plant growth requirements. In the latter case, all existing topsoil and favorable subsoil must be salvaged and redistributed together with the substitute material. As in the No Action Alternative, the applicant also must demonstrate that the resulting soil medium will be more suitable than the existing topsoil and subsoil to sustain vegetation and that the selected overburden materials are the best available within the permit area for that purpose. Alternative 2 differs slightly from the No Action Alternative in that the No Action Alternative allows the use of topsoil substitutes or supplements when the resulting soil medium will be equally or more suitable than the existing topsoil to sustain vegetation, while Alternative 2 allows their use only when the resulting soil medium will be more suitable to sustain vegetation.

Under Alternative 2, the permittee must salvage and redistribute all organic matter (duff, other organic litter, and vegetative materials such as tree tops, small logs, and root balls) above the A soil horizon to increase the moisture retention capability of the soil and provide a source of the seeds, plant propagules, mycorrhizae, and other soil flora and fauna needed to support and enhance reestablishment of locally adapted and genetically diverse plant communities as well as to improve soil productivity. Alternative 2 prohibits burning or burying vegetation or other organic materials.

Under Alternative 2 the permittee must reforest lands that were previously forested, or that would naturally revert to forest under conditions of natural succession, in a manner that would enhance recovery of the native forest ecosystem as expeditiously as possible. Prime farmland is exempt from this requirement.

The permittee must revegetate the entire reclaimed area (other than water areas and impervious surfaces like roads and buildings) using native species to restore or reestablish the plant communities native to the area unless a conflicting postmining land use is actually implemented before the end of the revegetation responsibility period.

2.4.2.4.2 Fish and Wildlife Protection and Enhancement

Alternative 2 would require incorporation of any Clean Water Act mitigation plan for the operation as a condition of the SMCRA permit. Bond release under SMCRA could not occur until completion of successful mitigation as determined by the regulatory authority and the agency implementing the Clean Water Act. Implementing this Alternative could require an amendment to SMCRA.

Alternative 2 is similar to the No Action Alternative with respect to the protection of threatened and endangered species. However, Alternative 2 would codify the dispute resolution provisions of the 1996 biological opinion concerning protection of threatened and endangered species. It also would expressly require that the fish and wildlife protection and enhancement plan in the permit application include any species-specific protective measures developed in accordance with the Endangered Species Act and any biological opinions implementing that law.

Alternative 2 is similar to the No Action Alternative with respect to the fish and wildlife resource information and protection and enhancement plan required in the permit application. It also includes similar performance standards for protection of fish and wildlife. The principal difference is that Alternative 2 would require creation of a streamside vegetative corridor at least 100 feet in width, comprised of native non-invasive species, along the entire reach of any ephemeral, intermittent, or perennial streams that are restored or permanently diverted.

2.4.3 Alternative 3

Alternative 3 differs from Alternative 2 in that it would prohibit the placement of excess spoil or coal mine waste in perennial streams, but not in intermittent streams. Otherwise, Alternative 3 contains no categorical prohibition on mining activities in or near perennial, intermittent, or ephemeral streams.

2.4.3.1 Protection of the Hydrologic Balance

2.4.3.1.1 Baseline Data Collection and Analysis

Same as Alternative 2 (see Baseline Data Collection and Analysis section for Alternative 2), except that Alternative 3 would require discrete measurement of streamflow and groundwater levels whereas Alternative 2 would require continuous measurements.

2.4.3.1.2 Monitoring During Mining and Reclamation

Under Alternative 3, all monitoring requirements are the same as under Alternative 2 (see Monitoring During Mining and Reclamation section for Alternative 2), with the exception of precipitation monitoring. In that case, the engineer would be required to conduct an inspection of the surface water runoff control system after each storm event with a two-year or greater recurrence-interval, rather than after each storm event with a one-year or greater recurrence interval as under Alternative 2.

2.4.3.1.3 Definition of Material Damage to the Hydrologic Balance Outside the Permit Area

Same as Alternative 2 (see Definition of Material Damage to the Hydrologic Balance Outside the Permit Area section for Alternative 2).

2.4.3.1.4 Evaluation Thresholds

Same as Alternative 2 (see Evaluation Thresholds section for Alternative 2).

2.4.3.2 Activities in or Near Streams

2.4.3.2.1 Stream Definitions

Same as the No Action Alternative (see Stream Definitions section for Alternative 1).

2.4.3.2.2 Activities In or Near Streams (Including Excess Spoil Fills and Coal Mine Waste Disposal Facilities)

Same as Alternative 2 except that Alternative 3 would allow the placement of excess spoil in intermittent streams. Alternative 3 lacks Alternative 2's categorical prohibition on mining activities in or near perennial streams, but it would prohibit the construction of excess spoil fills and coal mine waste disposal facilities in perennial streams. Alternative 3 would require that the permittee establish permanent streamside vegetative corridors along the banks of restored or diverted perennial or intermittent stream channels, but, unlike Alternative 2, it would not require establishment of streamside vegetative corridors along the banks of restored or diverted ephemeral streams. Alternative 3 would require that the streamside vegetative corridor be at least 300 feet in width, compared to the minimum 100-foot width under Alternative 2. Unlike Alternative 2, Alternative 3 would not require that the SMCRA permit incorporate any mitigation plan under section 404 of the Clean Water Act. Alternative 3 would also allow the permittee to construct excess spoil fills with flat decks, rather than requiring the use of landforming principles as under Alternative 2.

2.4.3.2.3 Mining Through Streams

Same as Alternative 2, except that Alternative 3 would not prohibit mining through perennial streams. Nor would it require the regulatory authority to make special findings for mining through ephemeral streams, although it would require the permittee to restore the hydrologic function of ephemeral streams to the extent required by geomorphic reclamation principles.

2.4.3.3 AOC and AOC Variances

2.4.3.3.1 Surface Configuration

Same as Alternative 2, except that Alternative 3 would not include any numerical limits or tolerances on differences between premining and postmining elevations. In addition, there is no requirement to use landforming principles on the surface of excess spoil fills.

2.4.3.3.2 AOC Variances

Alternative 3 would allow mountaintop removal mining operations and AOC variances for steep-slope mining operations under conditions generally similar to those in the No Action Alternative. However, Alternative 3 would impose additional requirements to better protect streams, aquatic ecology, and biological communities. In addition, it would require that the permittee post bond in an amount sufficient to return the site to AOC if the permittee has not implemented the approved postmining land use before expiration of the revegetation responsibility period.

For approval of mountaintop removal mining operations, Alternative 3 would require the permit applicant to demonstrate that:

No damage would result to natural watercourses within the proposed permit and adjacent areas;

- There would be no adverse changes in parameters of concern in discharges to surface water and groundwater;
- No change would occur in the size or frequency of peak flows as compared to the peak flows that would occur if the permittee mined the site and restored it to AOC; and that
- The total volume of flow during any season of the year would not vary; i.e., there would be no change in the seasonal flow regime and no increase in potential damage from flooding.

In addition, the permittee must reforest the site with native species if the site was forested before submission of the permit application, unless reforestation would be inconsistent with the postmining land use.

Finally, the permittee must install drains through the outcrop barrier to prevent saturation of the backfill.

For approval of steep-slope variances, Alternative 3 would require permit applicants to demonstrate each of the following:

- The operation, including any fish and wildlife enhancement measures, will result in fewer adverse impacts to the aquatic ecology of the cumulative impact area than would occur if the site were mined and restored to AOC;
- Surface-water flow in the watershed would be improved over both premining conditions and conditions that would exist if the area were mined and restored to AOC;
- The variance would not result in construction of an excess spoil fill in an intermittent or perennial stream; and
- Any deviations from the premining surface configuration are necessary and appropriate to achieve the postmining land use.

In addition, the permittee must reforest the site with native species if the site was forested before submission of the permit application or would revert to forest under natural succession. This requirement would not apply to permanent impoundments, roads, and other impervious surfaces to be retained following mining and reclamation or to those portions of the permit area covered by the variance.

2.4.3.4 Revegetation, Topsoil, and Fish and Wildlife Protection and Enhancement

2.4.3.4.1 Revegetation, Reforestation and Topsoil Management

Alternative 3 has the same requirements for soil management and revegetation as Alternative 2, except that Alternative 3 requires salvage and redistribution of all organic matter (duff, other organic litter, and vegetative materials such as treetops, small logs, and root balls) from native species in accordance with an approved plan developed by a qualified ecologist or similar expert. The plan would specify the amount of organic materials the permittee must retain and redistribute to promote reestablishment of native vegetation and soil flora and fauna. Alternative 3 prohibits the burning of native vegetation and vegetative debris, but, unlike Alternative 2, it would allow the permittee to bury these materials.

2.4.3.4.2 Fish and Wildlife Protection and Enhancement

Alternative 3 is similar to the No Action Alternative with respect to the protection of threatened and endangered species. However, Alternative 3 would codify the dispute resolution provisions of the 1996 biological opinion concerning protection of threatened and endangered species. It also would expressly require that the fish and wildlife protection and enhancement plan in the permit application include any species-specific protection and enhancement plans developed in accordance with the Endangered Species Act and any biological opinions implementing that law.

Alternative 3 is similar to the No Action Alternative with respect to the fish and wildlife resource information and protection and enhancement plan required in the permit application. It also includes similar performance standards for protection of fish and wildlife. However, Alternative 3 would require that the permittee establish permanent streamside vegetative corridors at least 300 feet wide, comprised of native, non-invasive species, along the banks of restored or diverted perennial or intermittent stream channels. The permittee must use appropriate species of woody plants if the land would naturally revert to forest under natural succession.

In addition, fish and wildlife enhancement measures would be mandatory whenever the proposed operation would result in the long-term loss of native forest, loss of other native plant communities, or filling of a segment of an intermittent stream. The enhancement measures must be commensurate with the long-term adverse impact to the affected resources and they must be located in the same watershed as the proposed operation (or the nearest appropriate adjacent watershed if there are no opportunities for enhancement within the same watershed). The permit area would include these areas of enhancement.

Finally, Alternative 3 would allow the regulatory authority to prohibit mining of high-value habitats within the proposed permit area.

2.4.4 Alternative 4

Alternative 4 is similar to Alternative 2 except that it would have slightly more relaxed requirements for the collection of baseline data and monitoring, it would define streams based on different criteria than Alternative 2, and it would be more permissive than Alternative 2 in activities in or near streams, and mining through streams.

However, Alternative 4 would impose additional permitting requirements on operations involving factors that OSMRE has determined pose additional risk to the environment and warrant enhanced permitting requirements. These operations are as follows:

- Surface mining activities (including surface activities of underground mining) in pristine or unique hydrologic environments (any unique historic, hydrologic, geologic, or other natural areas, with a special designation status). Examples include state-designated High-Quality or Exceptional streams and any stream with an elevated Clean Water Act use designation. Other examples include mine sites situated within or adjacent to designated natural, wild, or wilderness areas; or local, state, or national parks;
- Operations in strata that have been known to produce acid or toxic mine drainage to ensure that mining and reclamation can be accomplished such that active or postmining water quality does not cause material damage to the hydrologic balance outside the permit area;
- Mining operations in watersheds with impaired waters or streams when the regulatory authority expects that the coal mining activity would exacerbate the conditions of the parameter(s) causing the impairment;
- Proposed operations on steep slopes (areas with slopes greater than 20 degrees on more than 10 percent of the proposed disturbed acreage); or
- Operations that propose to place excess spoil or coal mine waste in intermittent or perennial streams or their buffer zones.

When the proposed mining activity includes any of these listed operations in all or part of the permit area certain additional permitting requirements would apply over the entire permit area. The regulatory authority would identify the additional requirements[23] specific to a proposed operation. The regulatory authority could modify or expand these requirements as needed to address the needs of a particular operation. For example, under this Alternative the regulatory authority could require any or all of the following when enhanced permitting design was warranted:

[23] The additional permitting and implementation costs on the operator, and the additional permit review and inspection effort for the regulatory authority, associated with the listed examples were accounted for in the economic analysis of the FEIS and in the RIA.

- Additional detail in the analysis of the receiving watershed including the location and type of current and past disturbances in the watershed and other activities that may affect water quality;
- Measured stream flows and recorded storm hydrographs to develop premining hydrologic models;
- Modeling of seasonal groundwater fluctuations. Analysis of the correlation between groundwater fluctuations, precipitation events and groundwater quality;
- Establishment of clear environmental goals for the proposed operation. Use of background data and a detailed mine plan to demonstrate how environmental goals would be achieved;
- Development of reclamation goals specific to the proposed operation and the site conditions that would include planning for timely redistribution of topsoil and organics, contemporaneous plantings, and any related actions that would help reduce water quality degradation from the proposed operation;
- Additional detail in the mine plan to show changes in 6-month increments, specific to disturbed and reclaimed areas, roads, sediment controls, topsoil storage, fills, Best Management Practices (BMPs) etc.;
- Use of premining hydrologic models to assess flood potential and need for flood control, to project sediment loads and determine the design criteria for sediment control structures and need for temporary sediment controls; and/or
- Use of on-bench ponds, where possible, in conjunction with in-stream ponds below placement of fill. Design of on-bench ponds to accommodate both a full sediment load and maintenance of a low permanent pool to allow recirculation from in-stream ponds as needed.

The text below discusses Alternative 4 proposed requirements for each element. These requirements would apply to all operations, including those involving enhanced permitting (at a minimum).

2.4.4.1 Protection of the Hydrologic Balance

2.4.4.1.1 Baseline Data Collection and Analysis

Alternative 4 would require the same baseline data collection and analysis as Alternative 2 (see Baseline Data Collection and Analysis section for Alternative 2), except that Alternative 4 requires discrete, rather than continuous measurements of streamflow and groundwater levels.

2.4.4.1.2 Monitoring During Mining and Reclamation

Under Alternative 4, all monitoring requirements are the same as under Alternative 2 (see Monitoring During Mining and Reclamation section for Alternative 2), with the exception of precipitation monitoring. Under Alternative 4 the engineer would be required to conduct an inspection of the surface water runoff control system after each storm event with a two-year or greater recurrence-interval, rather than after each storm event with a one-year or greater recurrence interval as under Alternative 2.

2.4.4.1.3 Definition of Material Damage to the Hydrologic Balance Outside the Permit Area

Same as Alternative 2 (see Definition of Material Damage to the Hydrologic Balance Outside the Permit Area section for Alternative 2).

2.4.4.1.4 Evaluation Thresholds

Same as Alternative 2 (see Evaluation Thresholds section for Alternative 2).

2.4.4.2 Activities in or Near Streams

2.4.4.2.1 Stream Definitions

Alternative 4 defines perennial, intermittent, and ephemeral streams in terms of flow regime, channel and substrate characteristics, and the biological community, if any, found in the stream. The definition of an intermittent stream would no longer include the one-square-mile watershed criterion.

The definitions of each stream type would be as follows:

- Ephemeral stream means a stream or segment of a stream with the following characteristics:
    - A defined channel and an identifiable streambed are present. The channel contains an ordinary high-water mark and the channel bottom is always above both the water table associated with the regional aquifer and any perched water-bearing zones.
    - Water flows in the channel only in direct response to discrete precipitation events or in response to the melting of snow and ice. Groundwater discharges and discharges from perched water-bearing zones above the water table are not a source of streamflow.
    - An ephemeral stream typically lacks the hydrological, and physical characteristics commonly associated with the continuous or seasonal conveyance of water.

- Intermittent stream means a stream or segment of a stream with the following characteristics:
    - A defined channel and an identifiable streambed are present. The channel contains an ordinary high-water mark and the channel bottom is below the water table associated with the regional aquifer or a perched water-bearing zone for at least part of the year.
    - Water flows in the channel for only part of the year, with those flows originating from both surface runoff and either groundwater discharge or a discharge from a perched water-bearing zone above the water table.
    - The hydrological, and physical characteristics commonly associated with the seasonal conveyance of water are present, while the hydrological, and physical characteristics commonly associated with the continuous conveyance of water typically are absent.
- Perennial stream means a stream or segment of a stream with the following characteristics:
    - A defined channel and an identifiable streambed are present. The channel includes an ordinary high-water mark.
    - In a typical year, water flows continuously in the channel during the entire calendar year as a result of both surface runoff and groundwater discharge. The term does not include any stream or segment of a stream that meets the definition of an intermittent stream or an ephemeral stream, but it does include stream segments in which continuous flow ceases because of a protracted period of deficient precipitation or meltwater relative to historical norms, as determined under § 780.19(c) or § 784.19(c) of this chapter.
    - The hydrological, and physical characteristics commonly associated with the continuous conveyance of water are present.

2.4.4.2.2 Activities in or near Streams (Including Excess Spoil Fills and Coal Mine Waste Disposal Facilities)

Alternative 4 would be the same as Alternative 2, except that Alternative 4 lacks Alternative 2's categorical prohibition on mining activities in or near perennial streams, and it would not prohibit the placement of excess spoil in intermittent streams. Similar to Alternative 2, Alternative 4 would require the permittee to establish permanent streamside vegetative corridors along both banks of the entire reach of restored or diverted perennial or intermittent stream channels, but it would not require establishment of streamside vegetative corridors along the banks of restored or diverted ephemeral streams. Alternative 4 would require that the streamside vegetative corridor be at least 300 feet in width, compared to the minimum 100-foot width under Alternative 2. Unlike Alternative 2, Alternative 4 would not require that the SMCRA permit incorporate any mitigation plan under section 404 of the Clean Water Act.

2.4.4.2.3 Mining Through Streams

Same as Alternative 2, except as described in the Activities in or near Streams section for Alternative 4 above. Unlike Alternative 2, Alternative 4 would not prohibit mining through perennial streams. Nor would it require the regulatory authority to make special findings to approve mining through ephemeral streams. It would require restoration of the hydrologic function of ephemeral streams only to the extent required by geomorphic reclamation principles.

2.4.4.3 AOC and AOC Variances

2.4.4.3.1 Surface Configuration

Same as Alternative 2 (see Surface Configuration section for Alternative 2).

2.4.4.3.2 AOC Variances

Same as Alternative 3 (see AOC Variances section for Alternative 3) for all operations.

2.4.4.4 Revegetation, Topsoil, and Fish and Wildlife Protection and Enhancement

2.4.4.4.1 Revegetation, Reforestation and Topsoil Management

Same as Alternative 2 (see Revegetation, Reforestation and Topsoil Management section for Alternative 2) for all operations.

2.4.4.4.2 Fish and Wildlife Protection and Enhancement

Same as Alternative 3 (see Fish and Wildlife Protection and Enhancement section for Alternative 3) for all operations.

2.4.5 Alternative 5

This Alternative applies to surface and underground coal mining operations that would generate or dispose of excess spoil or coal mine waste outside the mined-out area, including the storage of material resulting from the creation of the face-up area for an underground mine. It also applies to all operations that would dispose of coal mine waste in perennial or intermittent streams. This Alternative would apply to the entire permit area whenever any portion of the operation met the criteria set forth above. It would also apply to contiguous permits if they were operated as a single operation with a permit that met the criteria.

However, this Alternative would not apply to any operation that would otherwise not meet the criteria set forth above. These operations would remain under the existing requirements of Alternative 1 (the No Action Alternative).

2.4.5.1 Protection of the Hydrologic Balance

2.4.5.1.1 Baseline Data Collection and Analysis

Same as Alternative 2 (see Baseline Data Collection and Analysis section for Alternative 2), with the exception that discrete measurements of streamflow and groundwater levels would be required as in Alternative 4.

2.4.5.1.2 Monitoring During Mining and Reclamation

Under Alternative 5, all monitoring requirements are the same as under Alternative 2 (see Monitoring During Mining and Reclamation section for Alternative 2), with the exception of precipitation monitoring. In that case, the engineer would be required to conduct an inspection of the surface water runoff control system after each storm event with a two-year or greater recurrence-interval, rather than after each storm event with a one-year or greater recurrence interval as under Alternative 2.

2.4.5.1.3 Definition of Material Damage to the Hydrologic Balance Outside the Permit Area

Same as the No Action Alternative (see Definition of Material Damage to the Hydrologic Balance Outside the Permit Area section for Alternative 1).

2.4.5.1.4 Evaluation Thresholds

Same as the No Action Alternative (see Evaluation Thresholds section for Alternative 1).

2.4.5.2 Activities in or Near Streams

2.4.5.2.1 Stream Definitions

Same as the No Action Alternative (see Stream Definitions section for Alternative 1).

2.4.5.2.2 Activities in or near Streams (Including Excess Spoil Fills and Coal Mine Waste Disposal Facilities)

Same as Alternative 2, except that Alternative 5 lacks Alternative 2's categorical prohibition on mining activities in or near perennial streams and it would not prohibit the placement of excess spoil in intermittent streams. Unlike Alternative 2, Alternative 5 would not require that the SMCRA permit incorporate any mitigation plan under section 404 of the Clean Water Act.

2.4.5.2.3 Mining Through Streams

Same as Alternative 2, except as described in the Activities in or near Streams section for Alternative 5 above. Unlike Alternative 2, Alternative 5 would not prohibit mining through perennial streams. Nor would it require special findings for mining through ephemeral streams, although it requires restoration of the hydrologic function of ephemeral streams to the extent required by geomorphic reclamation.

2.4.5.3 AOC and AOC Variances

2.4.5.3.1 Surface Configuration

Same as Alternative 2 (see Surface Configuration section for Alternative 2), except that Alternative 5 does not require the use of landforming principles. Nor would it establish any numerical limits or tolerances with respect to the extent to which the postmining elevation may differ from the premining elevation. Alternative 5 would require the permittee to return as much spoil material to the mined-out area as possible to minimize the need for and creation of excess spoil fills.

2.4.5.3.2 AOC Variances

Same as Alternative 3 (see AOC Variances section for Alternative 3).

2.4.5.4 Revegetation, Topsoil, and Fish and Wildlife Protection and Enhancement

2.4.5.4.1 Revegetation, Reforestation and Topsoil Management

Same as Alternative 3 (see 2.4.3.4 - Revegetation, Topsoil, and Fish and Wildlife Protection and Enhancement for Alternative 3).

2.4.5.4.2 Fish and Wildlife Protection and Enhancement

Same as Alternative 3 (see 2.4.3.4 - Revegetation, Topsoil, and Fish and Wildlife Protection and Enhancement for Alternative 3).

2.4.6 Alternative 6

This Alternative is limited to mining activities conducted in intermittent or perennial streams or within 100 feet of those streams. It would prohibit all mining activities within those areas unless the regulatory authority makes specific findings concerning the environmental impacts of the proposed operation. Alternative 6 would be the same as Alternative 1 (the No Action Alternative) for mining activities on all other areas of the permit, with the exceptions of new requirements proposed for baseline data collection and monitoring as described below.

2.4.6.1 Protection of the Hydrologic Balance

2.4.6.1.1 Baseline Data Collection and Analysis

Same as Alternative 2 (see Baseline Data Collection and Analysis section for Alternative 2).

2.4.6.1.2 Monitoring During Mining and Reclamation

Same as Alternative 2 (see Monitoring During Mining and Reclamation section for Alternative 2).

2.4.6.1.3 Definition of Material Damage to the Hydrologic Balance Outside the Permit Area (Alternative limited to the Enhanced Stream Buffer Zone)

Same as Alternative 1, the No Action Alternative (see Definition of Material Damage to the Hydrologic Balance Outside the Permit Area section for Alternative 1).

2.4.6.1.4 Evaluation Thresholds Alternative limited to the Enhanced Stream Buffer Zone)

Same as Alternative 1, the No Action Alternative (see Evaluation Thresholds section for Alternative 1).

2.4.6.2 Activities in or Near Streams

2.4.6.2.1 Stream Definitions

Same as Alternative 1, the No Action Alternative (see Stream Definitions section for Alternative 1).

2.4.6.2.2 Activities in or near Streams (Including Excess Spoil Fills and Coal Mine Waste Disposal Facilities)

Alternative 6 would prohibit mining activities in or within 100 feet of perennial and intermittent streams unless the applicant demonstrates each of the following:

- The ecological function of the stream would be protected or restored;
- Placement of excess spoil or coal mine waste within that area would not result in the formation of toxic mine drainage as that term is defined at 30 CFR 701.5;
- Long-term adverse impacts, including impacts within the footprint of any fill, to the environmental resources of the stream would be offset through fish and wildlife enhancement measures in the same or an adjacent watershed;
- Mining activities to be conducted within 100 feet of the stream, but not in the stream itself, would not adversely affect the water quality or quantity or other environmental resources of the stream; and
- The revegetation plan requires establishment of a permanent streamside vegetative corridor at least 100 feet in width along the entire reach of any restored or permanently diverted perennial, intermittent, or ephemeral stream segment.

Alternative 6 would require the mining operation design to minimize the generation of excess spoil. It also requires the design of excess spoil fills and coal mine waste disposal facilities to minimize their footprints. The intent of both requirements is to reduce the length of stream that the operation would cover.

Each applicant proposing to place excess spoil or coal mine waste in an intermittent or perennial stream or within 100 feet of such a stream must identify and analyze a range of reasonable operational alternatives. The applicant must select the alternative that would have the least adverse impact of all reasonable operational alternatives on fish, wildlife, and related environmental values.

Under Alternative 6, the permittee must construct any excess spoil fills in lifts not to exceed four feet in thickness. Alternative 6 would eliminate the current regulation at 30 CFR 816.73, which allows construction of durable rock fills that rely upon end-dumping and the construction of underdrains by gravity segregation of the end-dumped material. This Alternative would require daily monitoring during excess spoil placement. It would revise the existing rules to require that the quarterly inspection reports filed with the regulatory authority include the daily monitoring logs.

Alternative 6 would allow construction of excess spoil fills with flat decks on top, and includes no landforming requirements for excess spoil fills.

2.4.6.2.3 Mining Through Streams

Same as Alternative 2, except that Alternative 6 would not prohibit mining through perennial streams. Nor would it require the regulatory authority to make special findings for mining through ephemeral streams, although it would require the permittee to restore the hydrologic function of ephemeral streams to the extent required by geomorphic reclamation principles. In addition, it would require the permittee to establish a streamside vegetative corridor at least 100 feet in width along the entire reach of all streams, including ephemeral streams, within the permit area after completing mining.

2.4.6.3 AOC and AOC Variances

2.4.6.3.1 Surface Configuration

Same as Alternative 1, the No Action Alternative (see Surface Configuration section for Alternative 1).

2.4.6.3.2 AOC Variances

Same as Alternative 1, the No Action Alternative (see AOC Variances section for Alternative 1).

2.4.6.4 Revegetation, Topsoil, and Fish and Wildlife Protection and Enhancement

2.4.6.4.1 Revegetation, Reforestation and Topsoil Management

Same as Alternative 1, the No Action Alternative (see Revegetation, Reforestation and Topsoil Management section for Alternative 1).

2.4.6.4.2 Fish and Wildlife Protection and Enhancement

Same as Alternative 1, the No Action Alternative, with the exceptions discussed below.

Alternative 6 would require that the permittee establish permanent streamside vegetative corridors at least 100 feet wide, comprised of native, non-invasive species, along both banks of all perennial, intermittent, and ephemeral stream segments within the permit area after the completion of mining. The permittee must use appropriate species of woody plants to reforest the site if the site would naturally revert to forest under natural succession.

In addition, fish and wildlife enhancement measures are mandatory whenever the proposed operation would result in the long-term loss of native forest, loss of other native plant communities, or filling of a segment of a perennial or intermittent stream. The enhancement measures must be commensurate with the long-term adverse impact to the affected resources and they must be located in the same watershed as the proposed operation (or the nearest appropriate adjacent watershed if there are no opportunities for enhancement within the same watershed). The areas upon which the enhancement measures are conducted must be included within the permit area.

Finally, Alternative 6 would allow the regulatory authority to prohibit mining of high-value habitats within the proposed permit area.

2.4.7 Alternative 7

Similar to Alternative 4, this Alternative would impose additional requirements (see 2.4.4 – Alternative 4) on the operations OSMRE has identified as warranting enhanced permitting. For these operations, Alternative 7 would also include new requirements based on the elements as discussed below.

All other operations (i.e. those that did not fall under the list of operations identified as warranting enhanced permitting) would continue to fall under the existing regulations of the No Action Alternative.

2.4.7.1 Protection of the Hydrologic Balance

2.4.7.1.1 Baseline Data Collection and Analysis

Same as Alternative 2 (see Baseline Data Collection and Analysis section for Alternative 2), but would apply only when the specified conditions exist that warrant enhanced permitting conditions. Otherwise baseline data collection and analysis requirements would be the same as the No Action Alternative (see Baseline Data Collection and Analysis section for Alternative 1).

2.4.7.1.2 Monitoring During Mining and Reclamation

Same as Alternative 2 (see Monitoring During Mining and Reclamation section for Alternative 2), but would apply only when the specified conditions exist that warrant enhanced permitting conditions. Otherwise baseline data collection and analysis requirements would be the same as the No Action Alternative (see Monitoring During Mining and Reclamation section for Alternative 1).

2.4.7.1.3 Definition of Material Damage to the Hydrologic Balance Outside the Permit Area

Same as the No Action Alternative (see Definition of Material Damage to the Hydrologic Balance Outside the Permit Area section for Alternative 1). OSMRE would expect each regulatory authority to establish criteria to measure material damage to the hydrologic balance for purposes of cumulative hydrologic impact assessments.

2.4.7.1.4 Evaluation Thresholds

In areas subject to enhanced permitting requirements, Alternative 7 would require the regulatory authority to develop evaluation thresholds. For these areas, the regulatory authority would be required to establish evaluation thresholds for critical parameters centered on baseline data, and associated conditions, and the analysis conducted for the Cumulative Hydrologic Impact Assessment (CHIA). The regulatory authority would define these thresholds based on the degree of environmental degradation that would require evaluation before the operation causes material damage to the hydrologic balance outside the permit area. The permittee would be required to conduct a water quality trend analysis of the monitoring data on a quarterly basis to determine environmental impacts from the site. If the analysis indicates that values or trends in values, for any surface water or groundwater parameter have reached the evaluation threshold specified in the permit, the permittee must notify the regulatory authority and evaluate the conditions that caused the threshold parameter to be met or exceeded. If the permittee finds, and the regulatory authority agrees, that the increase is due to the permittee's mining activity, then the operator must develop and implement corrective measures to ensure that material damage to the hydrologic balance outside the permit area does not occur. The requirement to take evaluation would not apply if the permittee demonstrates, and the regulatory authority concurs in writing, that the adverse values or trends for the parameters of concern are not the result of the mining operation.

2.4.7.2 Activities in or Near Streams

2.4.7.2.1 Stream Definitions

Same as the No Action Alternative, except that Alternative 7 would remove the one-square-mile criterion in the existing definition of an intermittent stream.

Alternative 7 would require coordination with the Clean Water Act authority on defining stream flow condition. Both the permit applicant and the regulatory authority must seek input from the Clean Water Act Authority for all new applications, and incorporate where applicable all CWA authority concerns and criteria.

2.4.7.2.2 Activities in or near Streams (Including Excess Spoil Fills and Coal Mine Waste Disposal Facilities)

In areas warranting enhanced permitting requirements, Alternative 7 would place the same new limitations and requirements on activities in or near streams as would Alternative 2 (see Activities in or near Streams section for Alternative 2). For all other operations, the requirements of the No Action Alternative (see Activities in or near Streams section for Alternative 1) would continue to apply.

2.4.7.2.3 Mining Through Streams

In areas warranting enhanced permitting requirements, this Alternative would place the same limitations and requirements on mining through streams as Alternative 2 (see Mining Through Streams section for Alternative 2). In these areas, Alternative 7 would allow mining through intermittent streams upon demonstration that: (1) the reclamation plan would result in restoration of both the physical form and the hydrologic and ecological function; (2) the extent of the mine-though would be minimized, and; (3) the bond includes separate calculations of the cost of restoration of both form and function. Also, the permittee would be required to reconstruct ephemeral streams (but not restore their ecological function) and to establish a 100-foot streamside vegetative corridor along the entire reach (including ephemeral) of any restored stream.

In all other areas outside those warranting the enhanced permitting conditions, the current requirements of the No Action Alternative (see Mining Through Streams section for Alternative 1) would continue to apply.

2.4.7.3 AOC and AOC Variances

2.4.7.3.1 Surface Configuration

In areas warranting enhanced permitting requirements, Alternative 7 would impose the same requirements as Alternative 2 (see Surface Configuration section for Alternative 2). In all other areas, the existing requirements of the No Action Alternative (see Surface Configuration section for Alternative 1) would continue to apply.

2.4.7.3.2 AOC Variances

Alternative 7 proposes no changes to the current regulations governing mountaintop removal mining operations and AOC variances for steep-slope mining operations. Requirements would be the same as they are under the No Action Alternative (see AOC Variances section for Alternative 1).

2.4.7.4 Revegetation, Topsoil, and Fish and Wildlife Protection and Enhancement

2.4.7.4.1 Revegetation, Reforestation and Topsoil Management

In areas subject to the enhanced permitting requirements, requirements for revegetation, topsoil management and reforestation would be the same as under Alternative 2 (see Revegetation, Reforestation and Topsoil Management section for Alternative 2). In all other areas, the existing requirements of the No Action Alternative (see Revegetation, Reforestation and Topsoil Management section for Alternative 1) would continue to apply.

2.4.7.4.2 Fish and Wildlife Protection and Enhancement

Under Alternative 7, for areas subject to the enhanced permitting requirements, the regulatory authority may prohibit mining of areas where high value habitats are present. All other requirements for fish and wildlife protection and enhancement within these areas would be the same as Alternative 3 (see Fish and Wildlife Protection and Enhancement section for Alternative 3) except that under Alternative 7 the required streamside vegetative corridor width would be 100 feet versus 300 under Alternative 3.

2.4.8 Alternative 8 (Preferred)

This Alternative is primarily comprised of selected stream protection elements (as indicated below) of the other Action Alternatives analyzed.

2.4.8.1 Protection of the Hydrologic Balance

2.4.8.1.1 Baseline Data Collection and Analysis

- Surface water: The applicant must provide surface-water quantity descriptions for perennial and intermittent streams within the proposed permit and adjacent areas. The applicant must collect these surface water samples for 12 consecutive months at approximately equally spaced monthly intervals. Under the final version of the Preferred Alternative, OSMRE has revised the collection requirements (since initially proposed) to allow the applicant to modify the interval between samples to allow for adverse weather conditions that would make it unsafe to travel to sampling locations.
- Groundwater: The applicant must measure the levels of groundwater in perched, regional, and local aquifers within the proposed permit and adjacent areas at approximately equally spaced monthly intervals for a minimum of 12 consecutive months. As with surface waters under the final version of the Preferred Alternative, OSMRE has revised the requirements to allow the applicant to modify the interval between groundwater samples to allow for adverse weather conditions that would make it unsafe to travel to sampling locations. OSMRE has also revised this Alternative to allow the applicant, with regulatory authority approval, to measure groundwater levels on a quarterly basis instead of monthly, but this would extend the minimum data-gathering period to 24 consecutive months.

- Parameters: The applicant must analyze surface water and groundwater samples for the parameters set forth in Table 2.4-1 below. Under the final version of the Preferred Alternative, OSMRE deleted the six parameters (ammonia, arsenic, cadmium, copper, nitrogen, zinc) that OSMRE had added to the Proposed Rule at EPA's request. Our research found that those parameters have little or no nexus to coal mining. Instead, they appear to relate to placement of coal combustion residues in mines, which is the subject of a separate rulemaking. However, in response to a comment, OSMRE added temperature as a mandatory baseline data collection and monitoring parameter for both surface water and groundwater. OSMRE also added a requirement for the applicant to collect baseline (and monitoring) data for all parameters of concern, as determined by the regulatory authority, regardless of whether the regulations specifically identify those parameters.

Table 2.4-1. Core Baseline Water-Quality Data Requirements for Surface Water and Groundwater Under the Preferred Alternative

Parameter	Surface Water	Groundwater
pH	Yes	Yes
Specific conductance corrected to 25°C (conductivity)	Yes	Yes
Total dissolved solids	Yes	Yes
Total suspended solids	Yes	No
Hot acidity	Yes	Yes
Total alkalinity	Yes	Yes
Major anions (dissolved), including, at a minimum, bicarbonate, sulfate, and chloride	Yes	Yes
Major anions (total), including, at a minimum, bicarbonate, sulfate, and chloride	Yes	No
Major cations (dissolved), including, at a minimum, calcium, magnesium, sodium, and potassium	Yes	Yes
Major cations (total), including, at a minimum, calcium, magnesium, sodium, and potassium	Yes	No
Cation-anion balance of dissolved major cations and dissolved major anions	Yes	Yes
Any cation or anion that constitutes a significant percentage of the total ionic charge balance, but that was not included in the analyses of major anions and major cations	Yes	Yes
Iron (dissolved)	Yes	Yes
Iron (total)	Yes	No
Manganese (dissolved)	Yes	Yes
Manganese (total)	Yes	No
Selenium (dissolved)	Yes	Yes

Parameter	Surface Water	Groundwater
Selenium (total)	Yes	No
Any other parameter identified in any applicable National Pollutant Discharge Elimination System permit, if known at the time of application for the SMCRA permit	Yes	No
Temperature	Yes	Yes

- Form of streams: Under the final version of the Preferred Alternative, the applicant must provide a detailed description of stream channel characteristics for perennial and intermittent streams located within the proposed permit area. General descriptions of the channels are required for ephemeral streams located within the proposed permit area. OSMRE decided not to apply this requirement to streams within adjacent areas (as previously proposed under this Alternative) because it is only within the permit area that channel characteristics are likely to be altered by mining.
- Biological condition of streams: Under the final version of the Preferred Alternative, OSMRE has removed the requirement for measurement of the biological condition of ephemeral streams. For perennial streams, this Alternative requires use of a scientifically defensible bioassessment protocol that will provide index values for both stream habitat and aquatic biota based on the reference condition. The protocol must be accepted by the agencies responsible for implementing the Clean Water Act and it must require identification of benthic macroinvertebrates to the genus level where possible, otherwise to the lowest practical taxonomic level. The index values must be capable of being used to assess the capability of the stream to support its designated uses under section 101(a) or 303(c) of the Clean Water Act, 33 U.S.C. 1251(a) or 1313(c). The same requirement applies to intermittent streams if scientifically defensible protocols have been developed for those streams. If no such protocols exist, this Alternative would require the baseline data to include a description of the biology of each intermittent stream within the proposed permit area and each intermittent stream in the adjacent area that could be affected by the proposed operation. The sampling protocol must be accepted by an agency responsible for implementing the Clean Water Act and it must identify benthic macroinvertebrates to the genus level where possible, otherwise to the lowest practical taxonomic level.
- Wetlands: Under the final version of the Preferred Alternative, OSMRE has added a requirement that the permit applicant identify the extent and quality of wetlands adjoining all streams within the proposed permit area, and wetlands adjoining perennial and intermittent streams that occur in adjacent areas.
- Precipitation: The Preferred Alternative requires the applicant to use continuous recording devices to record all precipitation and storm events to provide baseline data that is adequate to generate and calibrate a hydrologic model of the site. Under the Preferred Alternative, OSMRE is not adopting the proposed requirement that the regulatory authority extend the baseline data collection period if the Palmer Drought Severity Index for that period exceeded certain values. Historical data indicate that there are few 12-month periods in which the selected values would not exist for at least part of the time. Instead, the Preferred Alternative would require that the applicant identify the Palmer Drought Severity Index values for the period during which baseline data were collected. The regulatory authority then would have the discretion to determine

whether and how long to extend the baseline data collection period under conditions of extreme drought or abnormally high precipitation.

- Geology: Requires collection of geologic data for the proposed permit and adjacent areas, with a focus on geological characteristics and properties that influence the hydrologic regime or that could alter the availability or quality of groundwater and surface water.

2.4.8.1.2 Monitoring During Mining and Reclamation

As with the Preferred Alternative proposed in the DEIS, the Preferred Alternative continues to require monitoring of surface water and groundwater during mining and reclamation at least quarterly for the same parameters measured during baseline sampling at locations designated in the permit.

As revised, the Preferred Alternative requires the permittee to monitor the biological condition of perennial streams and intermittent streams for which scientifically defensible bioassessment protocols exist annually until final bond release.

The Preferred Alternative now contains an additional requirement that the regulatory authority establish threshold values for water quality and quantity parameters that, when exceeded, as documented by monitoring, would result in an evaluation by the regulatory authority and the Clean Water Act authority to determine the reason for the exceedance. If the evaluation determines that discharges from the mining operation were responsible for the exceedance and that exceedances are likely to reoccur in the absence of corrective action, the regulatory authority must issue a permit revision order requiring that the permittee reassess the determination of the probable hydrologic consequences of the operation (the PHC determination) and the hydrologic reclamation plan and develop measures to prevent material damage to the hydrologic balance outside the permit area. These are the corrective action thresholds that were proposed for other Alternatives at the DEIS stage, but not for the Preferred Alternative, and that OSMRE is now referring to as "evaluation thresholds" in response to comments.

The Preferred Alternative continues to require that the permittee collect on-site precipitation measurements using self-recording rain gauges. Precipitation records must be adequate to generate and calibrate a hydrologic model of the site in the event the regulatory authority requires modeling.

Under the final Preferred Alternative, OSMRE has clarified that the regulatory authority must reevaluate the cumulative hydrologic impact assessment (CHIA) at intervals not to exceed three years. This evaluation is required to determine whether the CHIA remains accurate and whether the material damage and evaluation thresholds in the CHIA and the permit are adequate to ensure that material damage to the hydrologic balance outside the permit area will not occur. This evaluation must include a review of biological and water monitoring data from both this operation and all other coal mining operations within the cumulative impact area.

The Preferred Alternative continues to require an inspection of the surface water runoff-control system following storm events that recur on a two-year or greater interval. The Preferred Alternative also continues to require the operator to submit a report after such an event that describes the performance of the hydraulic control structures, assesses and describes any potential material damage to the hydrologic balance, and addresses any remedial measures taken. In the Preferred Alternative, OSMRE has revised the requirement for how soon the regulatory authority must receive the report, from the previously proposed 48 hours to 30 days.

The Preferred Alternative continues to require that monitoring continue until final bond release. The regulatory authority may not approve a bond release application if an analysis of water monitoring data and other relevant information indicate that the operation is causing material damage to the hydrologic balance outside the permit area or is likely to do so in the future. Under this Alternative, OSMRE added a requirement for restoration of the hydrologic function of mined-through perennial and intermittent streams before the regulatory authority may approve a Phase II bond release application. As proposed, the regulatory authority may not grant final Phase III bond release until the permittee demonstrates restoration of the ecological function of mined-through perennial and intermittent streams.

2.4.8.1.3 Definition of Material Damage to the Hydrologic Balance Outside the Permit Area

The Preferred Alternative in the DEIS defined material damage to the hydrologic balance outside the permit area as any adverse impact from surface or underground mining operations, including subsidence, on the quantity or quality of surface water or groundwater, or on the biological condition of a perennial or intermittent stream, that would preclude attainment or continuance of any designated surface water use under sections 101(a) and 303(c) of the Clean Water Act or any existing or reasonably foreseeable use of surface water or groundwater outside the permit area.

OSMRE has revised the Preferred Alternative definition of material damage to the hydrologic balance outside the permit area by removing all criteria and instead providing a list of factors that the regulatory authority, in consultation with the Clean Water Act authority, must consider in identifying material damage thresholds. Those factors include baseline data and reasonably anticipated or actual effects that the operation may have with respect to compliance with any applicable state or federal water quality standards and the Endangered Species Act of 1973, as well as the effects on premining uses of surface water and groundwater.

When selecting material damage thresholds, the revised Preferred Alternative requires that the regulatory authority, in consultation with the Clean Water Act authority as appropriate undertake a comprehensive evaluation that considers baseline data, the PHC determination, applicable water quality standards under the Clean Water Act, applicable state or tribal standards of surface water or groundwater, ambient water quality criteria developed under section 304(a) of the Clean Water Act, the biological requirements of species listed as threatened or endangered under the Endangered Species Act of 1973, and other pertinent information and considerations to identify the parameters for which thresholds are necessary. Thresholds may be either numeric or narrative, with the exception that, at the discretion of the Clean Water Act authority, numeric thresholds are required for relevant contaminants for which there are water quality criteria under the Clean Water Act, The intent of these changes is to ensure that the definition of this term does not foreclose the possibility of approving permits in watersheds with impaired streams, which could in turn drive mining into watersheds with higher quality streams.

2.4.8.1.4 Evaluation Thresholds

The Preferred Alternative within the DEIS did not include a requirement for specific evaluation thresholds. Instead, the Preferred Alternative relied on existing regulations that require permit applicants proposing to conduct surface or underground coal mining under § 780.21(h) or § 784.14(g) respectively, to provide a plan of measures the applicant would take to avoid adverse potential adverse hydrologic consequences, including preventative and remedial measures. The Preferred Alternative also relied on existing requirements at 30 CFR 816.41(c)(2) and (e)(2) and 817.41(c)(2) and (e)(2) that state that if monitoring results demonstrate noncompliance with permit conditions or federal, state, or tribal water quality laws and regulations, the permittee must promptly notify the regulatory authority and then take all possible steps to minimize any adverse impact to the environment or public health and safety, and must immediately implement measures necessary to comply with permit conditions (30 CFR 773.17(e)).

In the Preferred Alternative OSMRE has added a requirement that the permit include evaluation thresholds for critical water quality and quantity parameters as determined by the regulatory authority. An exceedance of an evaluation threshold, as documented by monitoring, would result in an evaluation by the regulatory authority and the Clean Water Act authority to determine the reason for the exceedance. If the evaluation determines that discharges from the mining operation were responsible for the exceedance and that exceedances are likely to reoccur in the absence of corrective action, the regulatory authority must issue a permit revision order requiring that the permittee reassess the PHC determination and the hydrologic reclamation plan and develop measures to prevent material damage to the hydrologic balance outside the permit area.

2.4.8.2 Activities in or Near Streams

2.4.8.2.1 Stream Definitions

The Preferred Alternative as described in the DEIS redefines "perennial stream" in a manner that is substantively identical to the manner in which the U.S. Army Corps of Engineers (USACE) defines that term in Part F of the 2012 reissuance of the nationwide permits under section 404 of the Clean Water Act. See 77 FR 10184, 10288 (Feb. 21, 2012). In response to comments, OSMRE has revised the Preferred Alternative definitions of ephemeral, intermittent, and perennial streams to limit the scope of those terms to conveyances with channels that have a bed-and-bank configuration and an ordinary high water mark, consistent with the approach taken by the USACE in implementing section 404 of the Clean Water Act. This change means that our rules would no longer classify an ephemeral drainage that does not have a bed-and bank configuration and an ordinary high water mark as an ephemeral stream.

In the final version of the Preferred Alternative, OSMRE clarifies that a stream with a bed that is always above the water table and with flows arising solely from snowmelt and precipitation events would be classified as ephemeral. In the final version of the Preferred Alternative OSMRE has also replaced the term "waters of the United States" (WOTUS) with "perennial, intermittent, and ephemeral streams" or its equivalent in areas of the Proposed Rule that pertain only to streams. The change is non-substantive, but provides additional clarity. The final version of the Preferred Alternative includes the following stream definitions:

- Perennial stream means a stream or part of a stream that has flowing water year-round during a typical year. The water table is located above the streambed for most of the year. Groundwater is the primary source of water for streamflow. Runoff from rainfall events and snowmelt is a supplemental source of water for streamflow. Perennial streams include only those conveyances with channels that display both a bed-and-bank configuration and an ordinary high water mark.
- Intermittent stream means a stream or part of a stream that has flowing water during certain times of the year when groundwater provides water for streamflow. The water table is located above the streambed for only part of the year, which means that intermittent streams may not have flowing water during dry periods. Runoff from rainfall events and snowmelt is a supplemental

source of water for streamflow. Intermittent streams include only those conveyances with channels that display both a bed-and-bank configuration and an ordinary high water mark.

- Ephemeral stream means a stream or part of a stream that has flowing water only during, and for a short duration after, precipitation and snowmelt events in a typical year. Ephemeral streams include only those conveyances with channels that display both a bed-and-bank configuration and an ordinary high water mark, and that have streambeds located above the water table year-round. Groundwater is not a source of water for streamflow. Runoff from rainfall events and snowmelt is the primary source of water for streamflow.

2.4.8.2.2 Activities in or near Streams (Including Excess Spoil Fills and Coal Mine Waste Disposal Facilities)

In the DEIS, Alternative 8 (Preferred) would prohibit mining activities in or through perennial and intermittent streams or on the surface of land within 100 feet of those streams unless the applicant makes certain demonstrations and the regulatory authority makes the corresponding findings listed below, that the proposed activity would not—

(1) Preclude attainment or maintenance of any existing, reasonably foreseeable, or designated use under section 101(a) or 303(c) of the Clean Water Act, of the affected stream segment following the completion of mining and reclamation;

(2) Result in conversion of the stream segment from intermittent to ephemeral, from perennial to intermittent, or from perennial to ephemeral;

(3) Cause or contribute to a violation of federal, state, or tribal water quality standards; or

(4) Cause material damage to the hydrologic balance outside the permit area.

These requirements apply to all mining activities except the construction of excess spoil fills and coal mine waste disposal facilities that cover perennial or intermittent streams. (Excess spoil fills and coal mine waste disposal facilities that extend into the buffer zone, but not the stream itself, are not exempt.)

As revised, Alternative 8 (Preferred) would prohibit mining activities in or through perennial and intermittent streams or on the surface of land within 100 feet of those streams unless the applicant makes the demonstrations and the regulatory authority makes the corresponding findings in Table 2.4-2. Additional discussion of requirements regarding mining through streams is provided in the next section of text following the table.

Table 2.4-2. Required Demonstrations for Activities in or Within 100 Feet of a Perennial or Intermittent Stream

1		2	3	4
When indicated in columns 2 through 4 of this table, your application must contain the demonstrations in column 1 if you propose to conduct surface mining activities in or through a perennial or intermittent stream or on the surface of land within 100 feet of a perennial or intermittent stream.		Any activity other than an activity listed in column 3 or column 4	Mining through or permanently diverting a stream	Construction of an excess spoil fill, coal mine waste refuse pile, or impounding structure that encroaches upon any part of a stream
(i)	The proposed activity would not cause or contribute to a violation of applicable water quality standards adopted under the authority of section 303(c) of the Clean Water Act, 33 U.S.C. 1313(c), or other applicable state or tribal water quality standards.	Yes	Yes	Yes
(ii)	The proposed activity would not cause material damage to the hydrologic balance outside the permit area.	Yes	Yes	Yes
(iii)	The proposed activity would not result in conversion of the affected stream segment from perennial to ephemeral.	Yes	Yes	Not applicable
(iv)	The proposed activity would not result in conversion of the affected stream segment from intermittent to ephemeral or from perennial to intermittent.	Yes	Yes, except as provided in paragraphs (e)(2) and (5) of this section	Not applicable
(v)	There is no practicable alternative that would avoid mining through or diverting a perennial or intermittent stream.	Not applicable	Yes, except as provided in paragraph (e)(3) of this section	Yes
(vi)	After evaluating all potential upland locations in the vicinity of the proposed operation, including abandoned mine lands and unreclaimed bond forfeiture sites, there is no practicable alternative that would avoid placement of excess spoil or coal mine waste in a perennial or intermittent stream.	Not applicable	Not applicable	Yes

1		2	3	4
(vii)	The proposed operation has been designed to minimize the extent to which perennial or intermittent streams will be mined through, diverted, or covered by an excess spoil fill, a coal mine waste refuse pile, or a coal mine waste impounding structure.	Not applicable	Yes, except as provided in paragraphs (e)(3) and (5) of this section	Yes
(viii)	The stream restoration techniques in the proposed reclamation plan are adequate to ensure restoration or improvement of the form, hydrologic function (including flow regime), streamside vegetation, and ecological function of the stream after you have mined through it, as required by § 816.57 of this chapter.	Not applicable	Yes, except as provided in paragraph (e)(5) of this section	Not applicable
(ix)	The proposed operation has been designed to minimize the amount of excess spoil or coal mine waste that the proposed operation will generate.	§ 780.35(b) of this part requires minimization of excess spoil	§ 780.35(b) of this part requires minimization of excess spoil	Yes
(x)	To the extent possible using the best technology currently available, the proposed operation has been designed to minimize adverse impacts on fish, wildlife, and related environmental values.	Yes	Yes	Yes
(xi)	The fish and wildlife enhancement plan prepared under § 780.16 of this part includes measures that would fully and permanently offset any long-term adverse impacts on fish, wildlife, and related environmental values within the footprint of each excess spoil fill, coal mine waste refuse pile, and coal mine waste impounding structure.	Not applicable	Not applicable	Yes
(xii)	Each excess spoil fill, coal mine waste refuse pile, and coal mine waste impounding structure has been designed in a manner that will not result in the formation of toxic mine drainage.	Not applicable	Not applicable	Yes
(xiii)	The revegetation plan prepared under § 780.12(g) of this part requires reforestation of each completed excess spoil fill if the land is forested at the time of application or if the land would revert to forest under conditions of natural succession.	Not applicable	Not applicable	Yes

Alternative 8 (Preferred) would require the applicant to demonstrate that (1) the operation has been designed to minimize, to the extent possible, the volume of excess spoil that the operation would generate and (2) the designed maximum cumulative volume of all proposed excess spoil fills is no larger than the capacity needed to accommodate the anticipated cumulative volume of excess spoil that the operation would generate. Both requirements are intended to reduce the length of stream that the operation will cover.

In addition, this Alternative would prohibit construction of durable rock fills, which use end-dumping as a means of spoil placement and rely upon gravity segregation to form underdrains.

Under Alternative 8 (Preferred), the permittee must construct excess spoil fills in lifts not to exceed four feet in thickness. The use of end-dumping for final placement would be prohibited and the current regulation at 30 CFR 816.73 allowing construction of durable rock fills that rely upon end-dumping and the construction of underdrains by gravity segregation of the end-dumped material would be eliminated.

This Alternative would require daily monitoring during excess spoil placement. It would revise the existing rules to require that the quarterly inspection reports filed with the regulatory authority include the daily monitoring logs.

Alternative 8 (Preferred) would prohibit the construction of excess spoil fills with flat decks on the top surface. The final surface configuration must resemble the surrounding terrain. Alternative 8 (Preferred) would provide that, to the extent that stability considerations allow, excess spoil fills must be constructed with sufficient barriers (e.g. aquitards) to groundwater infiltration to ensure restoration of a stream's water quality and quantity and aquatic life after the completion of mining. Placement of a layer of lower-permeability spoil or other material near the surface but below the root zone for trees and shrubs could provide the subsurface flow needed to restore flow in intermittent and ephemeral stream segments.

2.4.8.2.3 Mining through Streams

As revised, Alternative 8 (Preferred) would allow mining through any type of stream (perennial, intermittent, or ephemeral) segment under the conditions described in the Activities in or near Streams (Including Excess Spoil Fills and Coal Mine Waste Disposal Facilities) section for Alternative 8 (Preferred) above. The permittee must restore the form, hydrological function, and the ecological function of all perennial and intermittent streams that are mined through.

The regulatory authority must establish standards for determining when the ecological function of a restored or permanently diverted perennial or intermittent stream has been restored. In establishing these standards, the regulatory authority must coordinate with the appropriate agencies responsible for administering the Clean Water Act, 33 U.S.C. 1251 et seq., to ensure compliance with all Clean Water Act requirements. The biological component of the standards must employ the best technology currently available. For perennial streams, the best technology currently available includes an assessment of the biological condition of the stream, as determined by an index of biological condition or other scientifically defensible bioassessment protocols consistent with § 780.19(c)(6)(vii). Standards established for perennial streams need not require that a reconstructed stream or stream-channel diversion have precisely the same biological condition or biota as the stream segment did before mining, but they must prohibit substantial replacement of pollution-sensitive species with pollution-tolerant species. In addition, they must require that populations of organisms used to determine the biological condition of the reconstructed stream or stream-channel diversion be self-sustaining within that stream segment.

Standards established for intermittent streams must meet the same requirements whenever a scientifically defensible biological index and bioassessment protocol have been established for assessment of intermittent streams in the state or region in which the stream is located. For all other intermittent streams, the best technology currently available consists of the establishment of standards that rely upon restoration of the form, hydrologic function, and water quality of the stream and reestablishment of streamside vegetation as a surrogate for the biological condition of the stream. The regulatory authority must reevaluate the best technology currently available for intermittent streams at five-year intervals. Upon conclusion of that evaluation, the regulatory authority must make any appropriate adjustments before processing permit applications submitted after the conclusion of that evaluation.

All standards must ensure that the reconstructed stream or stream-channel diversion will not—

(1) Preclude attainment of the designated uses of that stream segment under section 101(a) or 303(c) of the Clean Water Act, 33 U.S.C. 1251(a) or 1313(c), before mining, or, if there are no designated uses, the premining uses of that stream segment; or

(2) Result in that stream segment not meeting the applicable anti-degradation requirements under section 303(c) of the Clean Water Act, 33 U.S.C. 1313(c), as adopted by a state or authorized tribe or as promulgated in a federal rulemaking under the Clean Water Act.

The postmining drainage pattern of perennial, intermittent, and ephemeral stream channels must be similar to the premining drainage pattern, unless the regulatory authority: approves a different pattern to ensure stability; prevent or minimize downcutting of reconstructed stream channels; promote enhancement of fish and wildlife habitat; accommodate any anticipated temporary or permanent increase in surface runoff as a result of mining and reclamation; accommodate the construction of excess spoil fills, coal mine waste refuse piles, or coal mine waste impounding structures; replace a stream that was channelized or otherwise severely altered prior to submittal of the permit application with a more natural and ecologically sound drainage pattern or stream-channel configuration; or reclaim a previously mined area.

Designs for permanent stream-channel diversions, temporary stream-channel diversions that would remain in use for three or more years, and stream channels to be restored after the completion of mining must adhere to design techniques that would restore or approximate the premining characteristics of the original stream channel. These original characteristics would include the natural riparian vegetation and the natural hydrological characteristics of the original stream necessary to promote the recovery and enhancement of the aquatic habitat and to minimize adverse alteration of stream channels on and off the site, including channel deepening or enlargement. The designed hydraulic capacity of all temporary and permanent stream-channel diversions must be at least equal to the hydraulic capacity of the unmodified stream channel immediately upstream of the diversion and no greater than the hydraulic capacity of the unmodified stream channel immediately downstream from the diversion.

The permittee must establish a 100-foot-wide or wider streamside vegetative corridor on each side of every perennial, intermittent, and ephemeral stream that is mined through and reconstructed. The corridor must be comprised of native species, including species with riparian characteristics when appropriate. Native trees and shrubs must be planted in areas that are forested at the time of permit application or that would revert to forest under conditions of natural succession. This revegetation requirement would not apply to prime farmland historically used for cropland or to situations in which revegetation would be incompatible with an approved postmining land use that is implemented during the revegetation responsibility period before final bond release.

2.4.8.3 AOC and AOC Variances

2.4.8.3.1 Surface Configuration

Same as Alternative 1, the No Action Alternative, with minor revisions to the definition of AOC to clarify its meaning, reflect state program amendment actions, and address implementation issues. Under the Preferred Alternative AOC means that surface configuration achieved by backfilling and grading of the mined area so that the reclaimed area closely resembles the general surface configuration of the land within the permit area prior to any mining activities or related disturbances and blends into and complements the drainage pattern of the surrounding terrain. All highwalls and spoil piles must be eliminated to meet the terms of the definition, but that requirement does not prohibit the approval of terracing, the retention of access roads or the approval of permanent water impoundments. For purposes of this definition, the term “mined area” does not include excess spoil fills and coal refuse piles.

Alternative 8 (Preferred) also requires that the postmining drainage pattern of perennial, intermittent, and ephemeral stream channels be similar to the premining drainage pattern, unless the regulatory authority approves a different pattern to ensure stability; prevent or minimize downcutting of reconstructed stream channels; promote enhancement of fish and wildlife habitat; accommodate any anticipated temporary or permanent increase in surface runoff as a result of mining and reclamation; accommodate the construction of excess spoil fills, coal mine waste refuse piles, or coal mine waste impounding structures; replace a stream that was channelized or otherwise severely altered prior to submittal of the permit application with a more natural and ecologically sound drainage pattern or stream-channel configuration; or reclaim a previously mined area.

2.4.8.3.2 AOC Variances

Alternative 8 (Preferred) would allow mountaintop removal mining operations and AOC variances for steep-slope mining operations under conditions generally similar to those in Alternative 1, the No Action Alternative. However, Alternative 8 (Preferred) would impose additional requirements to better protect streams, aquatic ecology, and biological communities. In addition, it would require that the permit include a condition prohibiting any bond release before substantial implementation of the approved postmining land use.

For approval of mountaintop removal mining operations, Alternative 8 (Preferred) would require the permit applicant to demonstrate that no damage would result to natural watercourses within the proposed permit and adjacent areas. The applicant can meet this requirement by making all of the following demonstrations:

- There would be no adverse changes in parameters of concern in discharges to surface water and groundwater;

- Flood hazards within the watershed containing the proposed permit area will be diminished by reduction of the size or frequency of peak-flow discharges from precipitation events or thaws.; and
- The total volume of flow during any season of the year would not vary; i.e., the seasonal flow regime would not change and there would be no increase in potential damage from flooding sufficient to adversely affect any designated use of surface water outside the proposed permit area under section 101(a) or 303(c) of the Clean Water Act, 33 U.S.C. 1251(a) or 1313(c), or, if there are no designated uses, any premining use of surface water outside the proposed permit area. Variations must also not adversely affect any premining use of groundwater outside the proposed permit area.
- The proposed operation would not result in any greater adverse impact to the aquatic and terrestrial ecology of the proposed permit and adjacent area than would occur if the area to be mined was restored to its approximate original contour.

In addition, the permittee must reforest the site with native species if the site was forested before submission of the permit application, unless reforestation would be inconsistent with the postmining land use.

Finally, the permittee must install drains through the outcrop barrier to prevent saturation of the backfill.

For approval of steep-slope variances, Alternative 8 (Preferred) would, in addition to the requirements in the existing rules, require permit applicants to demonstrate that all of the following criteria are met:

- The operation, including any fish and wildlife enhancement measures, will result in fewer adverse impacts to the aquatic ecology of the cumulative impact area than would occur if the site were mined and restored to AOC;
- The variance would not result in construction of an excess spoil fill in an intermittent or perennial stream; and
- Any deviations from the premining surface configuration are necessary and appropriate to achieve the postmining land use.

In addition, the permittee must reforest the site with native species if the site was forested before submission of the permit application or would revert to forest under natural succession. This requirement would not apply to permanent impoundments, roads, and other impervious surfaces to be retained following mining and reclamation or to those portions of the permit area covered by the variance.

2.4.8.4 Revegetation, Soils, Fish and Wildlife Protection and Enhancement

2.4.8.4.1 Revegetation, Reforestation and Topsoil Management

Alternative 8 (Preferred) includes provisions similar to those of the No Action Alternative with respect to soil management and revegetation, but with a greater emphasis on restoration of the site's ability to support the uses it supported before any mining, regardless of the approved postmining land use. Alternative 8 (Preferred) also places greater emphasis on construction of a growing medium with an adequate root zone for deep-rooted species and on revegetation with native tree and plant species, especially reforestation of previously forested areas.

Like the No Action Alternative, Alternative 8 (Preferred) requires salvage and redistribution of all topsoil (the A and E soil horizons). However, it also requires salvage and redistribution of the B and C soil horizons (or other suitable overburden materials) to the extent necessary to achieve a growing medium with the optimal rooting depths required to restore premining land use capability or comply with revegetation requirements. Under the No Action Alternative, the regulatory authority has the discretion, but not necessarily the obligation, to require salvage and redistribution of the B and C soil horizons or other suitable overburden materials.

Alternative 8 (Preferred) allows use of selected overburden materials as substitutes for (or supplements to) either topsoil or subsoil or both only if the applicant demonstrates that either (1) the quality of the existing topsoil and subsoil is inferior to that of other overburden materials or (2) the quantity of the existing topsoil and subsoil is insufficient to provide the optimal rooting depth or meet other plant growth requirements. In the latter case, all existing topsoil and favorable subsoil must be salvaged and redistributed together with the substitute material. As in the No Action Alternative, the applicant also must demonstrate that the resulting soil medium will be more suitable than the existing topsoil and subsoil to sustain vegetation and that the selected overburden materials are the best available within the permit area for that purpose. Alternative 8 (Preferred) differs slightly from the No Action Alternative in that the No Action Alternative allows the use of topsoil substitutes or supplements when the resulting soil medium will be equally or more suitable than the existing topsoil to sustain vegetation, while Alternative 2 allows their use only when the resulting soil medium will be more suitable to sustain vegetation.

Under Alternative 8 (Preferred), the permittee must salvage and redistribute all organic matter contained in or above the A soil horizon. This includes duff, other organic litter, and vegetative materials such as tree tops, small logs, and root balls. Salvaging these materials would increase the moisture retention capability of the soil and provide a source of the seeds, plant propagules, mycorrhizae, and other soil flora and fauna needed to support and enhance reestablishment of locally adapted and genetically diverse plant communities as well as to improve soil productivity. Burning vegetation or other organic materials would be prohibited.

The final version of Alternative 8 (Preferred) provides limited exceptions to the requirement for redistribution of salvaged organic material. Those exceptions apply to land used for row crops or intensive hay production and to land upon which structures, water impoundments, or other impermeable surfaces are sited as part of the postmining land use. The final version of Alternative 8 (Preferred) also requires that permit applications identify areas with substantial populations of invasive or noxious non-native species. The final version prohibits salvage and redistribution of organic materials from those areas. Instead, the operator must bury these materials at a depth sufficient to prevent regeneration.

Under Alternative 8 (Preferred) the permittee must reforest lands that were previously forested, or that would naturally revert to forest under conditions of natural succession, in a manner that would enhance recovery of the native forest ecosystem as expeditiously as possible. Prime farmland historically used for cropland is exempt from this requirement.

The permittee must revegetate the entire reclaimed area (other than water areas and impervious surfaces like roads and buildings) using native species to restore or reestablish the plant communities native to the area unless a conflicting postmining land use is actually implemented before the end of the revegetation responsibility period.

2.4.8.4.2 Fish and Wildlife Protection and Enhancement

Alternative 8 (Preferred) is similar to the No Action Alternative with respect to the protection of threatened and endangered species. At the DEIS stage, this Alternative would have included dispute resolution procedures in the regulations, codifying these procedures. In response to agency and public comment OSMRE has removed this from the final version of the Preferred Alternative.[24] However, Alternative 8 (Preferred) would make it a requirement that the applicant demonstrate to the regulatory authority that the proposal is in compliance with the Endangered Species Act of 11973, 16 U.S.C. 1531 et seq. through one of the following mechanisms:

(1) Providing documentation that the proposed surface coal mining and reclamation operations within or adjacent to the permit area would have no effect on species listed or proposed for listing as threatened or endangered under the Endangered Species Act of 1973, 16 U.S.C. 1531 et seq., habitat occupied by those species, or on designated or proposed critical habitat, under that law; or

(2) Documenting compliance with a valid biological opinion that covers issuance of permits for surface coal mining operations and the conduct of those operations under the applicable regulatory program; or

(3) Providing documentation that interagency consultation under section 7 of the Endangered Species Act of 1973, 16 U.S.C. 1536, has been completed for the proposed operation; or

(4) Providing documentation that the proposed operation is covered under a permit issued pursuant to section 10 of the Endangered Species Act of 1973, 16 U.S.C. 1539.

Revised Alternative 8 (Preferred) requires that the applicant describe the steps that that applicant has taken or will take to comply with the Endangered Species Act of 1973, 16 U.S.C. 1531 et seq., including any biological opinions developed under Section 7 of that law and any species-specific habitat conservation plans developed in accordance with Section 10 of that law. It also provides that the regulatory authority may not approve the permit application before there is a demonstration of compliance with the Endangered Species Act of 1973, 16 U.S.C. 1531 et seq., through one of the mechanisms listed above.

Alternative 8 (Preferred) is similar to the No Action Alternative with respect to the fish and wildlife resource information and protection and enhancement plan required in the permit application. It also includes similar performance standards for protection of fish and wildlife. However, Alternative 8 (Preferred) requires that the permittee establish permanent streamside vegetative corridors at least 100 feet wide, comprised of native, non-invasive species, along the banks of restored or diverted ephemeral, intermittent or perennial stream channels. The permittee must use appropriate species of woody plants if

---

[24] OSMRE has undertaken formal Section 7 consultation with the U.S. FWS on the Preferred Alternative. The biological opinion, once issued, will be available on www.osmre.gov and on www.regulations.gov under the Stream Protection Rule docket. OSMRE is also coordinating with U.S. FWS to provide guidance to OSMRE, the U.S. FWS, and regulatory authorities for demonstrating compliance with the terms and conditions of the Incidental Take Statement that will accompany the biological opinion.

the land would naturally revert to forest under natural succession.

In addition, fish and wildlife enhancement measures would be mandatory whenever the proposed operation would result in the long-term loss of native forest, loss of other native plant communities, or filling of a segment of a perennial or intermittent stream. The enhancement measures must be commensurate with the long-term adverse impact to the affected resources and they must be located in the same watershed as the proposed operation (or the nearest appropriate adjacent watershed if there are no opportunities for enhancement within the same watershed). Enhanced areas must be included within the permit area.

Finally, at the DEIS stage, the preferred Alternative 8 (Preferred) would have allowed the regulatory authority to prohibit mining of areas within the proposed permit area that are of such exceptional environmental value that any adverse mining-related impacts must be prohibited. In response to comments on the Proposed Rule, the final version of the Preferred Alternative does not include this authority. However, like the existing rules, this Alternative retains language intended to minimize adverse impacts to habitats of unusually high value to fish and wildlife.

2.4.9 Alternative 9 –2008 Stream Buffer Zone Rule

Alternative 9 is identical to the 2008 SBZ rule, which was vacated by court order on February 20, 2014. See 79 FR 76227-76233 (Dec. 22, 2014).

2.4.9.1 Protection of the Hydrologic Balance

2.4.9.1.1 Baseline Data Collection and Analysis

Same as Alternative 1, the No Action Alternative (see Baseline Data Collection and Analysis section for Alternative 1).

2.4.9.1.2 Monitoring During Mining and Reclamation

Same as Alternative 1, the No Action Alternative (see Monitoring During Mining and Reclamation section for Alternative 1).

2.4.9.1.3 Definition of Material Damage to the Hydrologic Balance Outside the Permit Area

Same as Alternative 1, the No Action Alternative (see Definition of Material Damage to the Hydrologic Balance Outside the Permit Area section for Alternative 1).

2.4.9.1.4 Evaluation Thresholds

Same as Alternative 1, the No Action Alternative (see Evaluation Thresholds section for Alternative 1).

2.4.9.2 Activities in or Near Streams

2.4.9.2.1 Stream Definitions

Same as Alternative 1, the No Action Alternative (see Stream Definitions section for Alternative 1).

2.4.9.2.2 Activities in or near Streams (Including Excess Spoil Fills and Coal Mine Waste Disposal Facilities)

The requirements in Alternative 9 differ depending upon whether the surface mining activities would occur in perennial or intermittent streams or whether they would be limited to the buffer zone for those streams (the surface of land within 100 feet, measured horizontally, of the stream). Under this Alternative, diversions of perennial and intermittent streams would be governed by a separate set of requirements. Also, as in Alternative 1, the No Action Alternative, coal preparation plants located outside the permit area of a mine would not be subject to these requirements.

Before approving any surface mining activities in a perennial or intermittent stream (other than a diversion of that stream), the regulatory authority must find in writing that avoiding disturbance of the stream is not reasonably possible. The permit also must include a condition requiring a demonstration of compliance with the Clean Water Act before the permittee may conduct any activities in a perennial or intermittent stream that require authorization or certification under the Clean Water Act.

Before approving any surface mining activities on the surface of land within 100 feet of a perennial or intermittent stream in situations where the activities would not take place in the stream segment itself, the SMCRA regulatory authority must find in writing that (1) avoiding disturbance of the surface of land within 100 feet of the stream either is not reasonably possible or is not necessary to meet the fish and wildlife and hydrologic balance protection requirements of the regulatory program and (2) that the measures proposed in the permit application constitute the best technology currently available to prevent the contribution of additional suspended solids to streamflow or runoff outside the permit area to the extent possible, and that the proposed measures would minimize disturbances and adverse impacts on fish, wildlife, and related environmental values to the extent possible There would be no requirement for the regulatory authority to make a separate finding approving activities such as disposal of excess spoil, coal mine waste, or construction of stream crossings or sediment ponds within the buffer zone for these stream segments.

However, the operation must be designed to avoid placement of excess spoil or coal mine waste in or within 100 feet of a perennial or intermittent stream to the extent possible. If avoidance is not reasonably possible, then the applicant must identify a reasonable range of alternatives and select the alternative with the least overall adverse impact on fish, wildlife, and related environmental values, including adverse impacts on water quality and aquatic and terrestrial ecosystems. However, an alternative with a cost substantially greater than the costs normally associated with this type of project need not be considered.

In addition, for excess spoil, the applicant must provide a demonstration that (1) the operation has been designed to minimize, to the extent possible, the volume of excess spoil that the operation would generate and (2) the designed maximum cumulative volume of all proposed excess spoil fills is no larger than the capacity needed to accommodate the anticipated cumulative volume of excess spoil that the operation would generate.

Excess spoil fill construction requirements are similar to those in Alternative 1, the No Action Alternative. Durable rock fills may be constructed by end-dumping and formation of underdrains by gravity segregation. Flat decks on the top surface of excess spoil fills are allowed. Inspections conducted at least quarterly and during critical stages of fill construction must be certified by a registered professional engineer. The permittee must submit to the regulatory authority an inspection report after every inspection specifying that the fill has been constructed and maintained as approved.

2.4.9.2.3 Mining through Streams

Under Alternative 9, the regulatory authority may approve the diversion of perennial or intermittent streams within the permit area if the diversion is located and designed to minimize adverse impacts on fish, wildlife, and related environmental values to the extent possible, using the best technology currently available.

Design and construction requirements for a permanent stream-channel diversion or a stream channel restored after the completion of mining are similar to those in Alternative 1, the No Action Alternative. The exception is that Alternative 9 would require the use of natural-channel design techniques to minimize adverse alteration of stream channels on and off the site, including channel deepening or enlargement, to the extent possible.

2.4.9.3 AOC and AOC Variances

Same as Alternative 1, the No Action Alternative (see 2.4.1.3 – AOC and AOC Variances for Alternative 1).

2.4.9.3.1 Surface Configuration

Same as Alternative 1, the No Action Alternative.

2.4.9.3.2 AOC Variances

Same as Alternative 1, the No Action Alternative.

2.4.9.4 Revegetation, Soils, Fish and Wildlife Protection and Enhancement

Same as Alternative 1, the No Action Alternative (see Fish and Wildlife Protection and Enhancement section for Alternative 1).

2.4.9.4.1 Revegetation, Reforestation and Topsoil Management

Same as Alternative 1, the No Action Alternative.

2.4.9.4.2 Fish and Wildlife Protection and Enhancement

Same as Alternative 1, the No Action Alternative.

2.5 Alternative Comparison Discussion

The following comparisons of the nine Alternatives represent the major similarities and differences between each of the Alternatives.

2.5.1 Protection of the Hydrologic Balance Functional Group

2.5.1.1 Baseline Data Collection and Analysis

2.5.1.1.1 Biological Conditions

- The No Action Alternative (also Alternative 9) -- No requirement for baseline biological assessment;
- Alternative 2 (also 3, 4, 5, 6, and 8 (Preferred)) -- Baseline biological conditions assessment required; and
- Alternative 7 – Same as Alternative 2 when enhanced permitting requirements apply, otherwise same as the No Action Alternative.

2.5.1.2 Hydrologic Conditions

2.5.1.2.1 Water Quality

- The No Action Alternative (also Alternative 9) -- Limited water-quality sampling points and analytical constituents. At a minimum, the analytical suite for surface water and groundwater consists of the following: temperature, total suspended solids (only surface water), pH, specific conductance, total dissolved solids (TDS), total iron, and total manganese;
- Alternative 2 (also 3, 4, 5, and 6) -- Baseline water-quality data are required on all intermittent and perennial streams and a representative number of ephemeral streams. Twelve evenly spaced samples are required from a consecutive 12-month period. The analytical suite for surface water and groundwater consists of the following: temperature, total suspended solids (only surface water), aluminum, bicarbonate, sulfate, chloride, calcium, magnesium, sodium, potassium, (hot) acidity, alkalinity, pH, selenium, specific conductance, TDS, total iron, arsenic, zinc, copper, cadmium, ammonia, nitrogen, and total manganese;
- Alternative 7 – Same as Alternative 2 when enhanced permitting requirements apply, otherwise same as the No Action Alternative.
- Alternative 8 (Preferred) – Requires detailed baseline water-quality data for intermittent and perennial streams. Twelve evenly spaced samples are required from a consecutive 12-month period, or with regulatory authority approval on a quarterly basis for 24 consecutive months. The analytical suite for surface water must include both total and dissolved fractions of the parameters. The parameters for both ground and surface water include the following, at a minimum: temperature, total suspended solids (only surface water), bicarbonate, sulfate, chloride, calcium, magnesium, sodium, potassium, (hot) acidity, alkalinity, pH, selenium, specific conductance, TDS, total (surface water only) and dissolved iron, total (surface water only) and dissolved manganese. Does not specifically require analysis of ammonia, arsenic, cadmium, copper, nitrogen, aluminum or zinc.

2.5.1.3 Surface Water Flow and Groundwater Levels

- The No Action Alternative (also Alternatives 3, 5, 8 (Preferred) and 9) -- Discrete stream flow and groundwater levels measurements required. Twelve evenly spaced samples required over a consecutive 12-month period;
- Alternative 2 (also 4 and 6) -- Continuous stream flow and groundwater levels measurements required; and
- Alternative 7 -- Same as Alternative 2 when enhanced permitting requirements apply, otherwise same as the No Action Alternative.

2.5.1.4 Rainfall Measurements

- The No Action Alternative (also Alternative 9) -- No onsite rainfall measurements required;
- Alternative 2 (also 3, 4, 5, 6, and 8 (Preferred)) -- Continuous on-site[25] rainfall measurement requirements; and
- Alternative 7 – Same as Alternative 2 when enhanced permitting requirements apply, otherwise same as the No Action Alternative.

2.5.1.5 Stream Hydrologic Form and Ecological Function

- The No Action Alternative (also Alternative 9) -- No documentation required of stream hydrologic form and ecological function;
- Alternative 2 (also 3, 4, 5, 6, and 8 (Preferred)) --Documentation of stream hydrologic form and ecological function required; and
- Alternative 7 – Same as Alternative 2 when enhanced permitting requirements apply, otherwise same as the No Action Alternative.

2.5.2 Monitoring During Mining and Reclamation

2.5.2.1 Biological Monitoring

- The No Action Alternative (also Alternative 9) -- No requirements for monitoring of biological condition;
- Alternative 2 (also 3, 4, 5, 6, and 8 (Preferred)) --Annual monitoring of biological condition required; and
- Alternative 7 – Same as Alternative 2 when enhanced permitting requirements apply, otherwise same as the No Action Alternative.

2.5.2.2 Water-Quality Monitoring

- The No Action Alternative (also Alternative 9) -- Monitoring for limited suite of analytes [temperature, total suspended solids (only surface water), pH, specific conductance, TDS, total iron, and total manganese] and the regulatory authority can release operator from monitoring before bond release;
- Alternative 2 (also 3, 4, 5, 6, and 8 (Preferred)) -- Quarterly monitoring until final bond release ; and
- Alternative 7 – Same as Alternative 2 when enhanced permitting requirements apply, otherwise same as the No Action Alternative.

2.5.2.3 Rainfall Measurements

- The No Action Alternative (also Alternative 9) -- No requirement for on-site rainfall measurements;

[25] In response to public comments the final version of Alternative 8 (Preferred) now allows for one single recording instrument to report precipitation data for multiple permits if the permits are close enough to each other.

- Alternative 2 (also 3, 4, 5, 6, and 8 (Preferred)) -- Continuous on-site rainfall measurements required; and
- Alternative 7 -- Same as Alternative 2 when enhanced permitting requirements apply, otherwise same as the No Action Alternative.

2.5.2.4 Runoff Control Structures

- The No Action Alternative (also Alternative 9) -- Certification of drainage control structures not required;
- Alternative 2 (also 6) -- Inspect and certify surface runoff control structures by a professional engineer after every one-year return interval precipitation event;
- Alternative 3 (also 4, 5 and 8 (Preferred)) -- Inspect and certify surface runoff control structures by a professional engineer after every two-year return interval precipitation event; and
- Alternative 7 – Same as Alternative 2 when enhanced permitting requirements apply, otherwise same as the No Action Alternative.

2.5.2.5 Regulatory Authority Hydrologic Data Review

- The No Action Alternative (also Alternative 9) -- No regularly scheduled hydrologic review required;
- Alternative 2 (also 3, 4, 5, and 6) -- Regulatory authority review of monitoring data at permit mid-term review and permit renewal;
- Alternative 7 – Same as Alternative 2 when enhanced permitting requirements apply, otherwise same as the No Action Alternative; and
- Alternative 8 (Preferred) – Regulatory authority review of monitoring data at 3-year intervals.

2.5.2.6 Definition of Material Damage to the Hydrologic Balance

- The No Action Alternative (also Alternatives 5, 6, 7 and 9) -- No national definition for material damage to the hydrologic balance. Regulatory authority discretion to determine material damage to the hydrologic balance criteria on case-by-case basis; and
- Alternative 2 (also 3, and 4) -- The term would be defined as any quantifiable adverse impact on the quality or quantity of surface water or groundwater or on the biological condition of intermittent and perennial streams that would preclude attainment or continuance of any designated surface-water use under sections 101(a) and 303(c) of the Clean Water Act or any existing or reasonably foreseeable use of surface water or groundwater outside the permit area. Includes areas overlying the underground workings of underground mines.
- Alternative 8 (Preferred) –<u>Material damage to the hydrologic balance outside the permit area</u> means an adverse impact, as determined in accordance with the rest of this definition, resulting from surface coal mining and reclamation operations, underground mining activities, or subsidence associated with underground mining activities, on the quality or quantity of surface water or groundwater, or on the biological condition of a perennial or intermittent stream. The determination of whether an adverse impact constitutes material damage to the hydrologic balance outside the permit area would be based on consideration of the baseline data and the following reasonably anticipated or actual effects of the operation:

(1) Effects that cause or contribute to a violation of applicable state or tribal water quality standards or a state or federal water quality standard established for a surface water outside the permit area under section 101(a) or 303(c) of the Clean Water Act, 33 U.S.C. 1251(a) or 1313(c), or, for a surface water for which no water quality standard has been established, effects that cause or contribute to non-attainment of any premining use of surface water outside the permit area.

(2) Effects that preclude a premining use of groundwater outside the permit area; or

(3) Effects that result in a violation of the Endangered Species Act of 1973, 16 U.S.C. 1531 et seq.

2.5.2.7 Evaluation Thresholds

- The No Action Alternative (also Alternatives 5, 6, and 9) -- No evaluation thresholds;
- Alternative 2 (also 3, and 4) -- Regulatory authority to develop evaluation thresholds that are less than the material damage to the hydrologic balance standards; and
- Alternative 7 – Same as Alternative 2 when enhanced permitting requirements apply, otherwise same as the No Action Alternative.
- Alternative 8 (Preferred) – Regulatory authority to develop evaluation thresholds for critical parameters in consultation with the Clean Water Act authority.

2.5.3 Activities In or Near Streams Functional Group

2.5.3.1 Stream Definitions

- The No Action Alternative (also Alternatives 3, 5, 6 and 9) -- No change in ephemeral, intermittent, and perennial stream definitions;
- Alternative 2 -- The definitions of intermittent, ephemeral, and perennial would be functionally replaced; all waterways defined as Waters of the U.S. under the CWA would be protected under this Alternative;
- Alternative 4 -- Streams defined based on flow and physical characteristics;
- Alternative 7 -- Existing definitions are not changed except that watershed size is not used as criteria to define intermittent streams; requires coordination with CWA authority; and
- Alternative 8 (Preferred) – Defines ephemeral, intermittent, and perennial streams in a way to limit the scope of those terms to conveyances with channels that have a bed-and-bank configuration and an ordinary high water mark, consistent with the approach taken by the USACE in implementing section 404 of the Clean Water Act. This change means that our rules will no longer classify a drainageway that has neither a bed-and bank configuration nor an ordinary high water mark as a stream. The existing rules classify all drainageways that do not qualify as perennial or intermittent streams as ephemeral streams. A stream with a bed that is always above the water table and with flows arising solely from snowmelt and precipitation events is ephemeral.

2.5.3.2 Activities in or near Streams, including Excess Spoil and Coal Refuse

- The No Action Alternative -- Prohibits mining activities through or within 100 feet of intermittent or perennial streams unless it can be demonstrated that the activity would not cause or contribute to the violation of applicable state or federal water quality standards and would not adversely affect the water quantity and quality or other environmental resources of the stream;
- Alternative 2 -- Prohibits surface mining activities in or within 100 feet of perennial streams. Prohibit surface mining activities in or within 100 feet of intermittent streams unless the applicant demonstrates that the activity would not: (1) preclude premining stream uses; (2) have more than a minimal adverse impact on the premining biological condition of the stream segment; or (3) cause material damage to the hydrologic balance outside the permit area. Requires a 100 foot forested streamside vegetative corridor for previously forested areas (or other native species for non-forested areas) adjacent to ephemeral or intermittent streams;
- Alternative 2 also prohibits placement of excess spoil within 100 feet of an intermittent stream (excess spoil placement is allowed in or near ephemeral streams). Under Alternative 2 disposal of coal mine waste in or within 100 feet of an intermittent or ephemeral stream is allowed;
- Alternative 3 (also 4 and 5) -- Prohibits surface mining activities in or within 100 feet of intermittent and perennial streams unless the applicant demonstrates that the activity would not: (1) preclude premining stream uses; (2) have more than a minimal adverse impact on the premining biological condition of the stream segment; or (3) cause material damage to the hydrologic balance outside the permit area;
- Alternative 6 --Prohibits mining activities within 100 feet of intermittent or perennial streams unless it can be demonstrated that: (1) the ecological function of the stream would be protected or restored; (2) placement of excess spoil fill or coal mine waste would not result in a discharge of "toxic mine drainage" and long-term adverse impacts to the environmental resources of the stream (within the footprint of the fill) would be offset in the same or adjacent watershed through fish and wildlife enhancement commensurate with the potential direct adverse impact to the stream; (3) other proposed mining activities within the stream buffer, but not within the stream itself would not adversely affect the water quantity and quality or other environmental resources of the stream; (4) a 100-foot streamside vegetative corridor would be required along the entire reach (including ephemeral streams) of any restored stream;
- Alternative 7 -- Same as Alternative 2 when enhanced permitting requirements apply, otherwise same as the No Action Alternative;
- Alternative 8 (Preferred) – Prohibits mining activities within 100 feet of intermittent and perennial streams unless the applicant demonstrates that the proposed activity would meet the criteria listed previously in Table 2.4-2.
- Alternative 9 --Prohibits mining activities (other than construction of stream-channel diversions) within a perennial or intermittent stream unless the regulatory authority finds that avoiding disturbance of the stream is not reasonably possible.

Additionally,

- The No Action Alternative – Excess spoil minimization not expressly required by regulation;
- Alternative 2 (also 3, 4, 5, 6, 8 (Preferred) and 9) --The applicant must demonstrate that (1) the operation has been designed to minimize, to the extent possible, the volume of excess spoil that

the operation would generate and (2) the designed maximum cumulative volume of all proposed excess spoil fills would be no larger than the capacity needed to accommodate the anticipated cumulative volume of excess spoil that the operation would generate; and

- Alternative 7 -- Same as Alternative 2 when enhanced permitting requirements apply, otherwise same as the No Action Alternative.
- And also,
- The No Action Alternative (also 9) -- Durable rock fills may be constructed by end-dumping. Placement in streams is not expressly prohibited if all other applicable requirements are met;
- Alternative 2 (also 3, 4, 5, 6 and 8 (Preferred)) --The practice of "end-dumping" or creating a "durable rock fill" of fill material into streams is prohibited wherever a specific Alternative is applicable. In addition, daily monitoring and maintenance of daily log is required during fill construction; and
- Alternative 7 -- Same as Alternative 2 when enhanced permitting requirements apply, otherwise same as the No Action Alternative.

2.5.3.3 Mining Through Streams

- The No Action Alternative -- Allows diversion of intermittent and perennial streams upon regulatory authority finding that the diversion would not adversely affect the water quantity and quality and related environmental resources of the stream;
- Alternative 2 (also 4) -- No mining activities allowed in or within 100 feet of a perennial stream. Mining allowed through all intermittent streams upon demonstration by the applicant that the reclamation plan would achieve complete restoration of the hydrologic form and ecological function of all perennial and intermittent streams in accordance with standards established by CWA permitting authority and baseline conditions; additional performance bond required for stream restoration. All ephemeral streams must be restored in form;
- Alternative 3 (also 5, and 6) -- Mining allowed through all streams upon demonstration by the applicant that the reclamation plan would achieve complete restoration of the hydrologic form and ecological function of all perennial and intermittent streams in accordance with standards established by CWA permitting authority and baseline conditions; additional performance bond required for stream restoration. Ephemeral streams restored in form to the extent required by geomorphic reclamation;
- Alternative 7 -- Same as Alternative 2 when enhanced permitting requirements apply, otherwise same as the No Action Alternative;
- Alternative 8 (Preferred) -- Requires restoration of both the hydrologic form and ecological function of intermittent and perennial streams that are mined through. Also requires establishment of postmining surface drainage pattern and stream-channel configuration that is similar to premining conditions, with certain exceptions;; and
- Alternative 9 -- Requires that restored stream channels for perennial and intermittent streams be designed and constructed using natural channel design techniques to restore or approximate the premining characteristics of the original stream channel.

2.5.4 AOC and AOC Variances Functional Group

2.5.4.1 AOC Variances

2.5.4.1.1 Mountaintop Removal Mining Operations

- The No Action Alternative (also 6, 7 and 9) – Achieve or support beneficial postmining land use; demonstrate equal or better land use. Assure investment in public facilities, and documentation of private financial capability to ensure completion. Requires demonstration that natural watercourses below lowest coal seam to be mined would not be damaged;
- Alternative 2 -- Prohibits all mountaintop removal mining operations (could require SMCRA amendment); and
- Alternative 3 (also 4, and 5) –Achieve or support beneficial postmining land use; demonstrate equal or better use. Requires implementation of the approved postmining land use prior to final bond release. Sufficient bond must be posted to ensure that, if the proposed postmining land use is not implemented, lands subject to the variance could be returned to approximate original contour. Requires assurance of investment in public facilities, and documentation of private financial capability to ensure completion. Requires demonstration that (1) no increase would occur in parameters of concern in discharges to surface or groundwater; (2) no change would occur in size or frequency of peak flow as compared to what would occur if the operator returned the site to approximate original contour; and (3) the total volume of flow during any season of the year would not vary (flooding potential cannot be altered). Requires demonstration that natural watercourses within the proposed permit and adjacent areas would not be damaged. If site was forested before permit application, then must return to forest and revegetate using native species except where inconsistent with the postmining land use.
- Alternative 8 (Preferred) – Same as Alternative 3 except that in the Preferred Alternative, the applicant is required to have substantially, and not fully, implemented the approved postmining land use prior to final bond release. And OSMRE has removed the proposed requirement that the applicant post a bond in amount sufficient to ensure that, if the proposed postmining land use is not implemented, lands subject to the variance could be returned to approximate original contour. All other demonstrations described above for Alternative 3 would still apply.

2.5.4.1.2 AOC Variances for Steep-Slope Operations

- The No Action Alternative (also Alternatives 6, 7 and 9) -- Achieve/support beneficial postmining land use; demonstrate equal or better land use. Demonstrate that surface water flow in the watershed would be improved over premining conditions ***or*** conditions what would have existed had the area been returned to AOC. Total suspended solids or pollutants to surface and ground water must be reduced in a manner that improves existing uses or ecology, ***or*** that reduces flood hazards due to reduced peak flow. Total flow volume in every season must not vary so as to adversely affect ecology of surface water or existing or planned use of surface or ground water;
- Alternative 2 -- Prohibits all variances from requirement to return the mined area to its AOC (could require SMCRA amendment); and
- Alternative 3 (also 4, and 5) -- Must demonstrate that surface water flow in the watershed would be improved over premining conditions ***and*** conditions that would have existed had the areas been returned to AOC. Must demonstrate that the AOC variance would result in fewer impacts to

aquatic ecology for the cumulative impact area than would occur if the site were returned to AOC. The AOC variance cannot result in any placement of excess spoil in an intermittent or perennial stream. The applicant must demonstrate that the proposed deviations from AOC are necessary and appropriate to achieve the postmining land use. The operator must post additional bond sufficient to ensure that, if the proposed postmining land use is not implemented, lands subject to the variance would be returned to AOC. If site was forested before permit application, then must return to forest and revegetate using native species except where inconsistent with the postmining land use.

- Alternative 8 (Preferred) – Same as Alternative 3 except that in the Preferred Alternative, OSMRE has removed the requirement for the operator to post additional bond sufficient to ensure that lands approved for a variance from AOC can be returned to AOC if the proposed postmining land use is not implemented.

2.5.5 Surface Configuration and Fills

2.5.5.1 Definition of AOC

- The No Action Alternative (also Alternatives 6, and 9) -- Definition of AOC would not change, includes backfilling and restoring disturbed areas to *closely resemble* premining topography;
- Alternative 2 (also 3, 4, and 5) -- Definition of AOC same as the No Action Alternative with the additional requirement that surface configuration achieved by backfilling and grading of the mined area be documented by landform measurements and analyses conducted before, during, and after mining and reclamation; and
- Alternative 7 -- Same as Alternative 2 when enhanced permitting requirements apply, otherwise same as the No Action Alternative.
- Alternative 8 (Preferred) –AOC means that surface configuration achieved by backfilling and grading of the mined area so that the reclaimed area closely resembles the general surface configuration of the land within the permit area prior to any mining activities or related disturbances and blends into and complements the drainage pattern of the surrounding terrain. All highwalls and spoil piles must be eliminated to meet the terms of the definition, but that requirement does not prohibit the approval of terracing, the retention of access roads or the approval of permanent water impoundments. For purposes of this definition, the term “mined area” does not include excess spoil fills and coal refuse piles.

2.5.5.2 Digital Terrain Analysis

- The No Action Alternative (also Alternatives 6, 8 (Preferred) and 9)-- Digital terrain analysis not required, requires mine plans to address postmining land use but introduces no new specific requirements for terrain analysis;
- Alternative 2 (also 3, 4, and 5)-- Requires use of digital terrain models during premining and backfilling to confirm premining topography, and adherence to the reclamation plan for backfilling except that remining sites and contiguous permits 40 acres or less are exempt; and
- Alternative 7 -- Same as Alternative 2 when enhanced permitting requirements apply, otherwise same as the No Action Alternative.

2.5.5.3 Permanent Impoundments and Final Elevations

- The No Action Alternative (also Alternative 3, 6, 8 (Preferred) and 9) -- No limits placed on final elevations. Still allows permanent impoundments, including final-cut impoundments provided they do not conflict with achieving AOC and they meet the postmining land use requirements. No requirements to use landforming principles during reclamation. ;
- Alternative 2 (also 4) -- Allowable deviation in the elevation of the backfilled and graded area postmining in comparison to the premining elevation based on the lowest coal seam mined. The allowable deviation in the postmining elevation could be no more than ±20 percent of the difference between the premining surface elevation and the premining bottom elevation of that lowest coal seam, with allowances for slope stability and minor shifts in the location of premining features. Allows exceedance of 20 percent tolerance to minimize excess spoil generation. In addition, tolerance requirement does not apply to that portion of the permit where steep-slope contour mining is conducted. Requires use of landforming principles (geomorphic reclamation). Still allows permanent impoundments, including final-cut impoundments provided they do not conflict with achieving AOC and they meet the postmining land use requirements;
- Alternative 5 – Same as the No Action Alternative except that it requires return of as much as spoil material to the mined area as possible (including transport of spoil above the original contour), and that it prohibits flat decks on excess spoil fills and coal refuse facilities; and
- Alternative 7 – Same as Alternative 2 when enhanced permitting requirements (other than steep slope conditions) apply, otherwise same as the No Action Alternative. This Alternative does not require compliance with the ±20 percent tolerance because stability and equipment constraints make it impracticable to impose this requirement on contour mining on steep slopes (defined as slopes greater than 20 degrees).

2.5.6 Revegetation, Topsoil, and Fish and Wildlife Functional Group

2.5.6.1 Revegetation

- The No Action Alternative (also Alternatives 6 and 9) -- Vegetative cover in accordance with the approved permit and reclamation plan, comprised of species native to the area, or of introduced species where desirable and necessary to achieve the approved postmining land use;
- Alternative 2 (also 3, 4, and 5) -- Requires that all reclaimed lands be revegetated with native species unless the postmining land use is actually implemented before the end of the revegetation responsibility period;
- Alternative 7 -- Same as Alternative 2 when enhanced permitting requirements apply, otherwise same as the No Action Alternative.
- Alternative 8 (Preferred) – Requires the use of native pollinator-friendly plants and planting arrangements that promote the establishment of pollinator-friendly habitat when practicable. The revegetation plan must create a diverse permanent vegetative cover that is consistent with native plant communities, and the species used must themselves be native with limited exceptions for temporary ground cover and certain postmining land uses.

2.5.6.2 Topsoil management

- The No Action Alternative (also Alternatives 6 and 9) -- Requires salvage and redistribution of all topsoil (A and E soil horizons) or the top 6 inches of soil material if less than that thickness of topsoil is present. Salvage and redistribution of the B and C soil horizons is at the discretion of the regulatory authority (except on prime farmland, where it is mandatory). Selected overburden materials may be substituted for, or used as a supplement to topsoil if the operator demonstrates to the regulatory authority that: (1) the resulting soil medium is equal to, or more suitable for sustaining vegetation than, the existing topsoil; and (2) the resulting soil medium is the best available in the permit area to support revegetation;
- Alternatives 2 (also 3, 4, 5 and 8 (Preferred)) -- Requires salvage and redistribution of all topsoil (A and E soil horizons). Also requires salvage and redistribution of the B and C soil horizons (or other suitable overburden materials) to the extent necessary to achieve a growing medium with the optimal rooting depths required to restore premining land use capability or comply with revegetation requirements. Allows use of selected overburden materials as substitutes for (or supplements to) either topsoil or subsoil or both if the operator demonstrates that either (1) the quality of the existing topsoil and subsoil is inferior to that of other overburden materials or (2) the quantity of the existing topsoil and subsoil is insufficient to provide the optimal rooting depth or meet other plant growth requirements. In the latter case, all existing topsoil and favorable subsoil must be salvaged and redistributed. The operator also must demonstrate that the resulting soil medium would be more suitable than the existing topsoil and subsoil to sustain vegetation and that the selected overburden materials are the best available within the permit area for that purpose. The operator would have to redistribute soils in a manner that limits compaction, and provides optimal rooting depth to support the approved plan for revegetation and reforestation; and
- Alternative 7 -- Same as Alternative 2 when enhanced permitting requirements apply, otherwise same as the No Action Alternative.

2.5.6.3 Salvage and Redistribution of Organic Materials

- The No Action Alternative (also Alternatives 6 and 9) -- Does not require salvage and redistribution or reuse of organic materials (duff, other organic litter, and vegetative materials such as tree tops, small logs and root balls) above the A soil horizon;
- Alternative 2 (also 4) -- Requires salvage and redistribution or reuse of ***all*** vegetative organic materials above the A soil horizon to promote reestablishment of locally adapted and genetically diverse native vegetation and soil flora and fauna and to enhance fish and wildlife habitats. Prohibits burning or burying of vegetation or other organic materials;
- Alternatives 3 (also 5) -- Requires salvage and redistribution of materials from native vegetation only (not from all vegetation) above the A soil horizon in accordance with an approved plan developed by a qualified ecologist or similar expert who would determine the amounts needed to promote reestablishment of native vegetation and soil flora and fauna. Prohibits burning of above-ground debris from native vegetation. Organic materials not needed for the approved plan may be used to construct fish and wildlife enhancement features;
- Alternative 7 -- Same as Alternative 2 when enhanced permitting requirements apply, otherwise same as the No Action Alternative; and

- Alternative 8 (Preferred) – Same as Alternative 3 except that it creates a limited exception to the requirement for salvage and redistribution or other use of organic matter. The Preferred Alternative also requires that organic matter from invasive species be buried rather than salvaged and redistributed.

2.5.6.4 Reforestation

- The No Action Alternative (also Alternatives 6 and 9) -- Lands that have returned to forest through natural succession classified as "undeveloped" are not required to be reforested;
- Alternative 2 (also 3, 4, 5 and 8 (Preferred)) -- Requires reforestation of previously forested areas and of lands that would revert to forest under conditions of natural succession (except for prime farmland historically used for cropland) in a manner that would enhance recovery of the native forest ecosystem as expeditiously as possible; and
- Alternative 7 -- Same as Alternative 2 when enhanced permitting requirements apply, otherwise same as the No Action Alternative.

2.5.6.5 Fish and Wildlife Protection and Enhancement

2.5.6.5.1 Enhancement of Fish and Wildlife

- The No Action Alternative (also Alternative 9) -- Achieve enhancement of fish and wildlife resources where practicable. Surface mining activities must enhance where practicable, or restore, habitats of unusually high value for fish and wildlife;
- Alternative 2--Enhancement required if mitigation required pursuant to the CWA. CWA mitigation incorporated as a condition of the SMCRA permit. Bond release on the SMCRA permit would be conditioned on successful mitigation as determined by the regulatory authority and the agency implementing the CWA. This option may require an amendment of SMCRA;
- Alternative 3 (also 4, 5, and 6) -- Enhancement measures would be mandatory whenever the proposed operation would result in the long-term loss of native forest, loss of other native plant communities, or filling of a segment of a perennial or intermittent stream (but not ephemeral streams). Resource enhancement must be: (1) commensurate with long-term adverse impact to affected resources; and (2) be located in the same or nearest adjacent watershed as the proposed operation if there are no opportunities for enhancement within the same watershed, and be on permitted area. Mining of certain areas within the permit area with exceptional environmental value may be prohibited by regulatory authority;
- Alternative 8 (Preferred) --Same as Alternative 3 except that it does not include provision for prohibiting mining on areas of exceptional environmental value within the permit area; and
- Alternative 7 – Same as Alternative 3 when enhanced permitting requirements apply, otherwise same as the No Action Alternative.

2.5.6.5.2 Endangered and Threatened Species Protection

- The No Action Alternative (also Alternatives 6 and 9) -- No surface mining activity can be conducted which is likely to jeopardize the continued existence of endangered or threatened species listed by the Secretary or which is likely to result in the destruction or adverse modification of designated critical habitat of such species in violation of the Endangered Species Act of 1973, as amended (16 U.S.C. 1531 *et seq.)*;
- Alternative 2 (also 3, 4, and 5) -- Same as Alternatives 1 and 6, in addition would (1) codify the dispute resolution provisions of the biological opinion concerning protection of threatened and endangered species and (2) add a provision to the regulations expressly requiring that the fish and wildlife protection and enhancement plan in the permit application include any species-specific protection and enhancement plans developed in accordance with the Endangered Species Act and any biological opinions implementing that law; and
- Alternative 7 – Same as Alternative 2 where enhanced permitting conditions apply, otherwise same as the No Action Alternative.
- Alternative 8 (Preferred) – The “adjacent area” includes those areas outside the proposed or actual permit area where surface coal mining operations or underground mining activities may affect a species listed or proposed for listing as endangered or threatened under that Act or designated or proposed critical habitat under that Act. Requires that the applicant document that the proposed operation would have no effect on species listed or proposed for listing as threatened or endangered or on designated or proposed critical habitat; or documentation of consultation on impacts and planned compliance with terms and conditions resulting from consultation. Does not codify the dispute resolution procedures but instead addresses them through the SPR biological opinion and the ESA MOU.

2.5.6.5.3 Streamside vegetative corridors

- The No Action Alternative (also Alternative 9) -- The operator must avoid disturbances to, enhance where practicable, restore, or replace, wetlands, and riparian vegetation along rivers and streams and bordering ponds and lakes;
- Alternative 2 (also 5, 6 and 8 (Preferred)) -- Requires creation of a 100-foot streamside vegetative corridor, comprised of native non-invasive species, to enhance restoration of the ecological function of ephemeral, intermittent, or perennial streams that are mined through. The streamside vegetative corridor must be established along the entire reach of any stream restored or permanently diverted;
- Alternative 3 (also 4) -- Requires establishment of a 300-foot streamside vegetative corridor comprised of native woody species along restored or permanently diverted intermittent and perennial streams, if the land would naturally revert to forest under natural succession (not required if this would conflict with the approved postmining land use); and
- Alternative 7 – Same as Alternative 2 when enhanced permitting requirements apply, otherwise same as the No Action Alternative.

2.6 Alternatives And Elements Considered But Dismissed

The discussion below summarizes Alternatives and elements that OSMRE considered but did not ultimately carry forward for analysis. As part of the development of this DEIS, OSMRE used a mine plan analysis of 13 model mines representative of all seven coal-producing regions to model the effects of the Alternatives and elements, and based on this analysis determined that the following Alternatives were not reasonable to carry forward. The text below describes the findings on two Alternatives that OSMRE considered but ultimately dismissed from further analysis. The text also describes an element that OSMRE considered including within the Alternatives. OSMRE modified this element from its original form and included it within the Alternatives carried forward; this section describes the reasons behind the modification.

2.6.1 Alternative - Absolutely prohibit all surface coal mining and reclamation activities, including fill placement and coal mine waste, in or within 100 feet of all streams, including ephemeral.

OSMRE preliminarily analyzed, but chose not to carry through, an Alternative that would prohibit all mining and reclamation activities within all streams (ephemeral, intermittent and perennial) and within a 100-foot buffer zone around those streams. The prohibited activities would include the disposal of excess spoil and coal mine waste as well mining through the stream.

According to the model mine analysis, implementation of this Alternative would significantly reduce production nationwide. In 2010, U.S. Energy Information Administration data showed that surface mining methods produced almost 69 percent of coal production in the United States. Table 2.6-1 shows, using modeled surface mines, the impact on coal resource recovery from surface mines under this Alternative. The analysis indicated that this Alternative would result in a net loss of access to 86 percent of mineable surface coal reserves (based on tonnage) in five regions.

The prohibition against mining activities within the buffer would leave large quantities of coal stranded, i.e. un-mineable. Coal within the buffer would not be accessible for mining, and the mining would leave some coal stranded in inaccessible pockets between intersecting buffer zones.

High stream densities would strand additional coal in other areas. Providing buffers around all streams in areas with high stream densities would create a situation where the remaining suitable area for mining would be too small to support an economic return. This is the case, for example, in extensive areas of the Colorado Plateau, Illinois Basin and Gulf Coast mining areas. In other areas the modeling showed that mineable area would still occur but the buffer would significantly reduce both mineable area and coal production. In the Northern Rocky Mountains and Great Plains regions, prohibition of mining activities in the buffer zone would leave only about 12 percent of the mineable reserves available for mining.

Table 2.6-1.
Comparison of Recoverable Coal Resources for the No Action Alternative and Alternative Prohibiting Mine Activity In or Within 100 Feet of all Streams

	Tons of Surface Mineable Coal (millions)[1]	Tons of Surface Mineable Coal (millions)[1]	Mineable Acreage	Mineable Acreage	Millions of Tons of Reserves Stranded	Percent Reserves Stranded (based on tons of mineable coal)
Coal Region	**No Action Alternative**	**Alternative w/ No Activity in Stream**	**No Action Alternative**	**Alternative w/ No Activity in Stream**	**Alternative w/ No Activity in Stream**	**Alternative w/ No Activity in Stream**
Central Appalachia (Area)	37	**19**	1260	**758**	**18**	**49%**
Central Appalachia (Contour)	5	**4.4**	458	**324**	**0.6**	**12%**

[1]Assumes off-site excess spoil disposal is available if needed.

The analysis of impacts from this Alternative assumed that adequate disposal for excess spoil and coal waste material would be available and economically obtainable off-site. Without this assumption, the prohibition against disposal of excess spoil in or within 100 feet of streams would have created additional impacts on coal production. Coal outside the buffer would be un-mineable in situations where the site topography left insufficient space for placement of spoil other than within the buffer zone. For example, due to the topography of Central Appalachia the availability of area not within 100 feet of either side of a stream is extremely limited and would likely be insufficient to accept the amount of materials produced from mining outside the buffer.

The potential impact to underground mining operations in regions with steeper topography or higher stream densities from a prohibition on coal mine waste disposal in streams was not analyzed but would be considerable. Since disposal facilities typically place coal waste in stream buffer zones, in particular the fine coal waste disposed in slurry impoundments, the expected consequence would be a reduction in underground coal production in these regions.

The results of the preliminary analysis indicated that implementation of this Alternative would result in a significant reduction in coal recovery in five of the seven coal-producing regions. OSMRE determined that the impacts to coal production from this Alternative were so substantial that they ran counter to the mandate under SMCRA 102(f) to balance the need for energy with the protection of the environment. While the prohibition would provide maximum protection for streams, it would result in an unacceptable impact on the nation’s energy production via coal. For this reason, OSMRE determined that this

Alternative did not fall within the range of reasonable Alternatives, and dismissed this Alternative from further consideration.

2.6.2 Alternative - Prohibit further mining activities in watersheds with 10 percent or more land area impacted by coal mining.

Under this Alternative, the ability to obtain a mining permit would be dependent on the extent of current and past mining within the watershed encompassing the proposed permit area. The regulatory authority would no longer issue permits for surface coal mining activities once 10 percent or more of the acreage within a Hydrologic Unit Code (HUC)-12[26] watershed had been impacted by coal mining either historic or ongoing (acreage on successfully reclaimed sites would also count). No exemptions would apply. OSMRE selected the 10 percent threshold based on a recent study that showed that biodiversity and water quality declined in West Virginia and adjacent states when coal mining related impacts to watersheds exceeded 10 percent by area (Palmer and Bernhardt, undated). The rationale for the selection of 10 percent was that this threshold might represent a point after which cumulative impacts would result in material damage to the hydrologic balance outside the permit area. Definition of actual thresholds for specific watersheds may require additional research; the actual threshold for material damage to the hydrologic balance in any particular watershed may in fact be higher or lower depending on a number of parameters. The 10 percent threshold selection allows for a preliminary discussion only.

To analyze the effect this Alternative would have on coal production OSMRE selected two areas of the country with the highest coal production in 2010, the Powder River Basin and three counties in Southern West Virginia. OSMRE utilized U.S. Geological Service (USGS) hydrographic data to map HUC-12 watershed boundaries in comparison to existing coal mine permit boundaries in the study areas. OSMRE then used the overlap of coal mine impacts to the watershed boundaries to allow the selection of those watersheds with greater than 10 percent of their acreage affected by mining.

The results showed that 15 of the 29 HUC-12 watersheds that contain coal resources in the Powder River Basin had greater than 10 percent of their acreage impacted by coal mining. This Alternative would therefore prohibit future mining in over 50 percent of the Powder River Basin watersheds. OSMRE used new and pending applications, as of 2011, for mining in the Powder River Basin to provide a basis for examining the effect the prohibition would have on the approval of future permits with the assumption that these 2011 applications were indicative of where future mining interest would focus.

OSMRE conducted a similar analysis of selected watersheds in southern West Virginia. OSMRE obtained data for watersheds encompassing Mingo, Logan, and Boone counties. These three counties combined produced 50 percent of West Virginia's coal in 2010. In that year, West Virginia produced 93 million tons of coal, which made up about nine percent of total U.S. production.

OSMRE overlaid USGS HUC-12 watershed boundary data over the boundaries of all mining activity (current and reclaimed, but excluding abandoned mine lands) within these counties. The analysis included impacts associated with underground mines also, but only the extent of surface disturbance

[26] A HUC-12 watershed map defines watershed boundaries at the sixth level of subdivision (the subwatershed) using a 12 digit code.

associated with the underground mine. The results of the analysis show that coal mining had affected less than 10 percent of the available acreage in only 18 of the 46 watersheds within these three counties. Therefore, if OSMRE implemented this Alternative future mining would be prohibited in 28 of 46 (over 60 percent) of the watersheds in these three counties. Additionally five of the 46 watersheds had coal mining impacts on over nine percent of their acreage; therefore limited acreage would remain before the prohibition would apply to these watersheds as well.

As described above, the analysis shows that this Alternative would significantly affect the ability to mine coal in three of the highest coal-producing counties in West Virginia and over half of currently mined watersheds in the Powder River Basin. It would greatly restrict the ability to mine coal in areas of the country that produce a sizeable percentage of the nation's coal. Additionally, this Alternative would impose these impacts on coal production based on an acreage threshold that has not been scientifically determined to be a suitable nationwide basis for determining the likelihood or extent of material damage to the hydrologic balance. For these reasons, OSMRE determined that this Alternative was not scientifically justifiable, and did not meet the purpose of the proposed action.

2.6.3 Element to include in an Alternative - Restrict final elevations for backfilled and graded areas reclaimed after mining to a maximum ± 10 percent of the difference between the premining surface elevation and the bottom elevation of the lowest coal seam mined.

Each Alternative consists of several elements as described in the previous section of this Chapter. In developing the Alternatives OSMRE considered an element that would restrict final elevations for backfilled and graded areas reclaimed after mining to a maximum ± 10 percent of the difference between the premining surface elevation and the bottom elevation of the lowest coal seam mined. The tolerance would not apply to steep slope permits because these permits would require the operator to minimize disposal of excess spoil and instead to maximize placement of spoil material on the mined area. This Alternative would also have allowed minor shifts in the location of premining features and landforms to accommodate certain mining techniques.

The initial analysis showed that the ±10 percent threshold would not be achievable in some western areas where the overburden is so thin in comparison to the thickness of the mined coal seam that it would not be possible to return the final elevation within the mandated tolerance without bringing in additional material to fill the excavated hole. The tolerance threshold would also not apply for most Central Appalachian surface mines, where the predominance of steep slopes would result in most operations being exempt.

The mining ratios presented in Table 2.6-2 are indicative of the ability for mining operations to comply with the proposed tolerance requirements. The mining ratio presented here is the ratio of spoil material (in cubic yards) produced for every ton of coal mined. The higher the ratio, the greater the amount of excess spoil which the operator must return either to the site or place offsite. Where the ratio is above 7.3 cubic yards of spoil per ton of coal mined the amount of excess spoil would produce a final elevation above the 10 percent maximum elevation change. Where the ratio is below 2.6 cubic yards of spoil per ton of coal mined the amount of spoil would be insufficient to replace the volume lost due to the removal of the coal volume. These ratios rely on the assumption that the overburden would swell in volume by 25 percent due to handling, which would create additional spaces between overburden particles when they are placed back versus their arrangement before the mining disturbance.

Table 2.6-2.
Mining Ratios for Model Surface Mines

Coal Region	Ratio of spoil (volume) to coal mined (weight)[1]
Central Appalachia (Area)	16.1
Central Appalachia (Contour)	13.2
Northern Appalachia	12.7
Colorado Plateau	9.8
Gulf Coast	10.3
Illinois Basin	15.5
Northern Rocky Mountains and Great Plains	1.5

[1]All figures represent cubic yards of spoil per ton of coal mined.

As shown in the Table 2.6-2, the modeled ratios for spoil to coal are outside the target range (2.6 to 7.3 cubic yards of spoil per ton of coal mined) in all of the regions. Therefore all but one region would have excess spoil and the remaining region (the Northern Rocky Mountains and Great Plains region) would have insufficient spoil. OSMRE therefore rejected the ±10 percent elevation threshold requirement, and instead incorporated a ±20 percent elevation threshold into Alternatives 2, 4 and 7. These Alternatives, including the revised threshold requirement, are carried forward for analysis in this FEIS.

Chapter 3. Affected Environment

3.0 Introduction

The Affected Environment chapter of the Final Environmental Impact Statement (FEIS) describes the environment of the area(s) influenced by the Alternatives under consideration, as described in Section 1502.15 of Council on Environmental Quality regulations implementing the National Environmental Policy Act (NEPA). The descriptions provide information essential to understanding the effects of the Alternatives. Data and analyses are commensurate with the importance of the impact, with less important material summarized, consolidated, or simply referenced.

3.0.1 Purpose and Organization of the Chapter

The Affected Environment Chapter in this FEIS addresses the following resources:

- Section 3.1 – Mineral Resources and Mining
- Section 3.2 – Geology
- Section 3.3 – Soils
- Section 3.4 – Topography
- Section 3.5 – Water Resources
- Section 3.6 – Air Quality
- Section 3.7 – Land Use
- Section 3.8 – Terrestrial and Aquatic Biology
- Section 3.9 – Wetlands
- Section 3.10 – Recreation
- Section 3.11 – Visual Resources and Noise
- Section 3.12 – Utilities and Infrastructure
- Section 3.13 – Archaeology, Paleontology, and Cultural Resources
- Section 3.14 – Socioeconomics and Environmental Justice

3.0.2 Area Under Consideration

Coal is the most abundant of the fossil fuels and is widely distributed across the world. According to the United States Energy Information Administration (U.S. EIA), approximately 27 percent of the global coal reserves are located across the U.S. (U.S. EIA, 2011a) (See Section 3.1 for detailed description of U.S. coal resources). For purposes of this FEIS, regional variations of the Affected Environment are summarized to the extent possible.

As further described in Section 3.1, the Office of Surface Mining Reclamation and Enforcement (OSMRE) has identified seven regions representing the coal-mining areas in the U.S. (Figure 3.1-1) for consideration in this FEIS. The physical, biological, and social/cultural variations within these regions are vast. Additionally, coal mining techniques differ within and between regions. The seven coal mining regions, presented in alphabetical order, are as follows, with areas of primary production described[3]:

- Appalachian Basin region: In the Appalachian Basin region, bituminous coal has been mined throughout the last three centuries within Pennsylvania, Ohio, Virginia, West Virginia, Maryland, Eastern Kentucky, Alabama and Tennessee. Based on geologic structure and stratigraphy, the Appalachian Basin region has historically been subdivided into three coal regions: the northern region, the central region, and the southern region. Historically, the northern and central regions have played the dominant role in coal production.
- Colorado Plateau: The Colorado Plateau contains a substantial quantity of high-quality, low-sulfur coal resources. The coal in this region lies within Colorado, Utah, Arizona, and New Mexico.
- Gulf Coast: The Gulf Coast generally yields about one twentieth of coal produced in the U.S. Coal production in this region currently is exclusively lignite with most of this production extracted in Texas, but also including production from Louisiana and Mississippi.
- Illinois Basin region: Coal production in the Illinois Basin began in the early 1800s. The reported 2014 coal production for the Illinois Basin is fairly evenly split between Indiana, Illinois, and Western Kentucky.
- Northern Rocky Mountains and Great Plains: Of the seven coal-bearing areas, this region contains the most coal resources and that coal is extracted primarily by surface mining methods. Most of this coal is located in a coal field referred to as the Powder River Basin, straddling northeastern Wyoming and eastern Montana. Also from this region, coal production comes from parts of Colorado and lignite mining in North Dakota.
- Northwest: This region includes Oregon, Washington, and Alaska. However, for purposes of this FEIS, only coal resources in Alaska, specifically the Nenana and Matanuska coal fields are included in the study area. For the Northwest region, coal production is not predicted in the reasonably foreseeable future in the coal resource areas within Oregon and Washington or in the other coal fields of Alaska. Oregon has not had coal mining to any degree for the past ten years. Production in the state of Washington is historically very low (a few 100 tons) with poor quality reserves.
- Western Interior: This region includes coal resources mainly within the states of Oklahoma, Missouri, Arkansas, and Kansas.

In some cases, this Chapter describes and analyzes existing conditions and characteristics at the state level. The 25 states within the seven coal mining regions included in the study area for this FEIS are:

- Alabama (Appalachian Basin region and Gulf Coast);
- Alaska (Northwest);
- Arizona (Colorado Plateau);
- Arkansas (Gulf Coast and Western Interior);
- Colorado (Colorado Plateau and Northern Rocky Mountains and Great Plains);
- Illinois (Illinois Basin region);

[3] Based on 2012 production numbers.

- Indiana (Illinois Basin region);
- Kansas (Western Interior);
- Kentucky (Appalachian Basin region and Illinois Basin region);
- Louisiana (Gulf Coast);
- Maryland (Appalachian Basin region);
- Mississippi (Gulf Coast);
- Missouri (Western Interior);
- Montana (Northern Rocky Mountains and Great Plains);
- New Mexico (Colorado Plateau);
- North Dakota (Northern Rocky Mountains and Great Plains);
- Ohio (Appalachian Basin region);
- Oklahoma (Western Interior);
- Pennsylvania (Appalachian Basin region);
- Tennessee (Appalachian Basin region);
- Texas (Gulf Coast and Western Interior);
- Utah (Colorado Plateau);
- Virginia (Appalachian Basin region);
- West Virginia (Appalachian Basin region); and
- Wyoming (Northern Rocky Mountains and Great Plains).

In some cases, the analysis in this Chapter was conducted at the county level. The study area includes the counties in which coal mining occurred in 2012 within those 25 states listed above based on data for 2012 obtained from the U.S. EIA, U.S. Department of Energy 2012 Annual Coal Report (U.S. EIA, 2013h).

3.0.3 Previous Environmental Analyses

While Chapter 3 describes the socioeconomic and resource conditions of the affected environment, it is also important to consider the existing regulatory environment in the context of potential changes to existing rules to implement the Surface Mining Control and Reclamation Act (SMCRA). On December 12, 2008 (73 FR 75814-75885), OSMRE published a final rule and Environmental Impact Statement (EIS) modifying the circumstances under which mining activities may be conducted in or near perennial or intermittent streams. That rule and EIS is generally referred to as the 2008 Stream Buffer Zone Rule (2008 SBZ); it took effect on January 12, 2009 (OSMRE, 2008). In summary, the 2008 SBZ rule:

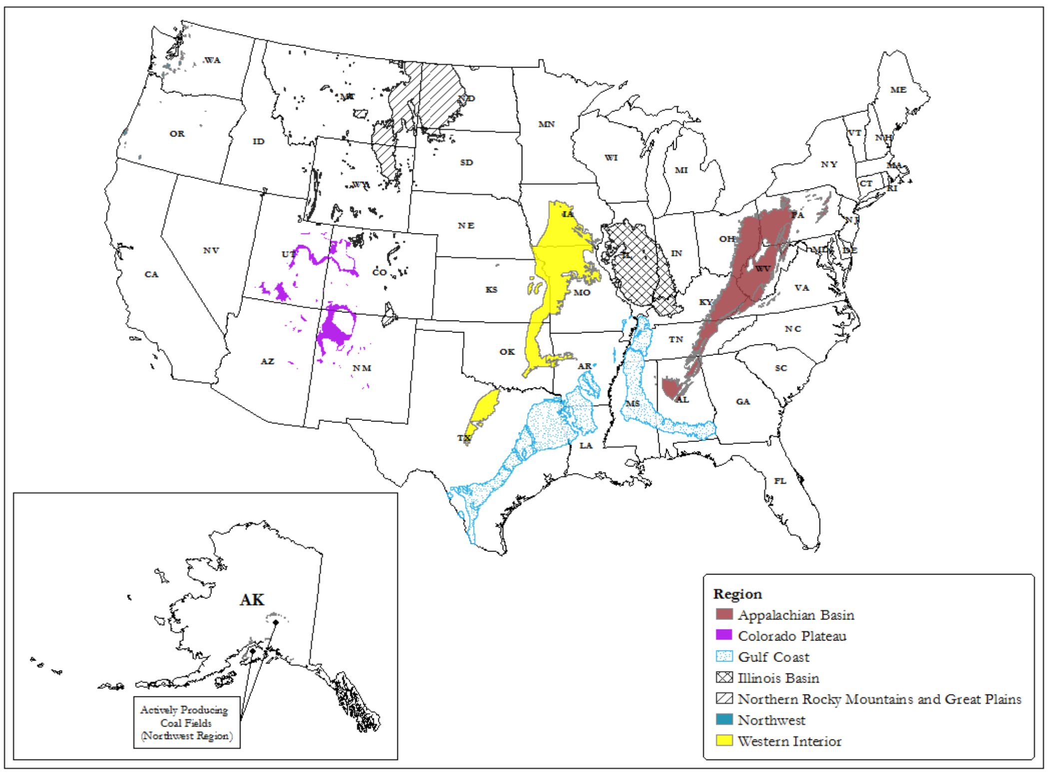
- Allowed placement of excess spoil material in intermittent or perennial streams after an analysis of the impacts to fish, wildlife, and aquatic ecosystems and a demonstration that the Alternative with the least environmental impact be selected;
- Required that this material placement, both in volume, footprint, and stream impact, be minimized; and
- Provided that a SMCRA permit does not authorize disturbance outside or in advance of Clean Water Act permits.

The 2008 SBZ rule was subsequently vacated, see 79 FR 76227-76233 (Dec. 22, 2014). Although the proposed action analyzed in this FEIS is generally more comprehensive than the 2008 SBZ rule, this FEIS relies on and tiers to the relevant analysis of the existing regulatory environment provided in the SBZ EIS that supported the 2008 rule when appropriate. However, this FEIS also incorporates additional analysis necessary to describe the existing regulatory environment relevant to this broader rulemaking.

3.1 Mineral Resources and Mining

The affected environment for this FEIS includes any area where mineable coal occurs or potentially occurs in the U.S. (Figure 3.1-1). These areas are depicted on the maps below and are located in seven regions analyzed throughout this FEIS: the Appalachian Basin region, the Colorado Plateau, the Gulf Coast, the Illinois Basin region, the Northern Rocky Mountains and Great Plains, the Northwest, and the Western Interior. Note that while the Michigan Basin in shown in the map below, coal has not been produced from that region since 1952; therefore, it is not being included in the analysis completed for this FEIS.

Figure 3.1-1. Major Coal-Producing Regions of the United States



Source: Data- United States Geological Survey (USGS), 2011a, *Coal Fields*, United States Department of the Interior (U.S. DOI), http://nationalatlas.gov/atlasftp.html?openChapters=chpgeol#chpgeol

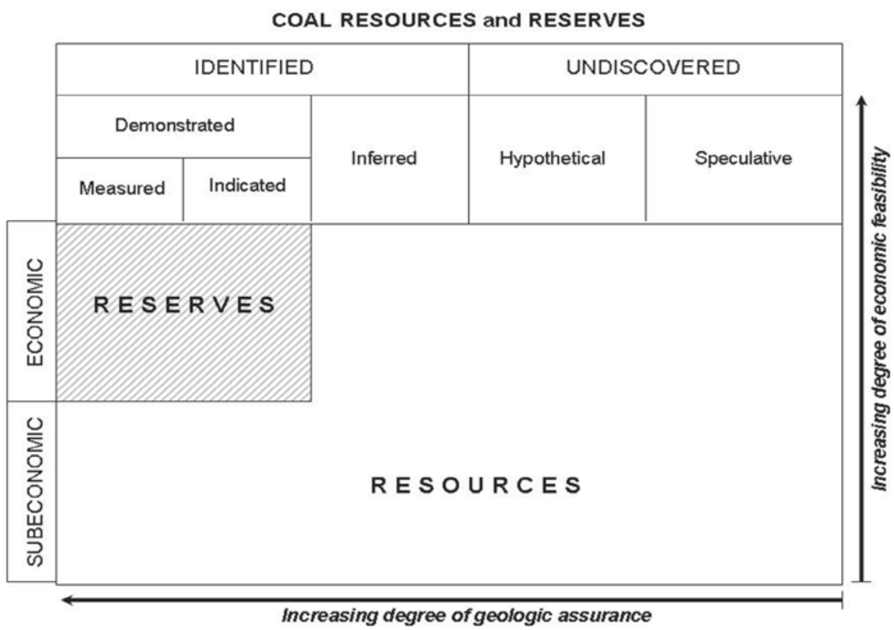
In 2014, coal was mined in 25 states, with production totaling 1,000,049 tons, a 1.5 percent increase from the previous year (U.S.EIA, 2016). Coal production in Central Appalachia declined 8.6 percent while production increased in the Illinois Basin by 3.8 percent (U.S. EIA, 2016).

3.1.1 Coal Resources and Coal Reserves

The distinction between a "resource" and a "reserve" is the suitability for mining of the coal bed (Figure 3.1-2). Resources refer to the presence of coal and do not consider suitability for mining. If a coal resource is considered commercially feasible to mine, then that resource is further classified as a reserve.

Different terms are used to describe resources and reserves based on the level of geologic confidence and the degree of economic suitability for mining of the coal bed. Coal resource figures can range from the least definite "Total Resources" to the highest geologically and economically proven "Recoverable Reserves at Active Mines."

Figure 3.1-2. Relationship Between Coal Reserves and Coal Resources



Source: Luppens, J. et al., 2009, *Figure 1; Coal Resources and Reserves*, USGS, U.S. DOI, http://pubs.usgs.gov/pp/1625f/downloads/ChapterD.pdf

3.1.2 Total Resources

"Total Resources" entails discovered and undiscovered total coal resources in a specific area. It considers both proven reserves and estimated reserves from geologic modeling without considering suitability for mining. Total resources in the U.S. are estimated to be about four trillion tons.[4]

3.1.2.1 Identified Resources

Coal deposits whose location, rank, quality, and quantity are known from geologic evidence supported by engineering measurements are "Identified Resources." Included are beds of bituminous coal and anthracite (14 or more inches thick) and beds of sub-bituminous coal and lignite (30 or more inches thick) that occur at depths to 6,000 feet. The existence and quantity of these beds have been delineated within specified degrees of geologic assurance as measured, indicated, or inferred. Also included are thinner and/or deeper beds that presently are being mined or for which there is evidence that they could be mined commercially. Identified Resources are approximately 1.5 trillion tons.

[4] This figure is based upon the most comprehensive assessment of U.S. coal resources, published by the USGS in 1975. More recent regional assessments have been conducted by the USGS; however, no new national level assessment of U.S. coal resources has been conducted since that time.

3.1.2.2 Demonstrated Reserve Base

Not all coal resources are economically feasible to mine and market. The "Demonstrated Reserve Base" estimates the total in-situ coal commercially feasible to mine at a given time, considering coal bed thickness, overburden depth, reported regional mining recovery, and coal seam accessibility. The Demonstrated Reserve Base was first assessed by the U.S. Bureau of Mines in 1974 and is now periodically evaluated and published by the U.S. EIA. The 2014 Demonstrated Reserve Base was 478 billion tons (U.S. EIA, 2016), or less than one-eighth of the estimated coal resources in the U.S.

3.1.2.3 Estimated Recoverable Reserves

The "Estimated Recoverable Reserve" represents coal that can be economically mined considering today's mining technology, accessibility constraints, and recovery factors. The Estimated Recoverable Reserve is generally less than the Demonstrated Reserve Base for a specified area. The Estimated Recoverable Reserve for the U.S. is 256 billion tons, about 54 percent of the Demonstrated Reserve Base (U.S. EIA, 2016).

Various factors affect the recoverability of a coal resource. These factors include geologic factors, mining operations, economics, processing, and restrictions on mining as explained below (Luppens, et al., 2009):

- *Coal Bed Thickness:* Coal bed thickness is generally considered one of the most important factors affecting coal recoverability. While most U.S. coal regions have thin to moderate bed thickness (ten feet thick or less), some western U.S. coal beds are more than 50 feet thick. Very thin coal beds may not be recoverable, and with current mining technology, minimum bed thickness for surface mining and underground mining are limited to about one foot and two feet, respectively. For underground mining, current technology demands a maximum practical bed thickness of about 15 feet, meaning portions of coal beds exceeding this thickness must be left in place, reducing recovery rates.
- *Coal Bed Depth:* Coal bed depth, or the depth of material overlying the coal bed, is also an important factor affecting coal recovery economics. For surface mining operations, recoverability depends on the depth of overburden to be removed. Greater overburden depth results in less recoverable reserves and vice versa. For underground mines, deeper coal beds can exhibit decreased recoverability due to the retaining of larger coal pillars for roof support (See Section 3.1.3.1 Underground Mining below); higher capital expenditures for mine access and infrastructure; roof/floor/coal stability issues due to increased stress at depth; increasing temperature at depth; and groundwater flow which generally increases with depth, resulting in greater pumping requirements to overcome the increased mine inflows. The current coal bed depth limit for underground coal mining ranges from 2,000 and 3,500 feet.
- *Stripping Ratio:* The stripping ratio is defined as the ratio of the overburden depth to the coal bed thickness at a given location. The "economic stripping ratio" is a basic, site-specific analysis for evaluating the maximum highwall height that can be economically mined. For example, 12:1 economic stripping ratio means that 12 feet of overburden material can be economically removed for every foot of coal mined. Thus, five feet of minable coal would equate to 60 feet of overburden or a 65 foot highwall.

- *Coal Rank:* Coal rank is a function of the degree of metamorphism and is dependent on the amount of heat, time, and pressure sustained by the coal deposit through burial history. As coal increases in rank, it decreases in moisture content, increases in carbon content, and increases in heating value. Coal rank progresses from peat (not considered coal) to lignite, then to subbituminous, then to bituminous, and finally to anthracite. Coal rank is further detailed in Section 3.1.2.
- *BTU*: The heating value of the coal is very important in power generation. It measures the energy contained in a unit of coal, expressed as British Thermal Units per pound (BTU/lb.). Higher BTU coal demands a higher price than lower BTU coal, all other qualitative parameters considered equal. A lower ranked coal, such as lignite (8,300 BTU/lb. or less), requires more tonnage to match the energy equivalent of a higher ranked coal, such as bituminous coal (13,000 BTU/lb.).
- *Sulfur Content*: Sulfur dioxide gas (SO_2) is released through oxidation of sulfur in the coal when it is burned, degrading air quality and contributing to acid rain production. The amount of SO_2 released depends on both the chemical composition and the concentration of the sulfur in the coal. Clean air standards limit SO_2 emissions from the burning of coal based on the BTU, making coal with lower SO_2 production more desirable.
- *Restrictions on Mining*: Restrictions on mining can limit the ability to recover coal. Outside of SMCRA, there exist federal[5] and other lands with societal or environmental values that have mining restrictions and land use limits imposed. Land use restrictions can also exist near population centers and around protected surface features that may be adversely impacted by surface subsidence related to underground mining. See 30 CFR 784.20 and 817.121.
- *Technological Effects:* Economic necessity for increased production rates has realized the use of larger or more productive mining equipment. For underground mining, limitations on resource recovery are influenced by state regulations, minimum accepted engineering practices, and equipment requirements. Additionally, conditions that may limit mining of underlying and overlying coal seams include weak geology that cannot provide adequate roof or floor support; hydrogeologic concerns; or mining in areas that were previously underground mined using high-extraction methods. In surface mining, large equipment is primarily used and is especially applicable to recovery of multiple coal seams in one mining operation, thereby greatly maximizing the resource recovery of these coal reserves.

The underground mining process results in some rock strata immediately above or below the coal bed being recovered along with the raw coal. This results in reduced BTU and inclusion of impurities in the run-of-mine coal product. Seams of non-coal material, called partings, are also typically found laminated within most coal beds and can range from very thin to a few feet in thickness. The underground mining extraction method for removing the coal and partings as comingled material results in further dilution of the raw coal product. These dilutions decrease the overall quality of the mined coal primarily by lowering the BTUs and increasing the ash content of the run-of-mine product. This is partially overcome by

---

[5] These include the National Park System, National Wildlife Refuge System, National System of Trails, National Wilderness Preservation System, National Wild and Scenic Rivers System, National Recreation Areas, lands acquired with money derived from the Land and Water Conservation Fund, National Forests, and federal lands in incorporated cities, towns, and villages (40 CFR 3461.5(a)).

processing or cleaning of the raw coal to improve the quality of the final coal product mined. This process involves loss of some of the raw coal and further reduces the resource recovery. The waste product, consisting of coarse and fine refuse slurry, requires disposal and is discussed in Section 3.1.6.3. In summary, coal processing adds cost to the marketed coal product and results in lost coal in the processed waste rock due to the imperfect cleaning process. Underground mining and coal processing losses are typically 17 to 25 percent higher than that of surface mining.

Surface mining generally does not require the same level of processing compared to underground mining. Surface mines by employing methods to selectively mine have the ability to separate parting materials some of which can be immediately disposed of in the pit. In underground mining these same partings would be extracted during mining and would require processing to remove.

3.1.2.4 Recoverable Reserves at Active Mines and National Coal Resource

Recoverable reserves at active mines were estimated at 19.4 billion tons at the end of 2014 (U.S. EIA, 2016).

As stated above, the Nation as a whole contains an estimated four trillion tons in total coal resources. The estimated demonstrated reserve base is 478 billion tons, with Estimated Recoverable Reserve of 256 billion tons, or about 54 percent of the demonstrated reserve base. Recoverable reserves at active mines are 19.4 billion tons, or about seven percent of Estimated Recoverable Reserve.

3.1.3 Types of Coal and Extraction Methods

The degree of alteration (or metamorphism) that occurs as coal matures is referred to as the “rank” of the coal. Coal is divided into four different ranks based on the degree of metamorphism caused by heat, pressure, and time applied to the coal, resulting in increased carbon content, decreased moisture, and generally increased heating values (Table 3.1-1). Rank varies from the lowest ranked lignite to subbituminous, then bituminous, up to the highest rank of anthracite. Typically a higher rank equates to higher economic value. High-ranked coal produces more energy per ton and/or has higher carbon content than lower rank coal. However impurities such as sulfur and ash, quality parameters such as volatile matter, and the cost of transportation affect the marketability of any particular coal product.

Table 3.1-1. Percent of Demonstrated Coal Reserves Base in U.S., by Rank

Coal Type	Percent
Bituminous	**48.0%**
Subbituminous	**43.9%**
Lignite	**7.9%**
Anthracite	**0.2%**

Source: U.S. EIA, 2016.

As seen in Table 3.1-1 (above), bituminous accounts for nearly half of the Demonstrated Coal Reserves and, as seen in Figure 3.1-3 is concentrated primarily east of the Mississippi River, with the largest amounts found in Illinois, Kentucky, and West Virginia. Wyoming and Montana contain the majority of the subbituminous Demonstrated Coal Reserves Base, while Montana, Texas, and North Dakota comprise the majority of the lignite. Anthracite, the highest ranking coal, makes up only 0.2 percent of the

Demonstrated Reserve Base and is concentrated almost entirely in northeastern Pennsylvania (U.S. EIA, 2016).

Coal production reflects regional differences in coal types. As shown in Figure 3.1-3, the Northern Rocky Mountains and Great Plains regions mine large amounts of subbituminous coal, while bituminous dominates in the Appalachian and Illinois regions.

Coal reserves are also categorized as either low, medium, or high sulfur content, in relation to the amount of sulfur dioxide (SO_2) released measured against the BTU content of the coal. The U.S. EIA reports the quantities of low, medium, and high sulfur coals as relatively equivalent for the U.S. Demonstrated Reserve Base, 33 percent, 28 percent, and 39 percent respectively. Most low-sulfur (84 percent) and medium-sulfur (61 percent) coal is located in the western U.S. The Appalachian Basin region contains a mixture of low, medium, and high sulfur coal reserves. Clean air standards limit SO_2 emissions from the burning of coal based on the BTU value, making coal with lower sulfur content desirable by complying with air quality standards without costly desulfurization treatment, typically accomplished through flue gas desulfurization also known as “scrubbers.” However with improved technology and the increasing number of scrubbers being installed, the marketability of the higher sulfur coals is increasing.

According to 2014 data approximately 69 percent of the U.S. Demonstrated Reserve Base is classified as minable by underground methods, while the remaining 31 percent is minable by surface methods. However, the percentage of estimated recoverable reserves by underground mining methods greatly diminishes to 58 percent of the Demonstrated Reserve Base (U.S. EIA 2016), due to lower recovery ratios inherent to underground mining methods (Section 3.1.3 below). Surface mining normally yields much higher coal bed recovery than underground mining.

3.1.4 Mining Methods: Underground

The method of underground coal mining depends on the geologic characteristics of the region, economics, property ownership, and other factors. Figure 3.1-4 illustrates the distribution of underground mining methods by region. The two most common underground mining methods are room-and-pillar and longwall mining. Each leaves some coal in place to maintain the roof stability of the mine. These pillars support the rock immediately overlying the intact coal pillar plus the overlying rock previously supported by the excavated coal. Underground mines typically recover 40 percent to 90 percent of the mined seam, depending on the extraction method

Figure 3.1-3. Coal Production by Type of Coal by Region, 2014

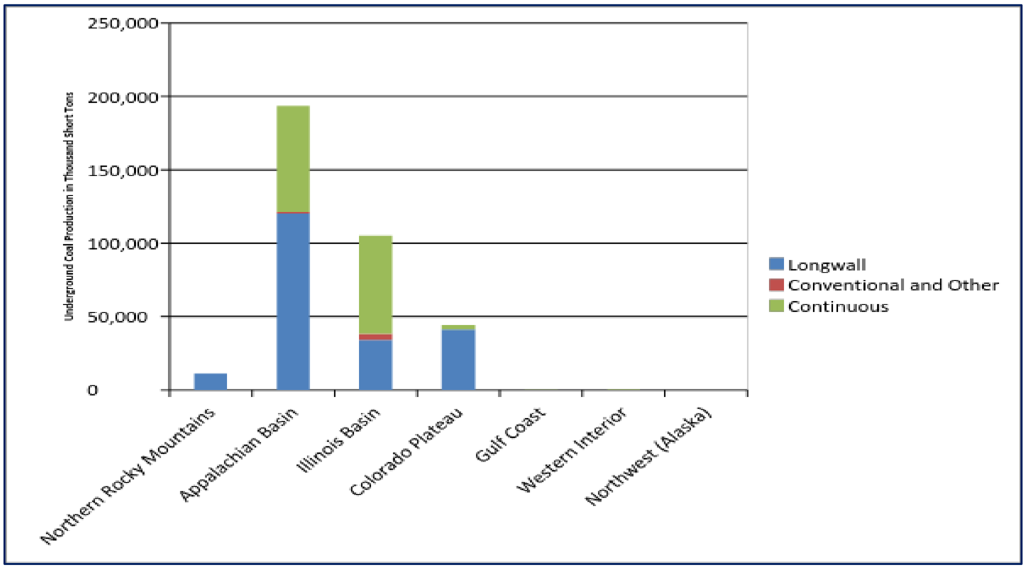
Figure 3.1-4. Underground Mining by Type and Region, 2014



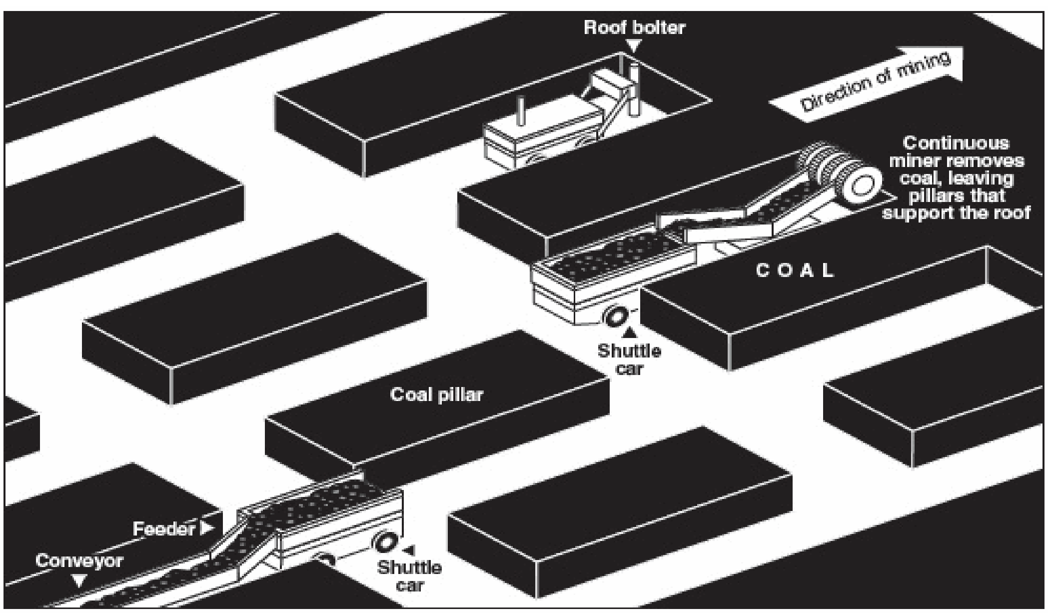
Source: Derived from Annual Coal Reports 1994-2014, U.S. Department of Energy; Energy Information Administration; http://www.eia.gov/coal/annual/; as retrieved July, 2016

For underground mining, access to the underground coal bed is gained by drifts, slopes, and/or shafts, governed chiefly by economics related to the geology, depth, mining method, mine production rates, and other constraints. Following the access development, underground mining is performed within the coal bed horizon without removing the overburden and is generally considered practical for depths greater than 100 feet; shallower mining can encounter difficulties with roof integrity and subsidence (Suboleski, 1999a), which is discussed in greater detail in Section 0. Historically, underground mining was performed throughout most of the U.S. by a type of room and pillar method mining referred to as conventional mining that includes direct drilling and blasting of the coal seam. This method may or may not include secondary pillar extraction (Section 3.1.3.2). The majority of modern room-and-pillar mining is now accomplished through a method called continuous mining that involves the use highly mechanized mining machines. An additional form of underground mining that allows for significantly higher percentages of coal extraction is a method called longwall mining.

3.1.4.1 Room and Pillar Mining

The room and pillar method leaves blocks of the coal seam in place to support the overlying strata and immediate mine roof while coal is extracted. Room and pillar mines are developed by making a parallel series of tunnel-like excavations called entries that are interconnected with tunnel-like excavations called crosscuts. These entries and crosscuts are used to mine the coal reserve in a grid-like pattern; the blocks of coal that remain between the entries and crosscuts are called pillars and they support the overlying strata and immediate mine roof. This process is used to mine areas called panels, which consist of an engineered number of entries and crosscuts based on the safety it provides to coal miners, the potential need to protect features and structures located above the mine on the land surface and economic factors of the mining conditions.

Figure 3.1-5. Continuous Mining



Source: Image downloaded August 2016 from the School of Mining, Energy and Materials Engineering of Oviedo http://eimem.uniovi.es/noticias/-/asset_publisher/piR6/content/actividad-minera-metodos-de-explotacion?redirect=%252Fnoticias

"Conventional Mining" is the traditional room and pillar mining method which employs under-cutting the coal production face, drilling, blasting, loading, and hauling to extract coal. Once the predominant mining method in the Appalachian coal fields, it accounts for less than 1.5 percent of underground production today (EIA 2014, https://www.eia.gov/coal/annual/pdf/table3.pdf). Advancements in mining equipment and technology have led to higher productivity and lower-cost production without the use of drilling and blasting. Conventional mining is currently used when unique geology economically precludes the use of the more productive mining equipment.

The prevalent technique for room and pillar mining in use today is called continuous mining, and uses a mining machine, commonly referred to as a continuous miner (Figure 3.1-5, above). The machine cuts the coal from the working face with bits attached to a rotating drum-like cutting head. The continuous miner cuts and loads the coal, replacing the separate steps of undercutting, drilling, blasting, and loading used in conventional mining.

Temporary roof support is established following coal extraction from the working face, typically through roof bolts installed with a machine called a roof bolter. Ventilation controls are then advanced as the mining moves forward to assure that dangerous accumulations of gasses and dust are diluted, rendered harmless, and carried away from the personnel. The cycle of cutting and loading, bolting and advancing ventilation, and cleanup and preparation, require equipment to move from one working face to another. The multiple entries and interconnected cross-cuts in a mine panel are developed by moving the mining equipment from one working face to another to ideally maximize equipment utilization, production, and resources.

After the maximum extent of a room and pillar mining panel has been fully developed, the mining direction may be reversed for secondary partial or total extraction of the coal pillars. This retreat mining process uses the same mining equipment, requiring supplemental roof support to safely control the mine roof and to manage planned caving and subsidence. The pillar extraction process begins at the farthest advanced development of the mine panel and extracts the pillars supporting the overlying strata and immediate mine roof; analysis of the coal and overburden material are used to predict the extent of the controlled roof collapse and resulting surface ground subsidence. Room and pillar mining operations with both primary and secondary (retreat) full-pillar extraction can achieve up to 90 percent recovery of a coal seam in the secondary mining areas, while primary extraction alone can achieve only about 40 to 60 percent.

3.1.4.2 Longwall Mining

Longwall mining uses multiple self-advancing hydraulic mine roof supports, a traversing coal cutting machine called a shearer, and an articulated armored face conveyor that transports the coal and interconnects the roof supports and the shearer to cumulatively create the longwall mining machine (Figures 3.1-6 and 3.1-7). The longwall machine is designed for complete coal extraction within the working area of the equipment. Initial room and pillar mining is used to delineate an unmined block of coal by excavating three to four entry wide mine developments around the block of coal. This unmined block of coal or longwall panel ranges from 650 to 1,580 feet wide by 2,400 to 21,500 feet long, with the average U.S. longwall panel having a face width of 1,137 feet, a length of 10,802 feet, and a cutting height of 90 inches (Coal Age, 2013).

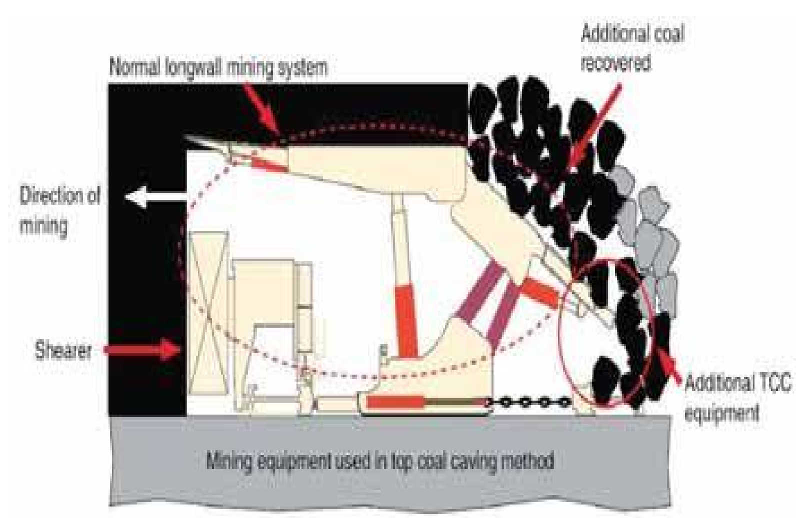
Figure 3.1-7. Longwall Mining Cross-Section



Source: Auster Coal, 2007, Figure *2; a simplified schematic showing the longwall as a vertical cross-section,* available at: http://www.womp-int.com/story/2007vol5/story025.htm

An armored face conveyor and mounted rotating drum shearer travels across the longwall face from one side of the panel to the other, cutting about a 32- to 42-inch deep strip of coal as the conveyor transports the broken coal from the longwall face to the mine's main haulage system. Once the shearer reaches one end of the longwall face, it traverses back to the other end of the face cutting another strip of coal as it moves. The shearer cuts coal in this back-and-forth action along the longwall face until the entire length of the panel has been mined, which results in the total extraction of the longwall panel block of coal. The conveyor and shearer are protected by multiple hydraulic powered roof supports, chocks or shields. These are connected, yet independently articulated, hydraulic roof supports that flank one another to support the overlying strata, and consequently protect the personnel and equipment along the entire longwall face. The shearer cuts the coal in front of a roof support, which leaves a span of newly created unsupported mine roof. The hydraulic shield support is depressurized and collapsed, moved forward, and re-pressurized against the mine roof, thereby minimizing both the unsupported roof exposure time and span created by the continuous cutting action of the traversing shearer. As the roof supports sequentially advance, the mine roof behind the advanced support is now left unsupported. Stresses induced by the unsupported overlying strata cause the roof in this 'mined-out area' to break and collapse, filling the mine void with broken rock known as gob.

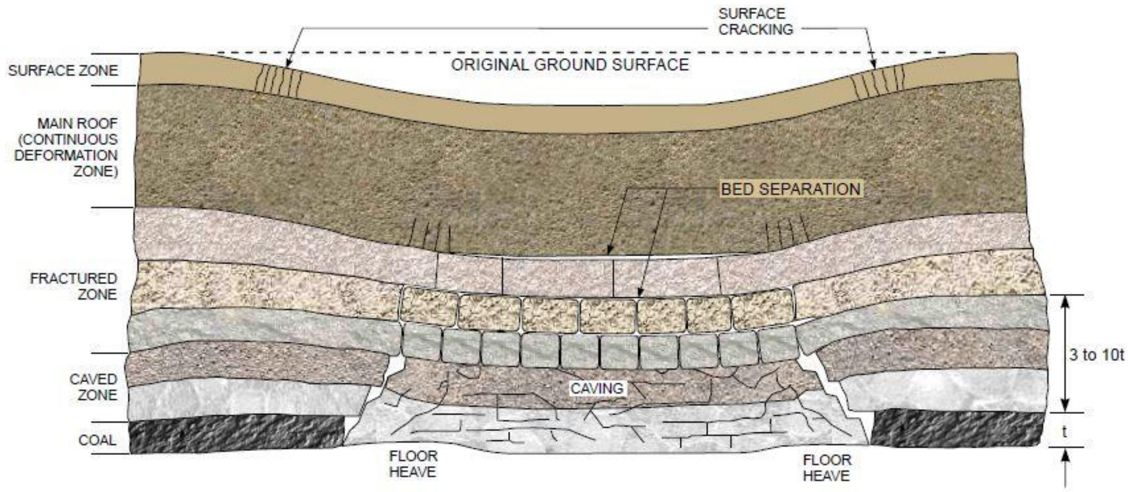
When compared to room-and-pillar mining methods, longwall mining requires both reserves with geology that will accommodate the large rectangular panels as well as a high capital investment in equipment and infrastructure. However, when conditions allow the use of longwall mining, the relatively high coal production rates offset the capital expenditures to make this an efficient production method. There are 42 longwall mines with 47 operating longwall mining machines in the U.S. (Coal Age, 2015). The combined production of these longwall mines equals the combined production of the approximately 500 non-longwall underground mines in the U.S. (U.S. EIA, 2012a). Accounting for only ten million tons of production in 1973, longwall mining accounted for 207 million tons of production, in 2014 (Coal Age, Feb. 2015).

3.1.4.3 Surface Effects of Underground Mining

The removal of underground material without leaving adequate underground support for the overburden can result in collapse that may induce measureable vertical movement of the surface lands, called subsidence (Figure 3.1-8). The downward movement and stratigraphic interactions can also produce horizontal movement, strain, tilt, surface cracking, and even upward movements of portions of the land surface, depending on the properties of the overlying geology and soil. Subsidence can occur naturally, as with the collapse of portions of cave systems, or can be a planned or unplanned result of the mining process. Both longwall mining and full-pillar extraction room and pillar mining allow for surface ground subsidence. Operators design the mines to control these planned subsidence effects. Full subsidence is normally about two-thirds of the thickness of the seam being mined (Suboleski, 1999a), but can range from near zero movement to subsidence equal to the thickness of the coal seam.

Surface subsidence manifests itself in two forms, sinkholes and trough (or area) subsidence. Mine-induced sinkholes are generally small in areal extent and commonly related to unplanned subsidence of a small portion of a shallow room and pillar mine. In contrast, trough or area subsidence typifies planned subsidence features from both room and pillar with total pillar extraction and longwall mines. A sinkhole is a circular depression in the ground surface that occurs when the shallow overburden collapses into an underground void. A trough is a ground surface depression formed by bending of the overburden into an underground void. Unplanned trough subsidence can also occur when large areas of a mine intended for long-term stability were under-engineered, resulting in failure.

Figure 3.1-8. Subsidence Mechanisms



Note: Observed surface subsidence in the above drawing is skewed. The subsidence trough has been exaggerated for the reader's benefit to understand the concept of ground movement.

Source: MSHA, 2009c, *Figure 8.1; Strata Disturbance and Subsidence Caused by Mining,* U.S. Department of Labor Adapted from Singh and Kendorski, 1981; Peng and Chiang, 1984, http://www.msha.gov/Impoundments/DesignManual/Chapter-8.pdf

The surface subsidence area is typically larger than the actual caved excavation area and is a function of the depth and rock properties of the strata overlying the mine workings. In the case of planned subsidence, the affected ground surface area can be determined by using the geology dependent angle of draw, which is the vertical deviation angle from the edge of the underground mined area to the edge of the surface subsidence.

Subsidence can lead to functional impairment of surface lands, facilities and structures, and surface and ground water features and systems. The extent, severity, and timing of subsidence depend on the mining method; the type, size, and condition of the underground support left in place; the size and geometry of a mined-out area; the thickness and properties of the coal seam; the depth to the coal seam; the thickness and structural composition of both the underlying rocks and the overburden (including the presence of geologic faults); the inclination of strata and surface; the soil composition; the locations of ground water; the relation of the mining to previously mined areas; and the method and quantity of any backfilling material placed in the excavation, which is rarely applied in coal mining (Hower et al., 1980; U.S. DOE, 1981).

3.1.5 Mining Method: Surface Mining

Surface mining operations typically recover about 90 percent of the coal reserve. Surface mining involves removal of overburden to expose underlying coal seams for extraction. For purposes of this FEIS, surface mining is categorized by three basic operational methods: contour mining, area mining, and open pit. Mountaintop removal mining, a subset of area mining, is defined as a surface mining operation that removes an entire coal seam or seams running through the upper fraction of a mountain, ridge or hill. Secondary extraction associated with surface mining, collectively known as highwall mining, occurs after the final highwall limits have been reached. Surface mines can employ any combination of these methods to maximize the coal recovery from a given land parcel.

Surface coal mining methods can vary between individual mines, but all share common site development activities:

- *Site Access:* The first step in mine development is construction of a primary haul road to the mine site to provide access for equipment, employees, and supplies.
- *Erosion and Sedimentation Controls*: Control structures include sedimentation ponds constructed to prevent siltation of receiving streams and ditches constructed to convey runoff from disturbed areas to the sedimentation ponds. Diversion ditches are also built around areas affected by mining to divert runoff from upslope areas to natural drainages. These facilities must be constructed prior to initiation of earth disturbance in a given area. In some cases, permanent or temporary stream relocations are employed to reroute streams around the mine.
- *Clearing and Grubbing:* This activity involves the removal of trees, stumps, shrubs, and other vegetation from the area to be affected. This allows for more efficient removal of any topsoil, for later use in reclamation. Topsoil is segregated by a dozer that typically removes the recoverable soil from mining areas to temporary stockpiles, which are temporarily seeded with fast-growing grass species until needed for reclamation. Valley/hollow fill areas are cleared and grubbed to prepare the foundation to ensure stability prior to excess spoil fill placement.
- *Excavation:* This activity is the physical removal of overburden soils and rock overlying the coal seams to allow for removal and haulage of uncovered coal. Unconsolidated surface material and weathered bedrock can usually be excavated by equipment without blasting. The underlying rock is fractured by drilling and blasting, or by ripping with bull dozers. The void left after excavation is referred to as a mine *pit*. The broken rock that is removed is known as *spoil*. As a result of the excavation process, this spoil material "bulks" as voids in the material are created. This bulking is commonly referred to as "swell." Where potentially acid-forming or toxic-forming overburden is encountered, this material requires special handling to segregate and bury it, in order to isolate it from oxygen and water, or to encapsulate it in water.

Surface mining practices have changed in the last three decades as larger equipment and larger-scale mines have resulted in higher productivity. Whereas surface mining and underground mining production was about equal in the early 1970s, the production share from underground mining declined by over 30 percent over the next three decades. This increase in surface coal mining has been concentrated predominantly in the western U.S., where large-scale area mines now account for almost 50 percent of the nation's coal production.

3.1.5.1 Contour Mining

Contour mining takes place in mountainous or rolling hill areas and limits mining to the side of a mountain or to the end of a ridge line. In contour mining, operations progress along the outcrop of a coal seam, removing overburden inward towards the mountaintop or ridge core to the highwall limit of that coal seam. This results in mine cuts that wrap around mountaintops or ridge lines parallel to contour in a sinuous pattern dictated by topography. Contour cuts may be conducted on multiple seams on a given mountain or ridge line. Near the tip of a ridge line on a contour mining operation, "point removal" may occur where the coal seam is mined from the outcrop on one side of the narrow point, through the center of the ridge, and to the outcrop on the opposite side of the point. This occurs where the overburden is shallow.

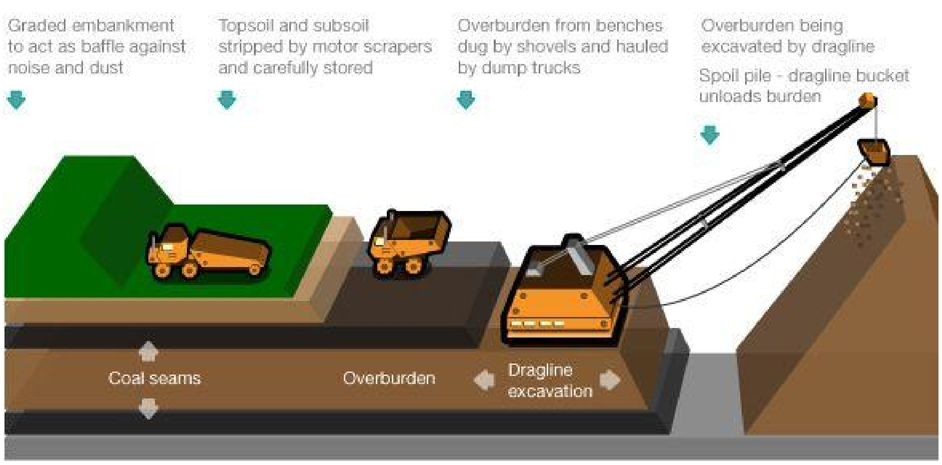
To begin a contour mine, an initial box cut is opened at the coal outcrop and excavated to the highwall limit, forming a mine pit. Spoil material from this first cut may be temporarily stockpiled on site for use in later backfilling, or hauled to an excess spoil disposal area.

Spoil from successive cuts are hauled and placed in the void created by the previous cut. Contour mining may also be employed to recover lower elevation coal seams on steep slopes, and coal seams from areas of excess spoil fills prior to fill placement.

3.1.5.2 Area Mining

Area mining occurs where the coal seam or multiple coal seams produce stripping ratios favorable for mining across the topography, rather than around it as in contour mining (Figure 3.1-9). The area mining method will generally have larger working areas than the contour method and may employ large earthmoving machines for primary overburden removal.

Figure 3.1-9. Area Mine Cross Section



Source: World Coal Association, 2011, *Coal Mining*, http://www.worldcoal.org/coal/coal-mining/

Area mining offers the advantages of a high coal recovery rate and high production rate potential. It also allows overburden placement that easily restores a site to the approximate original contour (AOC). However, area mining requires a large capital investment and a large reserve base to be practical. In steep slope areas, area mining may require disposal of large volumes of excess spoil, depending on how the mine operation is planned, as well as specific postmining land uses that allow for a variance from AOC. In areas that have been previously mined, excess spoil may be used to complete reclamation of previously mined benches.

Area mines may begin by excavating an initial cut across the entire width of a flat or gently-sloping area, mountaintop, or ridge line (Figure 3.1-9, above). Where potentially acid-forming or toxic-forming overburden is encountered, this material may require special handling to be segregated and buried (to isolate it from oxygen and water) or to encapsulate it in water.

In steeper sloping areas, this initial cut may start as a contour cut on the basal coal seam and progress inward until a highwall is established. Smaller equipment, such as excavators, loaders and dozers make these initial cuts and work in advance of the highwall to remove upper coal and create a flat working bench. In steep slope areas, such as in the Appalachian Basin region, excess spoil from area mines is often placed in excess spoil disposal areas, or transported to nearby unreclaimed pre-SMCRA open pits.

3.1.5.3 Area Mining Dragline Method

The dragline method of area mining involves opening an initial box cut, removing the coal exposed in the box cut, and then placing the overburden from the next cut into the mined-out, box cut area. A dragline machine is used in this process; it has a very large shovel capable of moving 100 cubic yards or more of material with each pass (Figure 3.1-10). The box cut procedure is repeated on a cut-by-cut basis. Spoil from the initial box cut is temporarily stored and later spread and blended into the backfilled mined area. This surface mining method is generally employed in flat or moderately dipping coal seams with constant overburden depths.

In a typical cycle of excavation, the dragline bucket is positioned above the material to be excavated. The bucket is then lowered and the drag cable is then drawn so that the bucket is dragged along the surface of the material. The bucket is then lifted by using the hoist cable. A swing operation is then performed to move the bucket to the dump area, generally into the preceding cut.

3.1.5.4 Mountaintop Removal Mining

Mountaintop removal mining is a subset of area mining that involves removing an entire coal seam or seams from the outcrop on one side of a mountain or hill through to the outcrop on the other side. Mountaintop removal mining operations run through the upper fraction of a mountain, ridge, or hill by removing substantially all the overburden above the coal seam and creating a level plateau or a gently rolling contour, with no highwalls remaining. Figure 3.1-11 shows an aerial photograph of mountaintop removal operations, with both active mining and ongoing reclamation operations. Pursuant to SMCRA, mining operations can only be permitted as mountain top removal mining if they are granted a variance from returning the mined lands to AOC, providing that the postmining land uses meet SMCRA requirements (30 U.S.C. 1265(c) and 30 CFR Parts 785, 816 and 824). These approved postmining land uses include industrial, commercial, residential, agricultural, or public facilities (including recreational facilities). A portion of the overburden from the top of the mountain (typically the “swell” portion of the broken rock) is transported to permanent placement in excess spoil disposal areas.

Figure 3.1-10. Draglines in an Area Mine Operation

Source: CU-Boulder Environmental Studies Program, 2009, *Dragline and Explosives, Navajo Coal Mine,* Environmental Issues in Mining, University of Colorado at Boulder.

Mountaintop removal mining operations can achieve essentially 100 percent recovery of coal reserves, a portion of which might otherwise be permanently isolated beneath the reclaimed mine site. Stripping ratios of 13 to 20 may be economically feasible for large operations (Suboleski, 1999a). Mountaintop removal mining operations require large capital investments and working reserves to be feasible, and can require disposal of substantial amounts of spoil in excess spoil fills.

The term “mountaintop mining” has often been confused with the term “mountaintop removal mining.” In the Draft Programmatic Environmental Impact Statement on Mountaintop Mining and Valley Fills (U.S. EPA et al., 2003) mountaintop mining is referred to as “coal mining by surface methods (e.g., contour mining, area mining, and mountaintop removal mining) in the steep terrain of the Central Appalachian coalfields.” The term “mountaintop removal mining” refers to those operations that receive a variance from the AOC restoration requirements to facilitate a specific postmining land use. This FEIS does not use the term “mountaintop mining,” and all other surface mining operations will be discussed in terms of the mining methods actually being employed at the operation.

Figure 3.1-11. Mountaintop Mining and Reclamation Operations

Source: Hamon, J. 2010, *Aerial Overflight of Permit 848-0285 Xinergy Corp, Harlan County, Kentucky,* Division of Mine Reclamation and Enforcement, Kentucky Department for Natural Resources, Middlesboro Office

SMCRA provisions allow surface coal mining operations in steep slope areas to apply for and receive a waiver from the AOC requirement, specifically for a steep slope variance, again in exchange for creation of specific postmining land use(s) compliant with the statute and current regulations (30 U.S.C. 1265(d)). SMCRA allows a steep slope variance that specifically accepts final configuration different than premining if it can be shown that the proposed Alternative postmining land use would result in an equal or better economic or public use. Under Section 1265(d) of SMCRA and 30 CFR 701.5, a steep slope is defined as any slope of more than 20 degrees. An applicant for a steep slope variance must demonstrate that total suspended solids or pollutants to surface and ground water from the permit area will be reduced, or flood hazards in the watershed of the permit area will be reduced; and that total volume of flow from the permit area will not vary in a way that adversely affects ecology of any surface water or any existing or planned use of surface or ground water.

3.1.5.5 Open Pit Mining

Open pit or terrace mining is generally used in thick-seam areas with low stripping ratios. This method often places the overburden in temporary off-site storage. Once coal is removed from the initial pit area, the next cut is taken in the direction of the mine advance with the overburden from the new cut hauled to the existing pit and dumped. The coal is removed and the process of hauling back the overburden is repeated as the pit advances. Modern open pit mines use large mechanical equipment. The amount, type, and size of equipment employed in an open pit mine depend on the characteristics of the coal seam and overburden.

3.1.5.6 Auger and Highwall Mining

Auger and highwall mining have historically been secondary extraction methods that may be employed allowing additional coal extraction horizontally beyond the existing highwalls after their stripping ratio limit has been reached (Figure 3.1-12). This is the last activity to be conducted in a final mine pit before it is backfilled. Depending on the regulatory authority, auger and highwall mining may be permitted as either surface or underground mining.

Figure 3.1-12. Auger Mining

Source: Friends of the Locust Fork River, 2011, *Figure 2; Auger Mining*.

In auger mining, horizontal holes are drilled into a coal seam with auger stems driven by a rotary shaft with a hydraulic ram, working on the principle of an Archimedes screw. While auger holes can reach a distance of 400 feet, 200 feet or less is a more practical limit, as the auger may intersect the bottom strata or wander laterally into adjacent holes as its depth of penetration increases. Augers have a maximum recovery rate of about 33 percent (Suboleski, 1999a).

A continuous highwall mining machine may be used in place of an auger when coal seam characteristics permit. A continuous highwall miner typically has a front set of rotary cutting heads that cut coal from a seam horizontally beyond the existing highwall and direct it onto conveyor cars for delivery to the pit area. There, a stacking conveyor piles the coal in preparation for truck loading. Continuous highwall miners have a better recovery rate than augers (up to 45 percent of the reserve) and can mine to distances over 1,500 feet (Suboleski, 1999a).

Highwall mining can reach coal reserves that cannot be economically mined by surface methods and is relatively inexpensive compared to other production methods. However, highwall mining has a lower recovery rate due to the coal that must remain between each hole. Maintaining the coal pillar is critical in preventing the intersection of holes, maintaining highwall stability, and preventing loss of equipment in collapsed holes. In many cases, highwall mining negates any possibility of future surface mining at the site because of mechanical damage to the coal seam and lower recovery rate. Normally, highwall mining can only be conducted in a down-dip direction to prevent gravity discharging of ground water.

3.1.5.7 Haul Roads

Haul roads within a mine site are constructed to accommodate the widths of vehicles used on that particular operation. They are usually 50 feet or more wide. The overall grade of a haul road normally does not exceed ten percent for ease of haulage and to minimize brake wear and failure. Lengths of haul roads vary according to the distances necessary to access development, mining, and fill disposal areas. In steep slope areas, ditches are constructed on the uphill sides of haul roads to collect runoff, and culverts are placed at intervals to convey runoff under the road to the downhill side. In flatter terrain, ditches are constructed on both sides of each road, and the road is crowned to allow for drainage to both sides. Temporary haul roads to working areas are usually surfaced with crushed overburden materials, while primary haul roads connecting to public roads are generally surfaced with gravel. Additional ancillary roads (small service roads) may be constructed to access erosion and sedimentation control facilities or support areas (Tannant and Regensburg, 2001).

3.1.6 Underground Mine Waste Disposal

Only a small amount of waste rock generated by the underground mining process can be disposed of in the active mine workings due to space limitations. This disposal is typically performed inside crosscuts. Large underground construction projects can generate excessive amounts of waste rock requiring outside disposal in the coarse refuse disposal areas.

As discussed in Section 3.1.1.4, producing a high-quality, low-sulfur, and low-ash product requires preparation of the raw underground mined coal product. Two kinds of waste result from this process: coarse refuse and fine refuse, commonly referred to as “slurry”. Operators sometimes dispose of fine coal refuse slurry in underground mines on a very limited basis by pumping the slurry into old mine workings through vertical boreholes. This atypical disposal is limited to mines well below the water table that demonstrate diminutive interaction with ground water aquifer systems and adequate outcrop barrier and/or seam depth to prevent a blow-out into the outside environment. This underground injection disposal can be performed in both active and abandoned mines; however, an active mine must develop supplementary safety measures to protect underground personnel from underground blow-outs into active portions of the underground mine. U.S. Environmental Protection Agency (EPA) approval is needed for underground injection of the waste slurry (unless the state has primacy) and an MSHA plan is required for disposal in an active underground mine. A special permit from the state regulatory authority or the EPA pursuant to the Safe Drinking Water Act is required for underground injection operations. These injection wells are considered Class V wells (mining, sand, or other backfill wells) under the federal regulations found at 40 CFR 144 and 146. State regulations pertaining to mine backfill wells vary significantly in their scope and stringency. Coarse coal processing refuse is not disposed of in an underground mine. Surface disposal of coal refuse is discussed below.

3.1.7 Material Handling and Mine Reclamation

3.1.7.1 Mine Reclamation

Mine reclamation is the process of backfilling, regrading, planting vegetation, and other actions necessary to meet permitting requirements, permit conditions, and performance standards under the applicable regulatory program, on a disturbed mine site.

Postmining land uses can range from what existed before mining, to alternate land uses determined to be higher and better, which may include but are not limited to industrial, commercial, agricultural or forestland uses. Reclaiming a mine site entails four essential steps:

- *Backfilling:* After coal removal, mine pits are backfilled with spoil from new excavations to restore the ground surface. Backfilling, also known as "backstacking" in steep slope areas, may be accomplished by a variety of methods, including casting by draglines or shovels, cast blasting, dozer pushes, and truck haulage and dumping. Normally, mining will advance through a mine site in a series of adjacent excavations, or cuts, with the spoil from each new cut being placed in the pit void left by the previous cut. Sites which generate excess spoil must haul that spoil to excess spoil fills or other disposal fill types adjacent to the immediate mining area.
- *Regrading*: This activity is the shaping of spoil areas to final reclamation contours. After spoil casting or haulage and dumping, spoil areas usually have a very irregular surface that must be smoothed to better resemble a natural land surface. Regrading of spoil is primarily accomplished by dozers, with the final site topography determined by the site reclamation plan and the approved postmining land use. These plans aim to fulfill the regulatory obligation to achieve AOC, unless that requirement is waived according to very specific and limited regulatory circumstances, which is discussed in greater detail later in this section.
- *Excess Spoil Generation*: After coal removal, the mine operator places spoil in the mined-out area for reclamation. Under SMCRA the operator must grade the spoil to closely resemble the general surface premining topography (30 U.S.C. 1265(b)(3), 30 CFR 701.5 and 816.102(a)(1)). This is referred to as returning the reclaimed mine to the AOC.

There are situations, particularly in steep terrain, where the volume of spoil is more than sufficient to return the reclaimed land to AOC or due to potential instability of the reclaimed slopes it is not technically feasible to return all the spoil to the mined-out area when reclaiming the site. Surplus spoil material disposed of in locations other than the mined-out area, except for material used to blend spoil with surrounding terrain in achieving AOC in non-steep slope areas, is referred to as "excess spoil." In steep slope terrain, the mine operator may place the excess spoil either in adjacent valleys, or on previously mined sites. There are several types of steep-slope excess spoil fills. For a detailed discussion of excess spoil disposal methods and trends, the reader is referred to Section 3.4 of this FEIS, which deals with topography.

- *Topsoil Redistribution or Substitution:* The final earthmoving activity is redistribution of stockpiled topsoil over the surface, or preparation of a topsoil substitute, if topsoil replacement is not employed. Where topsoil has been stockpiled, it is redistributed by dozers or scrapers at an application rate determined by available quantities. Use of topsoil substitutes requires a variance during the mine permitting process. When redistributing soil materials it is important that compaction of the materials be avoided or minimized so as not to inhibit root growth and development when reestablishing vegetation in the reclaimed mine area. Areas in which over compaction occurs may require the ripping of soil materials to alleviate compaction problems. This issue is particularly critical in locations requiring the successful reestablishment of deeply rooted plants such as trees and some restored agricultural land use types, frequently lands identified as prime farmlands.
- *Revegetation:* Following spreading or preparation, the topsoil or topsoil substitute is planted and seeded with species mixes reflecting the intended postmining land use. Many coal mine sites occur in forested areas, and tree planting is sometimes part of the revegetation process. Other shrub and herbaceous species may be included in the revegetation mix for wildlife habitat. Planting may be conducted by hand or with tractor-towed mechanical planters, and seeding accomplished using hydroseeders that concurrently apply a stabilizing cellulose mulch and fertilizer. Revegetation planting and seeding mixes are approved as part of the mine permitting process. If vegetation types or postmining land uses are proposed that differ from the premining land use of a site, then the change must be approved by the regulatory authority.

Forestry Reclamation Approach: In addition to the steps outlined above, the recently introduced Forestry Reclamation Approach is one method of reclaiming surface coal mines to forested postmining land use (ARRI, 2011). This approach entails several steps:

1) Create a suitable rooting medium for good tree growth that is no less than four feet deep and comprised of topsoil, weathered sandstone and/or the best available material;

2) Loosely grade the topsoil or topsoil substitute established in step one to create an appropriate growth medium;

3) Use ground covers that are compatible with growing trees;

4) Plant two types of trees: early succession species for wildlife and soil stability, and commercially valuable crop trees; and

5) Use proper tree planting techniques.

Many coal-bearing lands were forested prior to mining. As a result of research and recent changes in regulatory policy, many surface coal mines are now being restored with native forest species after mining using the Forestry Reclamation Approach.

3.1.7.2 Processing Facilities

Coal mined by both underground and surface mining methods may contain waste rock and excessive sulfur and may not be suitable for immediate consumer use. This coal must be processed to reduce the impurities and may be blended with higher quality coal before delivery. Some coals must also be sized for the end use. Coal mined by underground methods may contain up to 50 percent rock or more because of rock seam partings removed with the raw coal or because it is necessary to mine rock from the roof or floor to gain access height; while under certain circumstances, coal may not need to be processed at all if it has few impurities, i.e., when the seam does not have partings, meets the contracted sulfur content, and is mined "within seam." Some surface operations do have to process the raw coal, but usually they can selectively mine the coal and remove waste rock without mixing the two; this is dependent on the geology and equipment used.

Processing facilities may include screens to separate coal into acceptable size grades; crushers to further reduce coal to desired size grades; and washing plants to clean rock and sulfur impurities from coal. Washing plants may use a high-density medium (usually fine magnetite) in water to separate low-density clean coal from contaminants with a closed-loop magnetite recycling system. Reject materials from screens and crushers and residue from washing plants are hauled or pumped to coal refuse disposal facilities.

Processed coal can then be blended with other coal stock to achieve the desired market quality grades and sizes. Blending may be accomplished by mobile equipment, such as loaders, or using a system of mobile stacking conveyors. Stockpiles and/or silos are typically present on site to store raw, cleaned, and blended coal prior to transport.

3.1.7.3 Coal Refuse Disposal Facilities

Coal mine waste or refuse (rock separated during the cleaning of coal, frequently shale) is typically disposed off-site adjacent to a coal processing facility. Most coal refuse disposal facilities are impoundments formed by constructing an embankment or dam across an existing hollow or valley in steep slope topography or in above-ground impoundments in flat or gently sloping areas. The embankment is often constructed from the coarser refuse material in a series of lifts as refuse slurry accumulates behind the embankment.

Coal refuse disposal facilities are long-term investments because of their size, support facilities, and reclamation requirements. The typical life of a coal refuse disposal facility is approximately 20 years. One or more mines may contribute to a single coal processing facility and/or shipping point.

Refuse with small particle sizes, known as "fines," is usually pumped in slurry form from the processing facility to a refuse slurry impoundment. Aside from storage, the refuse impoundments serve to settle fines and decant water. As a mixture, these slurries may also include other materials including, sand, mill tailings, or other materials (e.g., coal combustion byproducts, coal cleaning wastes, acid mine drainage (AMD) treatment sludge). At surface mines in less mountainous areas, final pit areas are frequently used to dispose of fine coal wastes and do not require the construction of an impounding embankment.

In addition to being stored in impoundments, slurry refuse can also be pumped or injected into abandoned underground mine workings after EPA and MSHA approval. Underground injection wells are used in many mining regions throughout the country to inject slurry refuse into mined-out portions of underground mines. On occasion, injection also occurs into the rubble disposal areas at surface mining sites. Mine shafts and pipelines in an underground mine, as well as more "conventional" drilled wells, are used to dispose of slurries and solids. This form of backfilling may be used to provide surface subsidence control (the most common purpose), enhanced ventilation control, mine fire control, disposal of mine waste, enhanced recovery of minerals, mitigation of AMD, and improved safety.

According to a 1999 state and EPA Regional survey, there are approximately 5,000 documented mine backfill wells and more than 7,800 additional wells estimated to exist in the U.S. A total of 17 states report having underground injection wells. More than 90 percent of the documented wells reported are in four states: Ohio (3,570), Idaho (575), West Virginia (401), and North Dakota (200) (U.S. EPA, 1999).

A special permit from the state regulatory authority or the EPA pursuant to the Safe Drinking Water Act is required for underground injection operations. These injection wells are considered Class V wells (mining, sand, or other backfill wells) under the federal regulations found at 40 CFR 144 and 146. State regulations pertaining to mine backfill wells vary significantly in their scope and stringency. Some states impose few restrictions while others require permitting, or impose requirements by contract rather than regulation. Some of these approaches include permit by rule (e.g., West Virginia, Idaho, North Dakota), general or area permits (e.g., Wyoming), and individual permits (e.g., Ohio). In states that have not obtained primacy under SMCRA and for surface coal mining operations on federal and Indian Program lands, federal permit requirements for mining must include information on injection or backfill activities (U.S. EPA, 1999).

3.1.7.4 Coal Refuse Secondary Recovery Operations

Coal refuse placed before 1970 often contains a low BTU-value material that can be reprocessed to recover the coal or burned as is in specialized fluidized bed reactors. The refuse is referred to by various names, including: “gob” (garbage of bituminous) or “boney” in the bituminous coal mining regions of western Pennsylvania, West Virginia and elsewhere; and “culm” in the eastern Pennsylvania anthracite region. These secondary operations may recover either course or fine coal refuse materials for market sales.

Large volumes of this coal refuse accumulated at mining sites from the time mining first began in the Appalachians through the late 1970s. Permit applications for reprocessing or removing this coal refuse include plans to safely excavate and reduce the loose, potentially combustible, and/or acid-forming potential of coal refuse. Final reclamation plans include geotechnical and hydraulic engineering design criteria to ensure long-term stability of any remaining material, eliminate a source of pollutional discharge and reclaim the land to a higher use (MSHA, 2009a).

Beginning in the late 1970s, coal preparation became more efficient, thus improving the coal product while lowering the BTU of the generated waste. Current mining operations continue to generate coal refuse, though likely at lower quantities than in previous decades.

3.1.8 Bonding and Financial Assurance

3.1.8.1 General Bonding Requirements

One of the major purposes of SMCRA is to ensure adequate reclamation of all areas disturbed by coal mining operations. Section 509 of SMCRA, and its implementing regulations at 30 CFR Part 800, require that, prior to permit issuance, the applicant file a performance bond with the regulatory authority. The bond guarantees that sufficient funds will be available to complete the approved reclamation plan in the event the permittee fails to do so.

The bond amount required for each bonded area must be determined by the regulatory authority, and depends on the requirements of the approved permit and reclamation plan. The amount of bond must be sufficient to assure completion of the reclamation plan if the regulatory authority must perform the work.

The method for determining required bond amounts varies with the regulatory authorities program requirements. Where OSMRE is the regulatory authority, OSMRE's Handbook for Calculation of Bond Amounts provides guidance for the bond calculation method (OSMRE, 2000c). The method is a standard engineering cost estimating procedure in which reclamation costs for the "worst case" reclamation scenario are determined. The "worst case" is the hypothetical point of maximum reclamation cost liability within the approved mining and reclamation plan. Some regulatory authorities use a similar approach, while others base bond amounts on unit costs per permitted acreage. The regulatory authority evaluates bond adequacy and adjusts bond amounts as appropriate at the time of permit revision, or when the cost of future reclamation changes. Bond reduction as a result of reclamation work accomplished is processed as an application for bond release.

There are three major types of reclamation bonds:

- Corporate surety bonds;
- Collateral bonds (cash; certificates of deposit; real property and first-lien interests in real estate; letters of credit; federal, state, or municipal bonds; and investment-grade securities); and
- Self bonds (legally binding corporate promises without separate surety or collateral, available only to permittees who meet certain financial tests).

Regulatory programs vary somewhat in terms of which financial instruments are acceptable. Some programs have excluded the self-bond option. Subject to regulatory authority approval, a permittee may post any combination of bond types and instruments recognized by that regulatory program, provided the total sum equals the required reclamation bond amount at all times. Each regulatory authority prescribes and furnishes forms for filing reclamation bonds. The forms differ for each type of bond. All bonds are payable to, or pledged to, the regulatory authority.

Reclamation performance bonds are posted to cover all mining and reclamation operations during the term of the permit. Prior to permit issuance, the permittee posts a bond to cover the entire permit area or an identified increment of land within the permit area upon which the operator will initiate and conduct surface coal mining and reclamation operations during the initial term of the permit. Prior to conducting operations on succeeding increments, the operator will file additional bond to cover such increments. Either a cumulative bond or an incremental bonding schedule may be used for bonding increments of land within the approved permit.

Reclamation bonds are typically released in three phases. Phase 1 bond releases are granted after satisfactory backfilling and regrading have been completed on the disturbed area. Phase 2 releases are granted after completion of revegetation activities. Phase 3 releases are granted after the operator has successfully completed all surface coal mining and reclamation activities and met water quality standards for runoff leaving the permit area. However, the remaining portion of bond may not be released before the expiration of the period of extended responsibility specified at 30 CFR 816/817.116 for establishing successful revegetation.

3.1.8.2 Alternative Bonding Systems

Alternative bonding systems are any system not specifically identified in 30 CFR 800.12. One type of alternative bonding system is the “bond pool”. In lieu of requiring permittees to post an individual bond covering the entire estimated cost of completing the approved reclamation plan, some states authorize or require permittees to participate in a bond pool.. Under these systems, the permittee normally posts a conventional bond (surety bond, letter of credit, etc.) for an amount determined by multiplying the number of acres in the permit area by a flat per-acre assessment. The bond amount may vary depending on the type and site-specific characteristics of the planned mining operation. In addition, the permittee generally must pay an annual acreage fee or a tonnage fee as coal is mined. These funds are used to reclaim any site for which a participant in the alternative bonding system fails to complete all reclamation obligations and available conventional bond funds (surety, letter of credit, etc.) are inadequate to complete the required reclamation.

Under OSMRE regulations, all alternative bonding systems must provide a significant economic incentive for the permittee to comply with reclamation requirements. They must also ensure that the regulatory authority has adequate resources to complete the reclamation plan for any sites that may be in default at any time.

3.1.8.3 Bonding for Long-term Treatment

Regulatory authorities only approve those permit applications in which the operation is designed to prevent off-site material damage to the hydrologic balance. In no case should a permit be approved if the determination of probable hydrologic consequences predicts the formation of a postmining pollution discharge that would require continuing long-term treatment without a defined endpoint. However, it is recognized that unanticipated discharge could develop on occasion despite the use of the best science available. In these cases a permit revision is required to incorporate the long-term treatment plan in the permit and the permittee must post sufficient financial assurance to cover all foreseeable long-term costs. The permittee may, subject to regulatory authority approval, establish a financial guarantee separate from the existing bond to cover these long-term costs. This assurance takes the form of a conventional bond, a trust fund or other appropriate instrument that meets the requirements of 30 CFR Part 800.

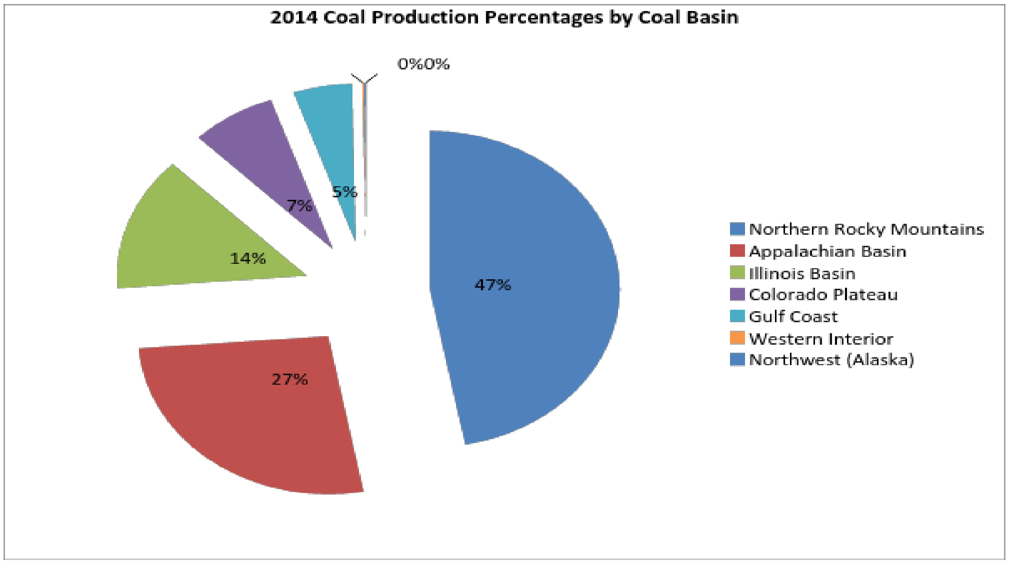
3.1.8.4 Liability Insurance

The regulatory authority requires that each permit application include a certification that the applicant has a public liability insurance policy in force for coal mining and reclamation activities for which the permit is sought. The certificate must be issued by an insurance company authorized to do business in the U.S. Such a policy provides for personal injury and property damage protection in an amount adequate to compensate any persons injured or property damaged as a result of the surface coal mining and reclamation activities, including the use of explosives, and who are entitled to compensation under the applicable provisions of state law. The policy remains in full force during the life of the permit. Minimum insurance coverage for bodily injury and property damage must be $300,000 for each occurrence and $500,000 aggregate.

3.1.9 Coal Resources and Coal Mining by Region

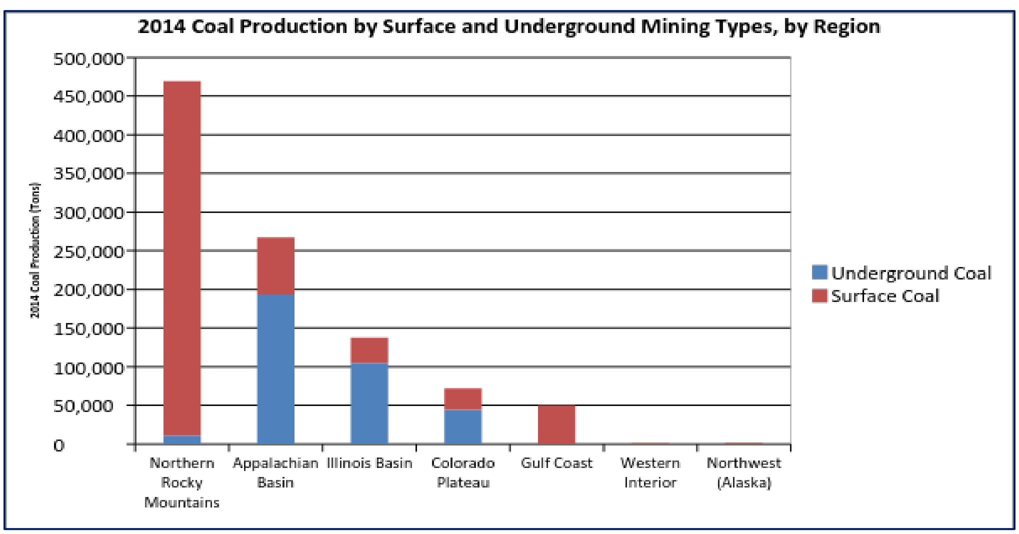
This section outlines the types of coal resources and reserves present in each of the seven study regions and coal production within each region. The charts below provide an overview of production and the type of mining method used by region (Figures 3.1-13 and 3.1-14).

Figure 3.1-13. Percent Coal Production by Region (2014)



Source: Derived from Annual Coal Reports 1994-2014, U.S. Department of Energy; Energy Information Administration; http://www.eia.gov/coal/annual/; as retrieved July, 2016.

Figure 3.1-14. Coal Production by Surface and Underground Mining by Region

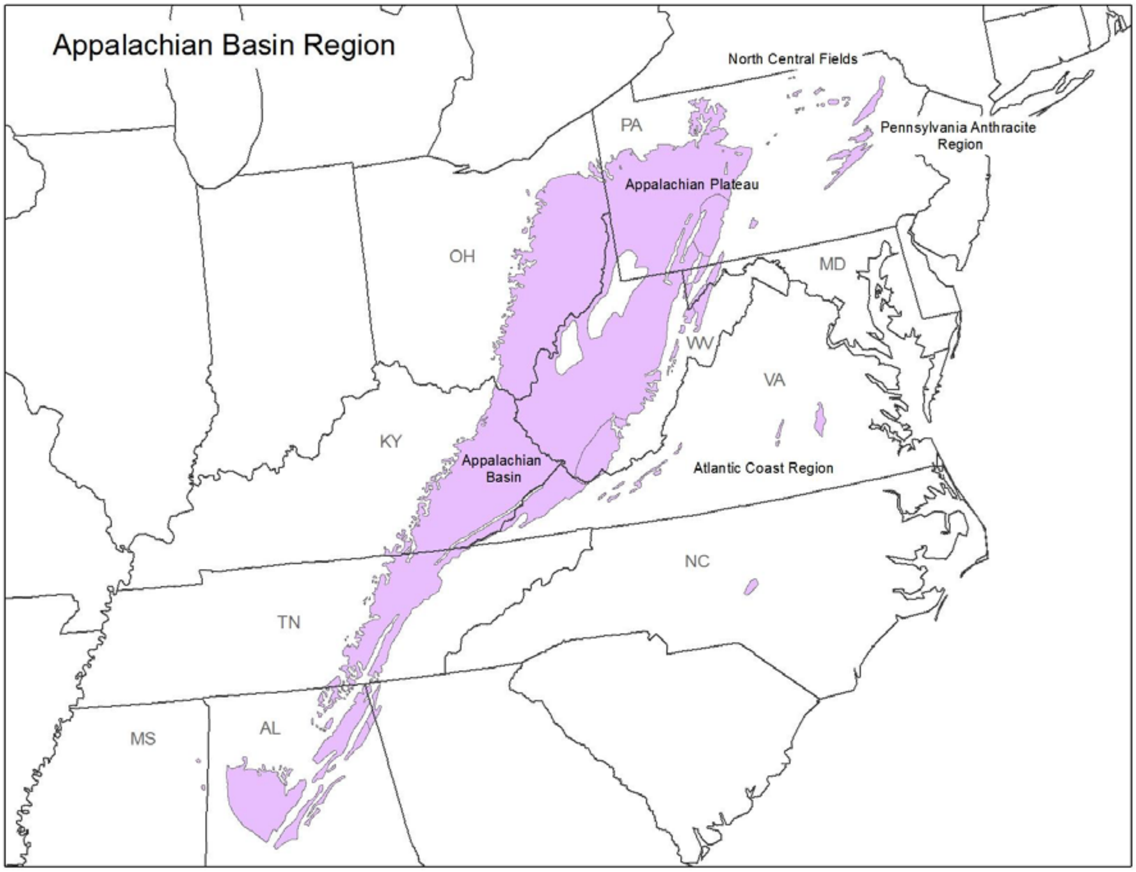


Source: Derived from Annual Coal Reports 1994-2014, U.S. Department of Energy; Energy Information Administration; http://www.eia.gov/coal/annual/; as retrieved July, 2016.

3.1.9.1 Appalachian Basin Region Mining

The Appalachian Basin region includes coal reserves located in Alabama, Georgia, eastern Kentucky, Maryland, North Carolina, Ohio, Pennsylvania, Tennessee, Virginia, and West Virginia (Figure 3.1-15). This region accounts for approximately 20 percent of the Nation's overall demonstrated reserves, 35 percent of the Nation's demonstrated bituminous reserves, and 98 percent of the Nation's demonstrated anthracite reserves.

Figure 3.1-15. Appalachian Basin Coal-Bearing Region

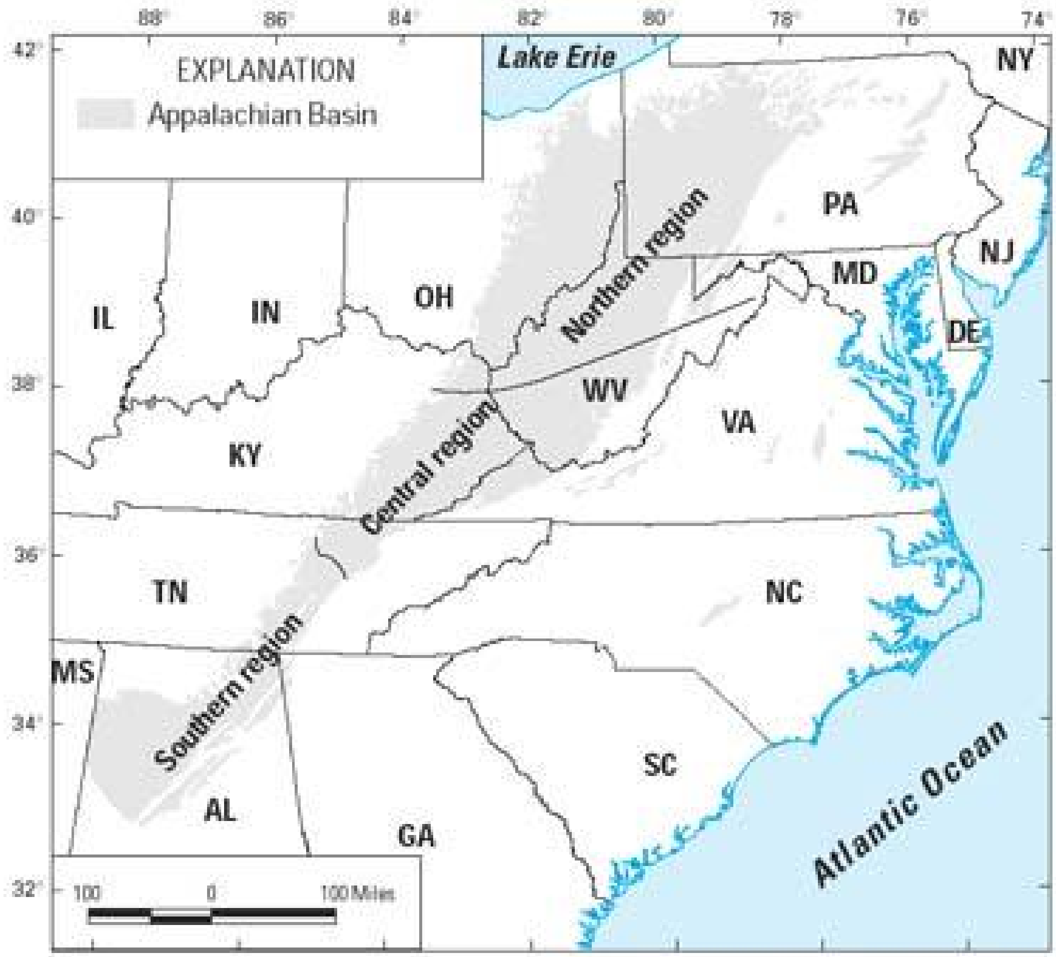


Source: Data- USGS, 2011a, *Coal Fields*, U.S. DOI, http://nationalatlas.gov/atlasftp.html?openChapters=chpgeol#chpgeol

3.1.9.1.1 Location of Regional Coal Reserves

In practice, the Appalachian region has traditionally been divided into three coal-producing regions based on geologic structure and stratigraphy: the Northern Appalachian region, located in western Pennsylvania, eastern Ohio, western Maryland, and northern West Virginia; the Central Appalachian region, located in west-central and southwestern West Virginia, eastern Kentucky, northern Tennessee, and southwestern Virginia; and the Southern Appalachian region, located in southern Tennessee, northern Alabama, and northwestern Georgia (Figure 3.1-16).

Figure 3.1-16. Locations of the Three Appalachian Basin Coal Regions



Source: Ruppert, L., et al., 2005, Coal Resources of Selected Coal Beds and Zones in the Northern and Central Appalachian Basin, Figure 1, USGS, Fact Sheet 004-02. http://pubs.usgs.gov/fs/fs004-02/fs004-02.html

3.1.9.1.2 Property Ownership

Federal surface lands along the eastern seaboard of the U.S. include U.S. military properties, national parks and forests, water bodies, and other recreational areas and monuments. The U.S. also holds some land in trust for Indian tribes or individual Indians. A U.S. Geological Survey (USGS) study determined that within four coal beds in the Appalachian Basin region, the federal surface ownership accounts for less than five percent of their total resource areas (USGS, 2005a).

While surface ownership does not necessarily imply ownership of mineral rights, remaining coal resources underlying federal surface ownership have been estimated by the USGS at about 8.3 billion tons in five coal beds in the Appalachian Basin region, of which only a portion is likely available or economically feasible to mine. These statistics show that a significant amount of coal resources appear to be located under federal lands in this region.

3.1.9.1.3 Types of Coal Resources

Bituminous and anthracite coal are mined in the Appalachian Basin region. Bituminous coal is found throughout the Appalachian Basin region, while anthracite is found almost exclusively in northeastern Pennsylvania. The majority of the coal resources in this region are located in thick beds with low to medium sulfur content and high BTU content. The remaining resources are located in medium to thin beds and generally have higher sulfur contents. High BTU resources remain recoverable through underground methods, while few large surface mineable resources remain (Luppens et al., 2009).

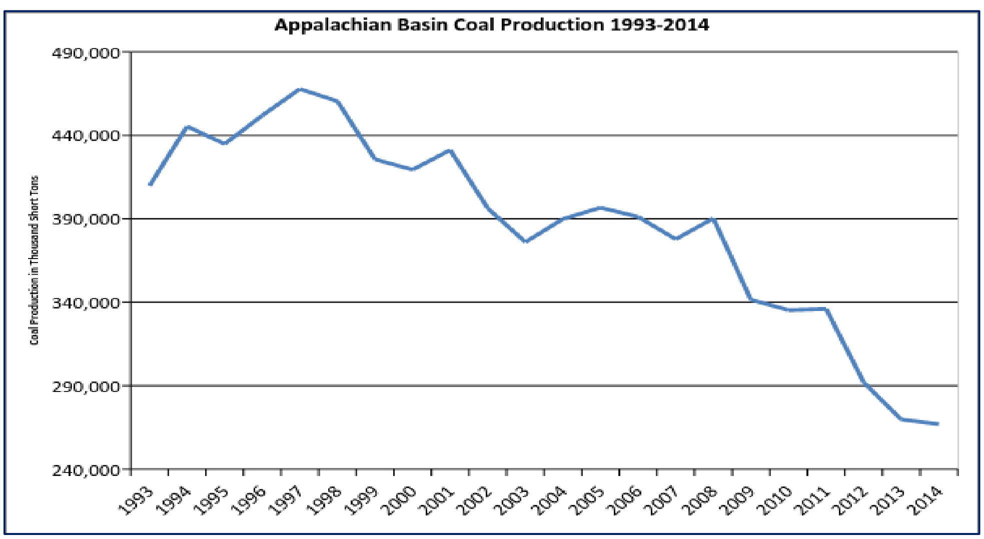
3.1.9.1.4 Extraction Method

Surface mining accounted for approximately 28 percent of the production in the Appalachian Basin region in 2014. Underground mining accounted for 72 percent of the production in the Appalachian Basin region in 2014; longwall mining operations accounted for 62 percent of the 2014 underground coal production in this region. As of the 2011 dataset, Appalachia leads the nation in underground coal production with 18 of the 41 total U.S. longwall installations, more than any other region.

3.1.9.1.5 Coal Production, Production Trends, and Number of Mines

Coal production numbers in Appalachia show a declining trend. Overall, Appalachia produced approximately 267 million tons of coal in 2014, a decrease of 21 percent from 2011 (Figure 3.1-17). As reported in the FEIS, fourth quarter 2012 production in the Appalachian Basin region totaled 67.9 million short tons, declining 1.7 percent and 17.3 percent from the third quarter 2012 and fourth quarter 2011, respectively. As of the 2012 the Appalachian Basin region contained 701 active surface mines which produced approximately 99 million tons, while 466 underground mines produced approximately 194 million tons.

Figure 3.1-17. Coal Production Trends in the Appalachian Region (Thousands of Tons)

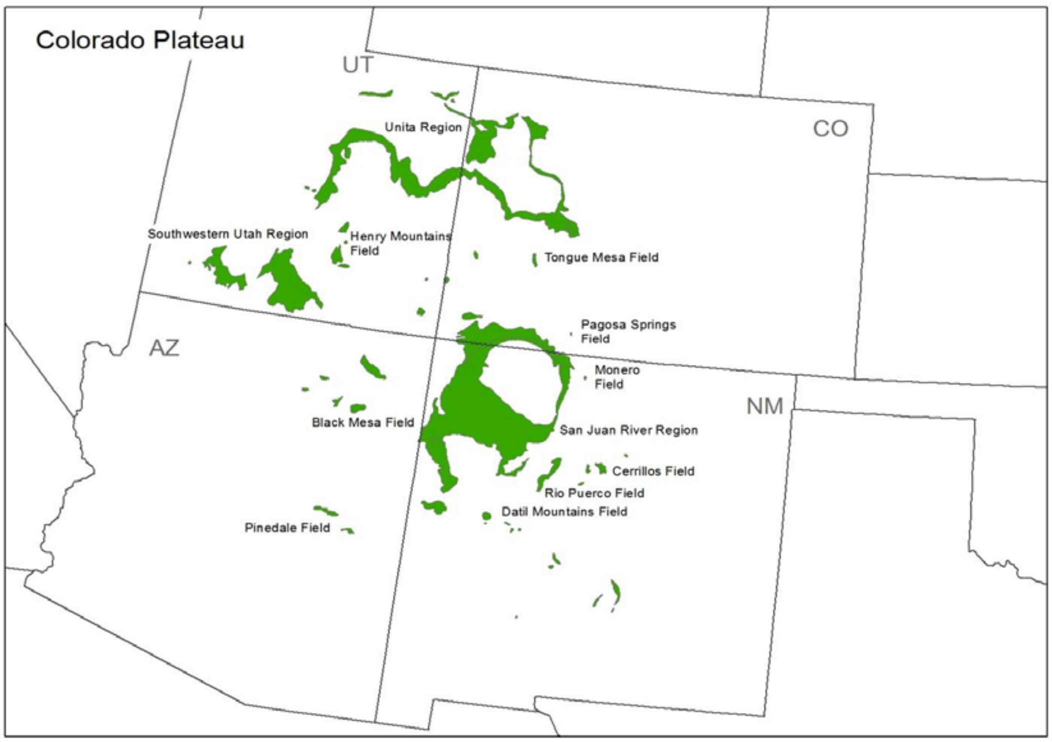


Source: Derived from Annual Coal Reports 1994-2014, U.S. Department of Energy; Energy Information Administration; http://www.eia.gov/coal/annual/; as retrieved July, 2016

3.1.9.2 Colorado Plateau Mining

The Colorado Plateau physiographic region includes coal reserves in Colorado, Utah, New Mexico and Arizona (Figure 3.1-18). Colorado, Utah, and New Mexico account for the majority of coal production within the Colorado Plateau. The total estimated demonstrated reserves within this region are 33.2 billion tons, 19.1 billion of which are considered recoverable. Recoverable reserves include mostly bituminous and subbituminous coal with a minimal amount of anthracite. Coal from this region is high in calorific value (BTU/lb.) and low in sulfur content.

Figure 3.1-18. Colorado Plateau Coal-Bearing Region



Source: Data- USGS, 2011a, *Coal Fields*, U.S. DOI, http://nationalatlas.gov/atlasftp.html?openChapters=chpgeol#chpgeol

3.1.9.2.1 Location of Regional Coal Reserves

The coal-bearing regions in the Colorado Plateau are predominantly located in western Colorado, eastern Utah, and northwestern New Mexico. As shown, major coal fields in this region are the Uinta Region, Henry Mountains, the Southwestern Utah Region in Utah; the San Juan River Region coal fields, which straddles the border between Colorado and New Mexico; the Black Mesa coal field in northern Arizona and the Datil Mountains; the Rio Puerco; the Cerrillos Field; and Monero Fields in Western New Mexico. The creation of the Grand Staircase – Escalante National Monument in 1996 in southern Utah has limited coal recovery in the Southwestern Utah Region.

3.1.9.2.2 Property Ownership

Coal is present beneath federal, tribal, state, and private lands in the Colorado Plateau region. About 50 percent of the surface coal-bearing areas in the Colorado Plateau region are administered by the Bureau of Land Management (BLM), the U.S. Forest Service (U.S. FWS), the National Park Service (NPS), or other federal agencies. About 23 percent of the coal-bearing area consists of tribal lands, which, although held in trust by the U.S. government, are not considered federal lands. About 26 percent of the coal-bearing region is administered by state agencies or is privately owned.

In 1997, about 30 percent or 330 million tons of coal mined in the U.S. came from federal lands; 52 million of those tons came from the Colorado Plateau region. Current tonnage from federal lands is higher; sales of coal from federal lands amounted to 402 million short tons in 2014 (U.S. EIA, 2016b). In FY2014 Wyoming produced 80 percent of the coal on federal and Indian lands (U.S. EIA, 2016b). Approximately 71 percent of the region's total coal resources (more than 360 billion tons) are federal coal (USGS, 2000a; USGS, 2001b).

3.1.9.2.3 Types of Coal Resources

The Colorado Plateau contains both bituminous coal, which spans the border of Colorado and Utah and the Black Mesa coal field in Arizona, and subbituminous coal, which exists predominantly in New Mexico and parts of Colorado. The San Juan Basin continues to contain large amounts of low to medium sulfur, low BTU, high ash coal that is recoverable through dragline or truck and shovel methods. Longwall operation is used for most deep mining, where coal seams are thicker, low in sulfur, and contain high BTU values.

3.1.9.2.4 Extraction Method

Surface mining accounted for about 38 percent of production in the Colorado Plateau in 2014; most of these operations employed medium or large open pit or area mines (U.S. EIA, 2016). As of 2011, the U.S. EIA estimated that about eight billion tons of coal were recoverable by surface methods (U.S. EIA, 2012a).

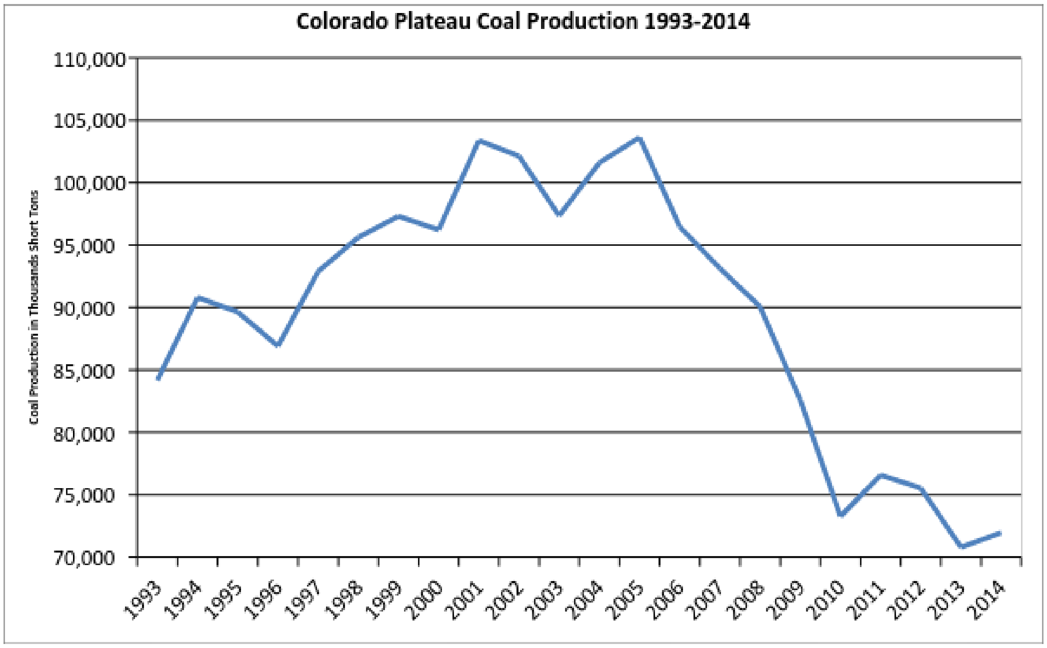
Underground mining accounted for 62 percent of production in 2014, with 93 percent of that coming from longwall mining operations with nearly all the remainder done through continuous mining methods (U.S. EIA, 2016). As of 2011, the U.S. EIA estimated that about 11.1 billion tons were recoverable by underground methods in the region (U.S. EIA, 2012a).

3.1.9.2.5 Coal Production, Production Trends, and Number of Mines

In 2014, the Colorado Plateau region produced a total of 71.9 million tons of coal (Figure 3.1-19) (U.S. EIA, 2016), a decrease of about 6 percent from the numbers derived from the 2011 annual coal production report (U.S. EIA, 2012a). In 2012, the Colorado Plateau contained 24 underground mines which produced approximately 45 million tons of coal and eight surface mines which produced approximately 30 million tons.

The U.S. EIA estimates that about 19.1 billion tons of coal is recoverable within this region, making up 58 percent of the region's demonstrated reserves. These reserves represent about seven percent of the nation's recoverable reserves.

Figure 3.1-19. Coal Production Trends in the Colorado Plateau (Thousands of Tons)



Source: Derived from Annual Coal Reports 1994-2014, U.S. Department of Energy; Energy Information Administration; http://www.eia.gov/coal/annual/; as retrieved July, 2016

3.1.9.3 Gulf Coast Region Mining

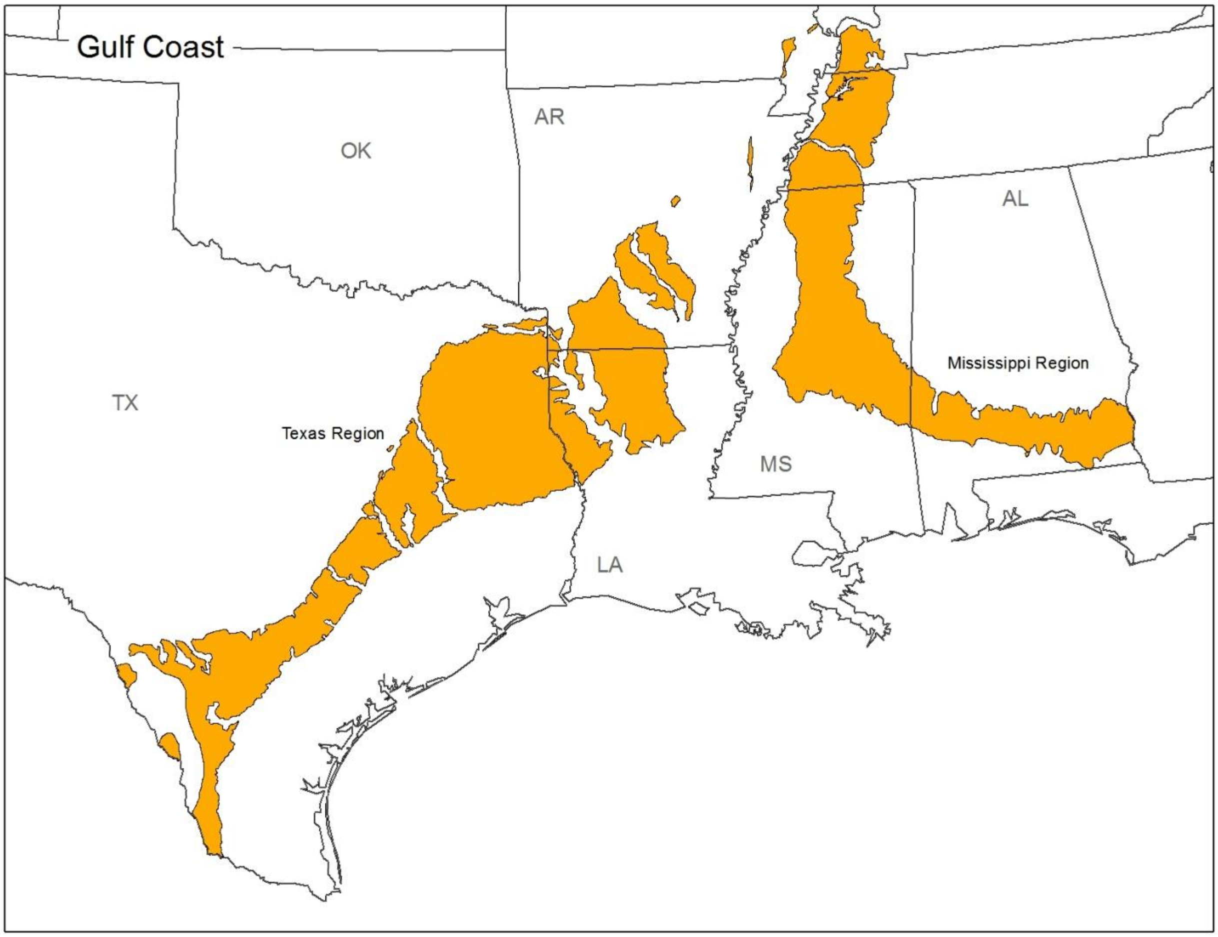
3.1.9.3.1 Location of Regional Coal Reserves

The Gulf Coast region is home to a widespread area of primarily lignite coal reserves, the majority of which are located in Texas, the largest coal-producing state in the region. The coal-bearing area runs mainly through southeastern Texas, northern and central Louisiana, Mississippi, southern Alabama, and southern and eastern Arkansas (Figure 3.1-20). These lignite-producing areas include coal measures from the Tertiary Period – Eocene Epoch of the Claiborne Group, the Wilcox Group, the Jackson Group, the Naheola Formation, and the Olmos Formation.

3.1.9.3.2 Property Ownership

Federal surface lands in the Gulf Coast region include lands managed by the U.S. Department of Defense, U.S. Department of Agriculture Forest Service, and the U.S. Fish and Wildlife Service. The U.S. also holds some land in trust for Indian tribes or individual Indians. Although no systematic inventory of federal mineral ownership exists for this region, initial studies indicate that about half of the federal surface estate in the Gulf Coast region is underlain by federally owned minerals.

Figure 3.1-20. Gulf Coast Coal-Bearing Region



Source: Data: USGS, 2011a, *Coal Fields*, U.S. DOI, http://nationalatlas.gov/atlasftp.html?openChapters=chpgeol#chpgeol

3.1.9.3.3 Types of Coal Resources

Virtually all of the remaining reserves in this region are lignite, the lowest rank of coal with the lowest amount of energy (BTUs). The demonstrated reserve base in the Gulf Coast region is estimated to be 16.6 billion tons. Remaining recoverable reserves in the region are estimated to be 12.3 billion tons, or 74.3 percent of the demonstrated reserve base. All of the remaining reserves in the region are lignite.

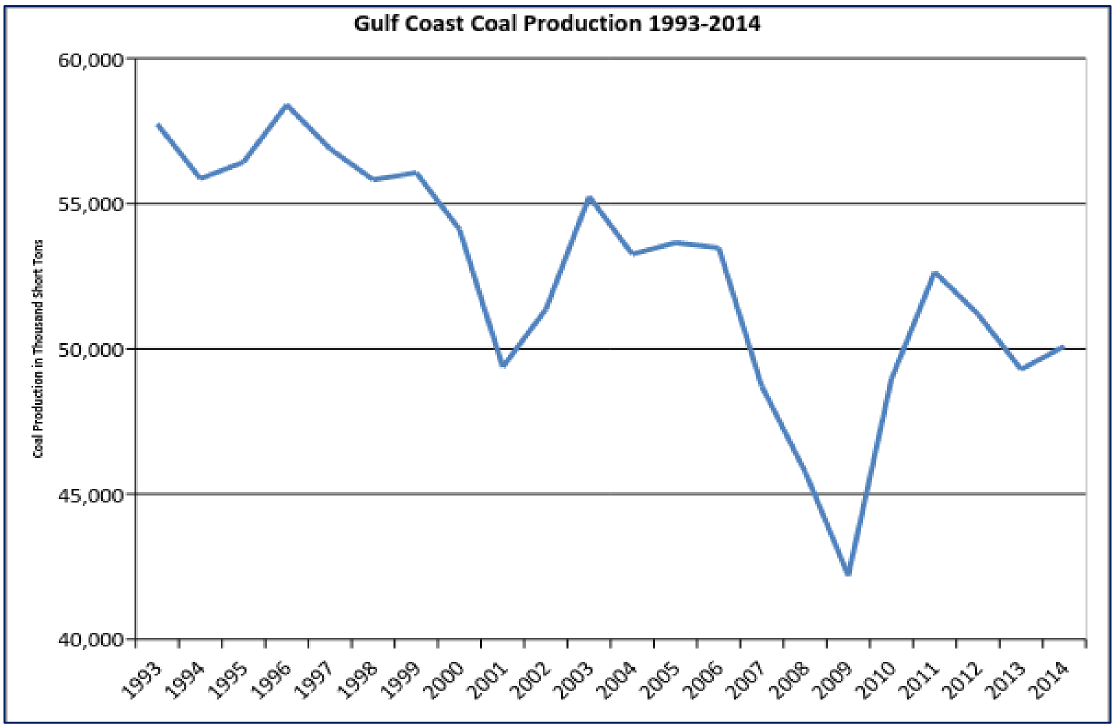
3.1.9.3.4 Extraction Method

Mining currently in this region occurs exclusively by surface methods, although historically prior to SMCRA underground mining occurred in Texas. The predominant mining technique is by dragline which is ideal due to the relatively unconsolidated overburden and flat digging conditions. Scrapers may be used in some operations with smaller outputs where thinner seams are mined. Most remaining deposits are multi-bedded and would require a combination of dragline and truck and shovel methods to extract. Bucket wheel excavator stripping operations are employed, as well, but limited to special conditions and circumstances (Kahle and Mosely, 1983).

3.1.9.3.5 Coal Production, Production Trends, and Number of Mines

Overall, the Gulf Coast produced 50.1 million tons of coal in 2014 (U.S. EIA, 2016). As of 2012 data the U.S. EIA reported that 86 percent of the regions coal was mined in Texas from a total of 19 active surface mines. The remaining 14 percent was mined in Mississippi and Louisiana (Figure 3.1-21). As of 2012, the Gulf Coast region had 19 active surface mines.

Figure 3.1-21. Coal Production Trends in the Gulf Coast Region (Thousands of Tons)



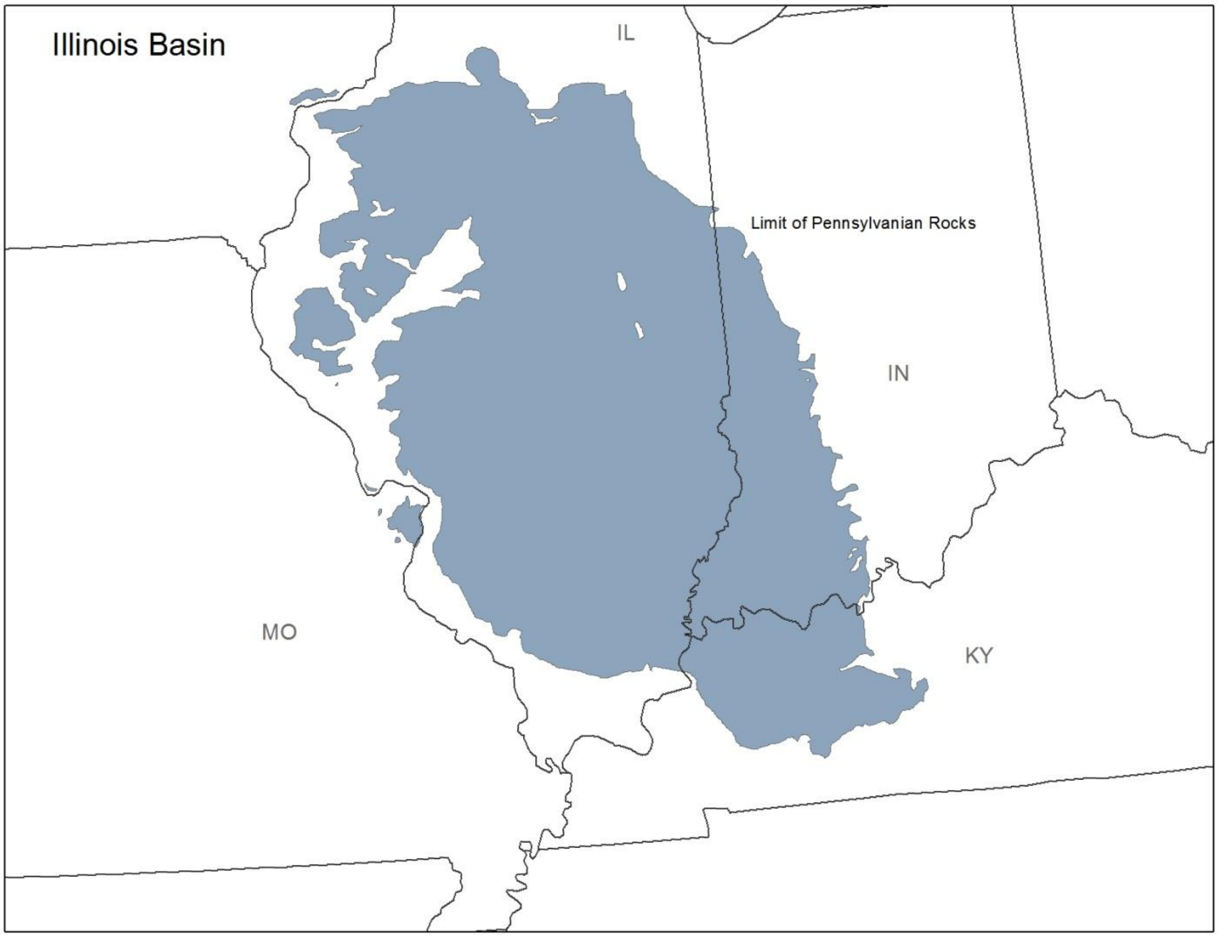
Source: Derived from Annual Coal Reports 1994-2014, U.S. Department of Energy; Energy Information Administration; http://www.eia.gov/coal/annual/; as retrieved July, 2016.

3.1.9.4 Illinois Basin Region Mining

3.1.9.4.1 Location of Regional Coal Reserves

The Illinois Basin region includes Illinois, Indiana, and Western Kentucky (Figure 3.1-22). Michigan, which has one coal-bearing region, while not part of the Illinois Basin region, is mentioned here, but will otherwise not be discussed as part of the EIS as there is currently no active mining in the state.

Figure 3.1-22. Illinois Basin Coal-Bearing Region



Source: Data- USGS, 2011a, *Coal Fields*, U.S. DOI, http://nationalatlas.gov/atlasftp.html?openChapters=chpgeol#chpgeol

3.1.9.4.2 Property Ownership

Federal land ownership in the Illinois Basin region is minimal, but includes the Shawnee National Forest in Southern Illinois, the Hoosier National Forest in Indiana, and several small National Wildlife Refuges.

3.1.9.4.3 Description of Coal Reserves

All coal in the Illinois Basin region is bituminous. About 78 percent of the coal resources in this region are located in Illinois. The vast majority of potential coal reserves in the region (about 93 percent) are considered high-sulfur, with just six percent and one percent of medium- and low-sulfur coal, respectively (USGS, 2009).

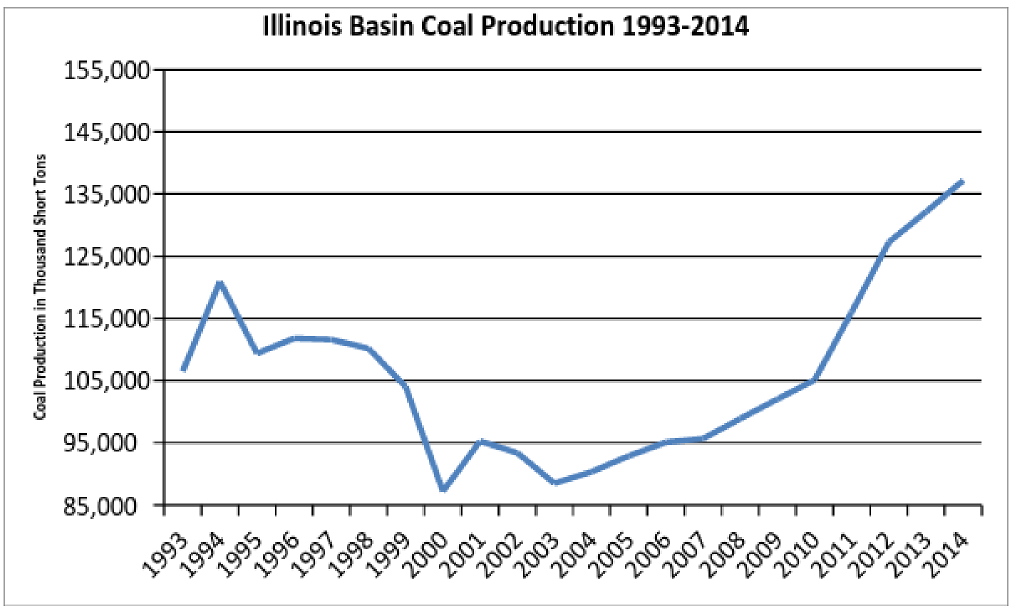
3.1.9.4.4 Extraction Method

Surface mining accounted for 23 percent of the production in the Illinois Basin region in 2014 (U.S. EIA, 2016). As of 2011, the U.S. EIA estimated that 12.6 billion tons of coal reserves were recoverable by surface methods (U.S. EIA, 2012a). The dragline method had been the primary surface mining method in this region, but as smaller surface mines have become more predominant the use of more flexibly and less expensive truck-shovel mining techniques have increased. Underground mining is the dominant mining method in this region, making up 77 percent of the production in the region in 2014 (U.S. EIA, 2016). Data within the U.S. EIA 2012 Annual Coal Report (U.S. EIA, 2013h) show that approximately 38 billion tons were recoverable from the Illinois Basin states through underground mining. Much of the coal produced by underground mining (68 percent) in 2014 was through the continuous room and pillar mining method, while the remainder was produced by longwall mining (U.S. EIA, 2016).

3.1.9.4.5 Coal Production, Production Trends, and Number of Mines

The Illinois Basin region produced 137 million tons of coal in 2014 (Figure 3.1-23). As of 2012, the U.S. EIA estimated that about 38 percent, or 50.7 billion tons, of the demonstrable reserves were recoverable (U.S. EIA, 2013h). The Illinois Basin region has seen a fairly significant increase in coal production over the last eleven years due to the installation of scrubber technology by Midwestern power generators that allow the use of higher sulfur coals typically produced in the basin. This technological conversion by utilities has allowed them to turn from lower sulfur energy sources, typically from the Powder River Basin in Wyoming, to sources from within the Illinois Basin.

Figure 3.1-23. Coal Production Trends in the Illinois Region (Thousands of Tons)



Source: Derived from Annual Coal Reports 1994-2014, U.S. Department of Energy; Energy Information Administration; http://www.eia.gov/coal/annual/; as retrieved July, 2016

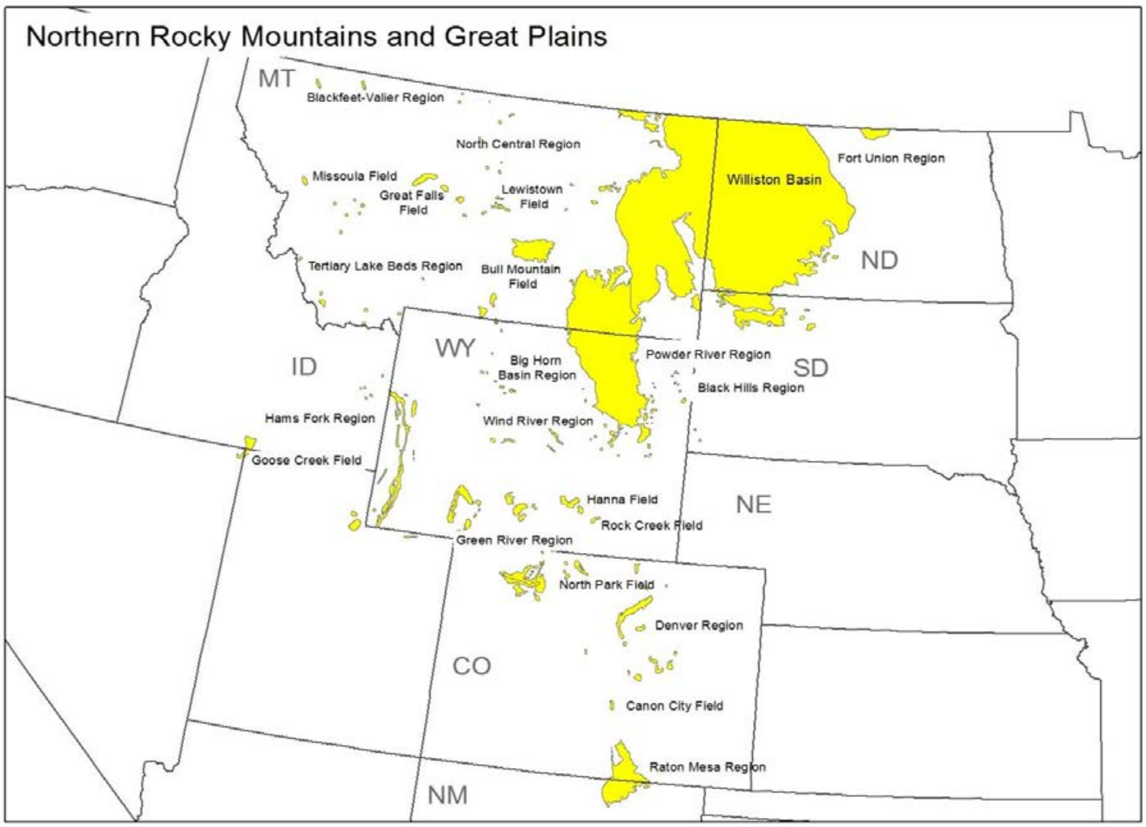
In 2012, there were 50 surface mines in the region, which produced approximately 35 million tons of coal, while 43 underground mines produced approximately 92 million tons (U.S. EIA, 2013h).

3.1.9.5 Northern Rocky Mountains & Great Plains Region Mining

3.1.9.5.1 Location of Regional Coal Reserves

The Northern Rocky Mountains and Great Plains has coal reserves distributed through parts of Wyoming, Montana, North Dakota, South Dakota, and Colorado (Figure 3.1-24). As shown, the predominant coal fields in this region are the Raton Basin, Green River Region, Powder River Region, Bull Mountain Field, and Williston Basin. The Power River Region, which straddles Montana and Wyoming, and the Williston Region in North Dakota and Montana represent some of the most abundant coal deposits in the U.S.

Figure 3.1-24. Northern Rocky Mountains and Great Plains Coal-Bearing Region



Source: Data- USGS, 2011a, *Coal Fields*, U.S. DOI, http://nationalatlas.gov/atlasftp.html?openChapters=chpgeol#chpgeol

3.1.9.5.2 Property Ownership

Most federal coal production comes from coal regions in the Northern Rocky Mountains and Great Plains region. The surface of about 32 percent of the 313 million acres of land in this region is federally managed. About 80 percent of coal in this region, 520 billion tons, is federally owned. Federal coal production in 1997 came predominantly from Wyoming and Montana and totaled about 280 million tons. Federal coal production generates more than a quarter billion dollars in royalties annually (USGS, 2000a).

Sixty-eight percent of surface property in this region is owned by tribal, state, and private entities.

3.1.9.5.3 Types of Coal Resources

The Northern Rocky Mountains & Great Plains region contains all ranks of coal, excluding anthracite. Bituminous and subbituminous resources are found in Wyoming and Montana, and lignite resources are found in the Montana, North Dakota, and South Dakota. Approximately 94 percent of the coal mined in this region is subbituminous, five percent being lignite and approximately one percent being bituminous (U.S. EIA, 2012a). The Powder River Basin is by far the nation's largest source of low sulfur coal (USGS, 2000a).

3.1.9.5.4 Extraction Method

About 98 percent of the mining in this region is surface mining (U.S. EIA, 2016). These mines tend to have a low stripping ratio, generally 1:1 to 4:1. Such minimal ratios are due to the combined benefits of shallow overburden and thicker coal seams. Recoverable reserves by surface mining are estimated to be 65.4 billion tons as of 2009.

Surface mines in this region are primarily medium or large open pit mines. In parts of the region, 70-foot or thicker seams exist and overburden to coal ratios of 1:1 or less are not uncommon. Open-pit mining in these seams begins with uncovering a sufficient area of coal to allow extraction and to provide an open area for future overburden placement. Initial overburden is spread and stored on adjacent land areas and revegetated. Coal thickness usually necessitates a benching operation for removal with a loading shovel or similar equipment. Expansion of the pit can proceed in any direction from this initial point, usually along only one course at a time until a limit is reached, such as a natural barrier, property line or outcrop. Overburden is sometimes removed by a dragline, and trucked and dumped in mined-out areas of the pit and later graded to a contour compatible with surrounding terrain.

Underground mining accounted for the remaining two percent of coal production in 2014. However, the resources estimated to be recoverable by underground mining in this region were 58.8 billion tons (U.S. EIA, 2012a).

3.1.9.5.5 Coal Production, Production Trends, and Number of Mines

In 2012, the region had 27 surface mines producing 455 million tons of coal and two underground mines producing ten million tons of coal (Figure 3.1-25). Production in 2014 was similar with 458 million tons from surface mines and 11 million from underground (U.S. EIA, 2016). In 2012, ten mines from this region were the top ten producing mines in the U.S. Of these top ten producing mines, nine are located in Wyoming, and the remaining one is in Montana. These ten mines produced 38 percent of the coal in the entire nation in 2012. The top two producing mines in Wyoming accounted for 20 percent of the coal produced in the U.S. in 2012.

The region contains about 206 billion tons in demonstrated reserves, 63.2 percent of which are estimated to be recoverable. About 82 percent of the demonstrated reserves consist of subbituminous coal found in Wyoming and Montana. At active mine sites, the region contains about nine billion tons in recoverable reserves, equal to about 53 percent of the unmined recoverable reserves at permitted mines in the United States. Montana has the largest amount of coal resources and coal reserves of any state in the nation, and Wyoming mines about 40 percent of the nation's coal, mostly coming from the Powder River Basin.

Figure 3.1-25. Coal Production Trends in the Northern Rocky Mountains and Great Plains Region (Thousands of Tons)

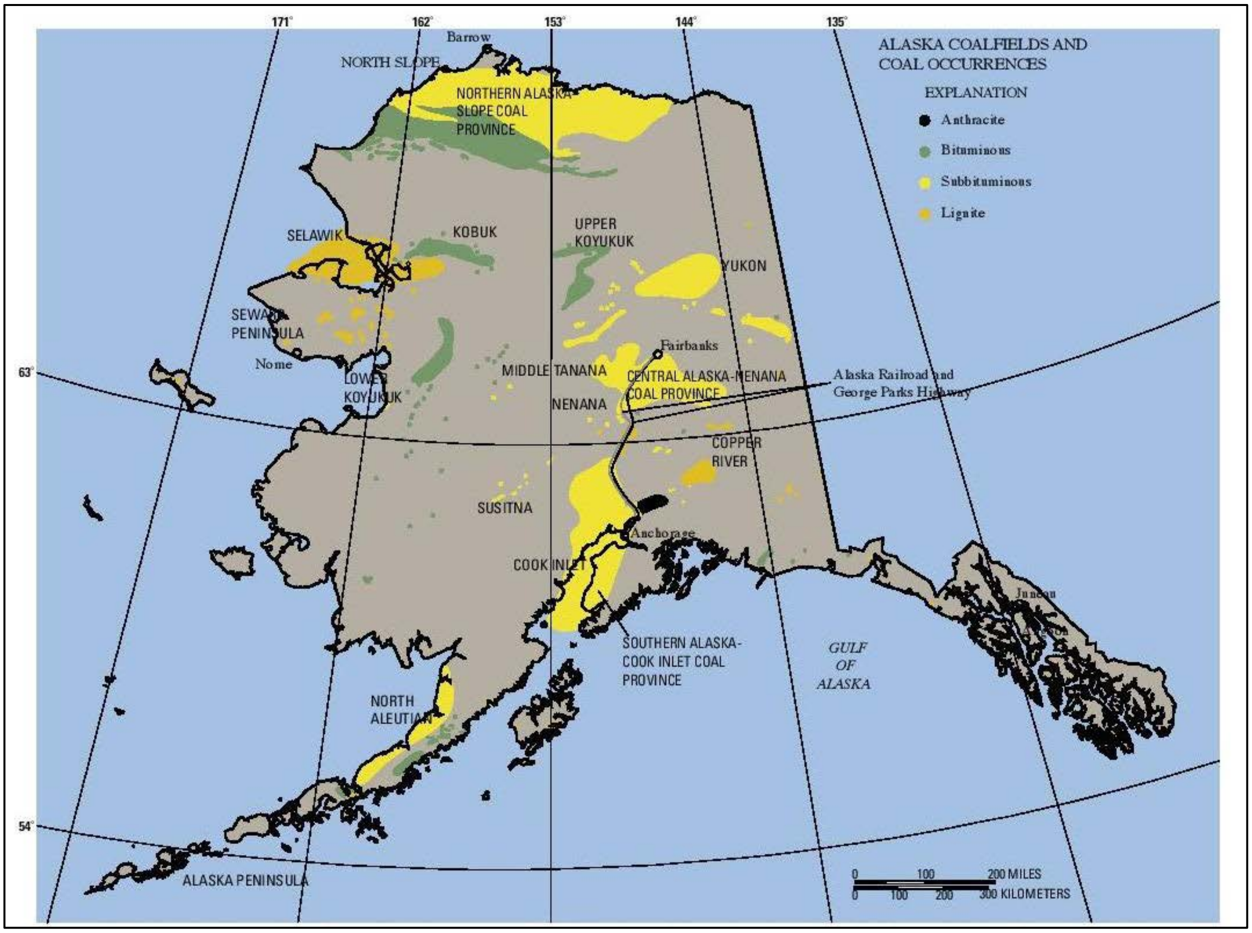
3.1.9.6 Northwest Region Mining

The Northwest Mining region combines potentially mineable coal resources in Oregon, Washington, and Alaska. However, no coal extraction has occurred in Oregon within the last ten years, and no new production is anticipated in the reasonable future. Likewise, no coal extraction is currently taking place in Washington, but there is one mine in that state that is reprocessing coal waste impoundments. Future significant production is not reasonably foreseeable in the state of Washington because coal production here is historically very low with poor quality reserves. Coal is actively being mined in Alaska, and, therefore, the area assessed for mining in the Northwest Region for this FEIS will be limited to Alaska.

Figure 3.1-26. Northwest Region (Alaska) - Coal-Bearing Resources



Source: Flores, R.M., Stricker, G.D., & Kinney, S.A. (2004). Alaska Coal Geology, Resources, and Coalbed Methane Potential. USGS DDS-77, U.S. Department of the Interior. http://pubs.usgs.gov/dds/dds-077/pdf/DDS-77.pdf

Coal resources in Alaska are distributed in three major provinces: the Northern Alaska-Slope, Central Alaska-Nenana, and Southern Alaska-Cook Inlet. These three coal provinces constitute about 87 percent of Alaska's coal resources. Previous studies have identified 50 coal fields in Alaska (Wood and Bour, 1988) (See Figure 3.1-26).

Coal in Alaska, while abundant, has not been produced in large quantities because of constraints involving coal depth, transportation options, and coal quality. Coal exportation in the northern Alaska is limited because of restricted access in the winter, remoteness of the area, the complexity of mine development, and the difficulty in transporting coal to regional markets and coastal shipping locations. Coal mining has been intermittent in the Central Alaskan-Nenana and Southern Alaska-Cook Inlet coal provinces, with only a small fraction of the identified coal resource having been produced from some dozen underground and strip mines in these two provinces (Flores, et al., 2004).

3.1.9.6.1 Location of Coal Reserves

For purposes of this action, the Nenana coal field and the Matanuska coal fields, located within the Central Alaskan-Nenana and Southern Alaska-Cook Inlet coal provinces respectively, constitute the affected area of the Northwest Region for the purposes of this EIS. Coal mining in these two provinces has been intermittent in with only a small fraction of coal mined and produced from the identified coal resources in these two provinces (Flores, et al., 2004). As of 2015 the Nenana coal field is the only actively mined area. The Nenana coal field exists primarily within the northern foothills of the Alaska Range. Usibelli Coal Mine, Inc. is currently the sole surface coal mine operator in Alaska. The Usibelli Coal Mine, Inc. holds five active mining permits in the Nenana coal field: Poker Flats, Gold Run Pass, Two Bull Ridge, Jumbo Dome and Rosalie mines.

The Matanuska coal field is located in the Matanuska River valley at the northeast head of Cook Inlet. It occupies an area of approximately 695 square miles. Surface coal mine permits have been issued in the Matanuska coal field, but no active coal extraction is currently taking place.

There are several exploratory and mining proposals in various stages of review within the Central Alaskan-Nenana and Southern Alaska-Cook Inlet coal provinces. However, the status, feasibility, and timeline for actual mining at these locations are unknown at this time. For purposes of the studies in this FEIS, proposals for mining in the exploratory and/or study phases are not considered reasonable foreseeable and not included in the review of this action. The names and descriptions of the proposals still in the exploratory and/or study stages include the following:

- Chickaloon – is an exploration activity located in the Matanuska coal field within the Southern Alaska-Cook Inlet coal province, approximately three miles northwest of the community of Chickaloon.
- Chuitna Coal Project – is a surface coal mining and export proposal for coal located in the Beluga Coal Field within the Southern Alaska-Cook Inlet coal province in Southcentral Alaska. The U.S. Army Corps of Engineers is preparing a Supplemental EIS for this project. To date, there is no completion date proposed for the Record of Decision.
- Healy Calley Cola Exploration – is an exploration activity within the Central Alaskan-Nenana coal province, approximately four miles southwest of Healy, Alaska.
- Hoseanna/Emma Creek Exploration – is under renewal request for two additional years of exploration and is located within the Central Alaskan-Nenana coal province, approximately two miles northeast of Healy, Alaska.
- Jonesville – is an exploration activity located within the Southern Alaska-Cook Inlet coal province, approximately two miles northwest of Sutton in Southcentral Alaska
- Linc Tynek – is an exploration activity located in the Beluga Coal Field within the Southern Alaska-Cook Inlet coal province approximately seven miles northwest of Tynonek, Alaska.

3.1.9.6.2 Property Ownership

The Northwest region has federal, tribal, state, and private surface ownership. Only a small percentage of Alaska's National Parks, National Wild and Scenic Rivers, National Wildlife Refuges, and National Wilderness Preservation Systems are coal-bearing. Approximately two percent of these lands, or about

142,000,000 acres, are coal-bearing, and contain only 0.6 percent of the Nation's demonstrated reserve base. In total, these areas contain approximately 4,086 million tons of mineable coal.

3.1.9.6.3 Types of Coal Resources

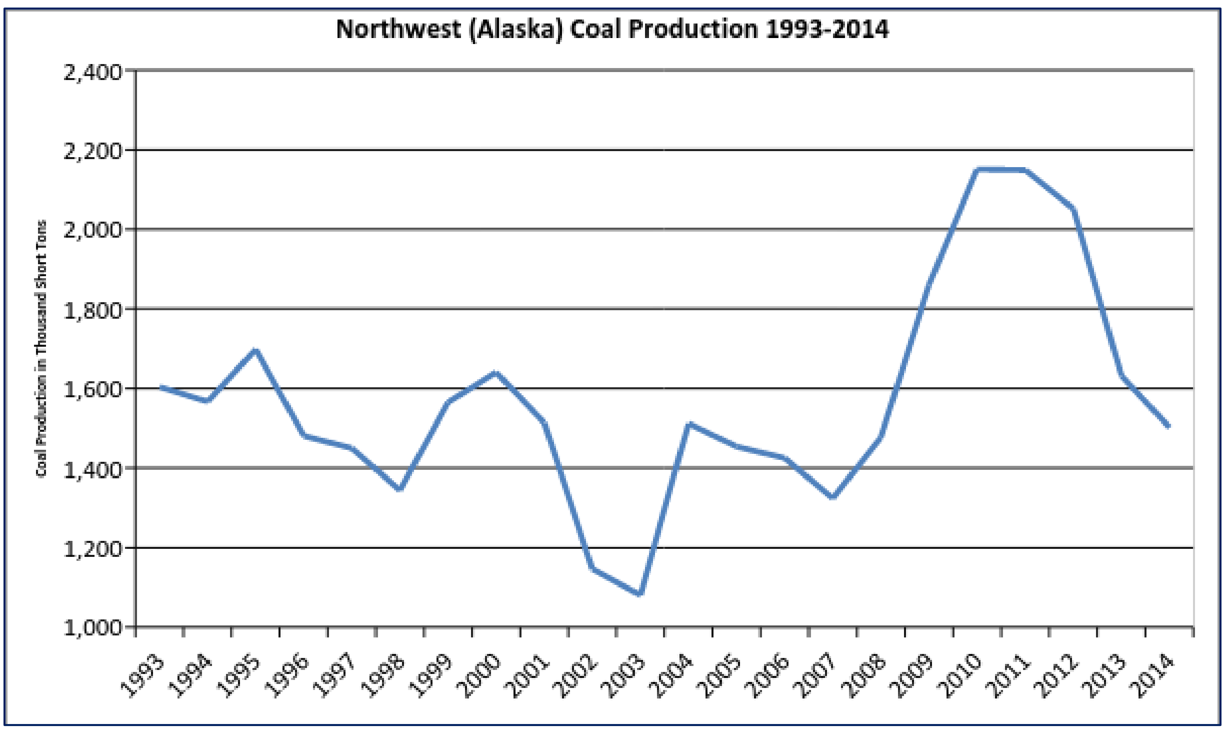
Alaska contains lignite, sub-bituminous, bituminous, and anthracite coal resources. The total estimated recoverable reserves mineable by surface methods in Alaska are 489 million tons, while 2335 million tons are estimated to be recoverable by underground methods, with only about 674 million tons of the demonstrated reserve estimated to be mineable by surface methods (U.S. EIA, 2012a).

The Usibelli surface coal mine is located about ten miles from the entrance to Denali National Park in the Healy-Nenana coal fields. While low in sulfur, the coal from the Usibelli mine has a low calorific value averaging 7,650 BTU/lb. (Coal Age, 2009).

3.1.9.6.4 Coal Production, and Production Trends

The Usibelli mine produced approximately 2.1 million tons of coal in 2012 and 1.5 million tons in 2014 (Figure 3.1-27) (U.S. EIA, 2012a and U.S. EIA, 2016).

Figure 3.1-27. Coal Production Trends in the Northwest Region



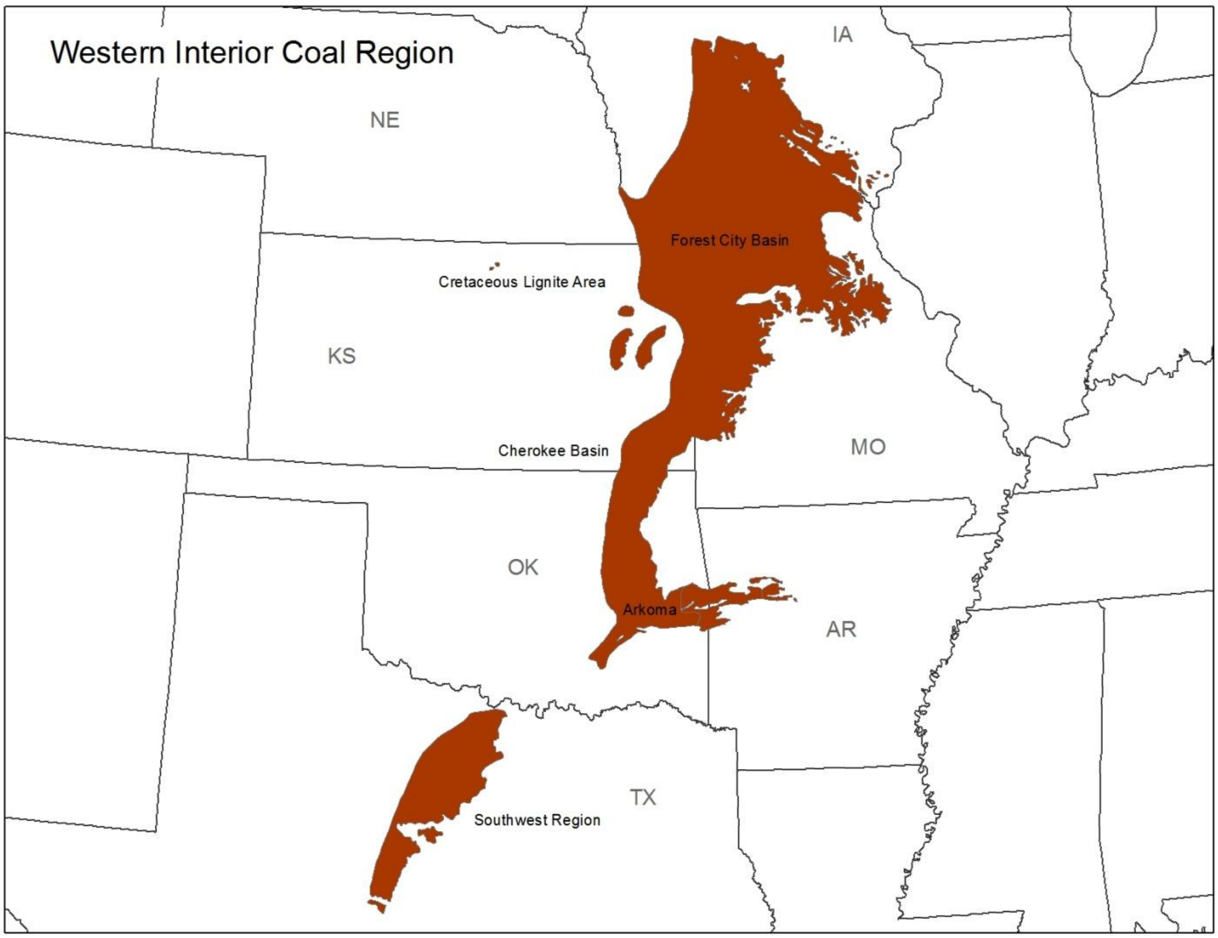
Source: Derived from Annual Coal Reports 1994-2014, U.S. Department of Energy; Energy Information Administration; http://www.eia.gov/coal/annual/; as retrieved July, 2016

3.1.9.7 Western Interior Mining

3.1.9.7.1 Location of Coal Resources

The Western Interior region includes the states of Oklahoma, Kansas, Missouri, Iowa, and the west-central region of Arkansas (Figure 3.1-28). Missouri contains 25.7 percent of the estimated demonstrated reserves in the region; however, Oklahoma produces 66 percent of the currently mined reserves as of 2012. Note that while the figure includes the "Southwest Region" in Texas, no coal production in that area has been reported since the enactment of SMCRA, therefore this region in not included in the FEIS analysis.

Figure 3.1-28. Western Interior Coal-Bearing Region



Source: Data -USGS, 2011a, *Coal Fields*, U.S. DOI, http://nationalatlas.gov/atlasftp.html?openChapters=chpgeol#chpgeol

3.1.9.7.2 Property Ownership

Federal land ownership in this region is limited largely to several national forests in Arkansas and Missouri. The U.S. also holds lands in trust for Indian tribes and individual Indians. Data on the location of coal reserves in relation to federally owned land for this region is lacking, though there is some SMCRA permitting of federally owned coal in Oklahoma.

3.1.9.7.3 Types of Coal Resources

The coal in this region is all bituminous, except for coal found in west-central Arkansas, which contains the third highest amount of demonstrated reserves of anthracite in the nation (after Pennsylvania and Virginia). All coal mined in 2012 and 2014 was bituminous in rank.

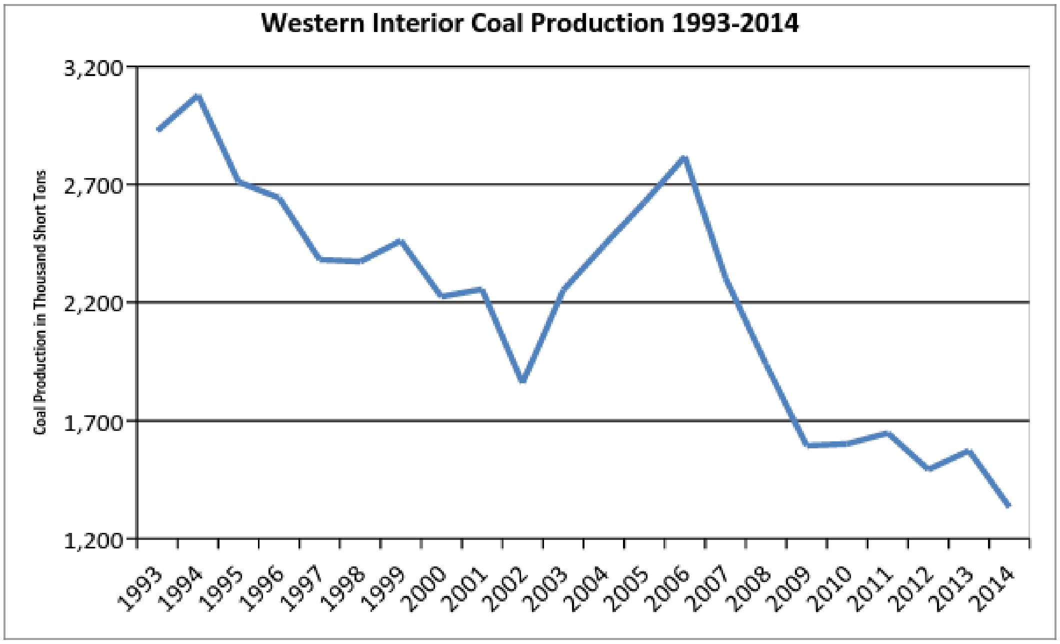
3.1.9.7.4 Extraction Methods

Mining methods in the Western Interior region include both area surface mining and underground mining methods. Surface mining accounted for 70 percent of production in this region in 2014. As of 2012 three of the underground mines in the Western Interior region were in Oklahoma, with the other producing mine in Arkansas. The projected remaining reserves recoverable by underground mining methods in the region are approximately 2.2 billion tons.

3.1.9.7.5 Coal Production, Production Trends, and Number of Mines

The Western Interior region consisted of ten surface mines which produced 1,143,856 tons and three underground mines which produced 445,689 tons in 2012 (Figure 3.1-29). Surface mining efforts produced about 935 thousand tons in 2014 (U.S. EIA, 2016). Underground mining produced approximately 0.4 million tons in 2012, decreasing to 398 thousand tons by 2014.

Figure 3.1-29. Coal Production Trends in the Western Interior (Thousands of Tons)



Source: Derived from Annual Coal Reports 1994-2014, U.S. Department of Energy; Energy Information Administration; http://www.eia.gov/coal/annual/; as retrieved July, 2016.

3.2 Geology

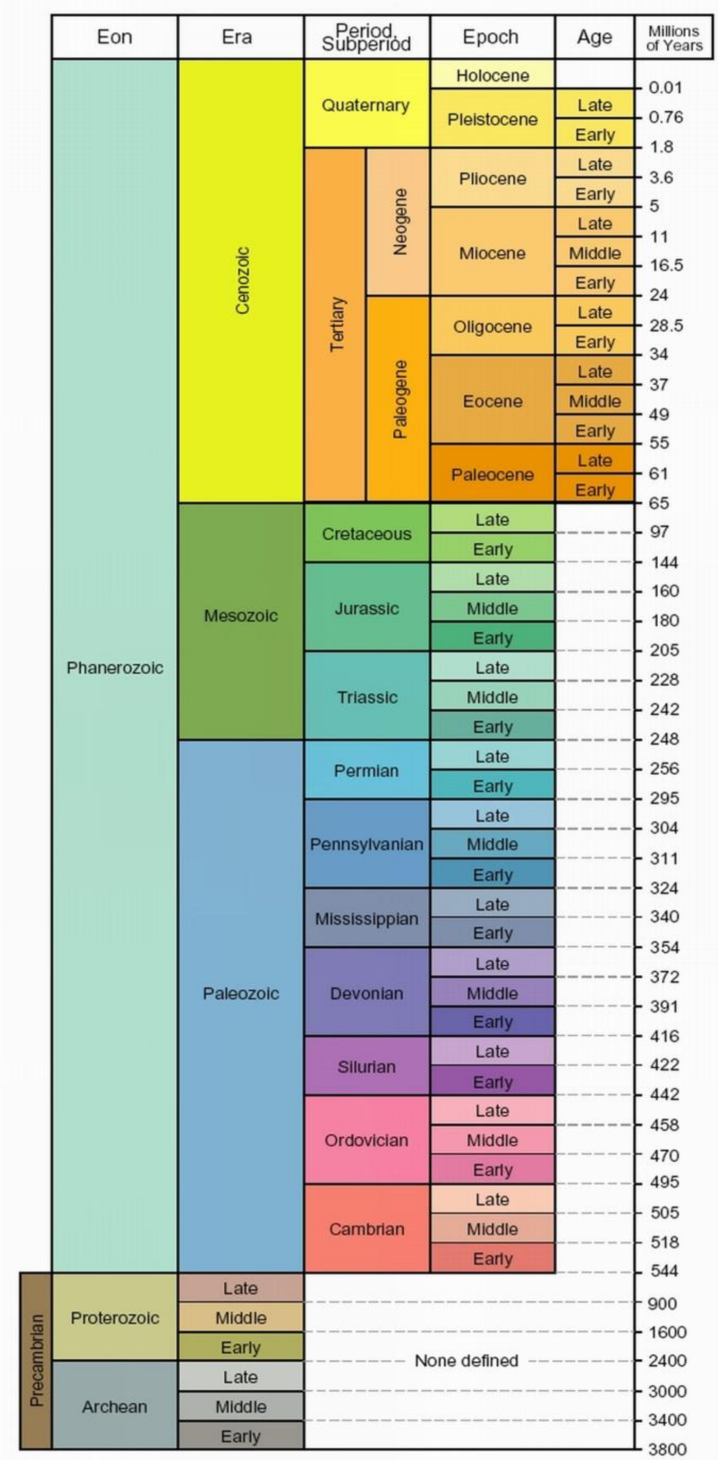
Geologic environments for the coal regions of the U.S. are analyzed relative to each region's depositional environment and geologic history. For purposes of this discussion, the geology is described according to each of seven coal-producing regions identified in Section 3.1. For a map depicting the location and extent of each of these regions see Figure 3.1-1.

The seven coal-producing regions described in this chapter are:

- Appalachian Basin;
- Colorado Plateau;
- Gulf Coast;
- Illinois Basin;
- Northern Rocky Mountains and Great Plains;
- Northwest; and
- Western Interior.

Within each region, discussions are further refined according to states, coal fields, or physiographic provinces. A physiographic province is a geographic region characterized by similarities of geology, landforms, and climate. Each province is notably distinct from surrounding areas. Some of the coal basins encompass such large areas that their geologic descriptions have been generalized. The geologic description of each basin is intended to familiarize the reader with each basin's geologic history as well as to introduce the names of major rock strata and coal-bearing units. A copy of the geologic time scale (See Figure 3.2-1) is provided here as a general reference for the geologic time terms used in the following discussions.

Figure 3.2-1 Geologic Time Scale



Source: The Science Education Resource Center at Carleton College, 2011, *Figure 1: Pre-Miocene- Geologic Time Scale*, Carleton College, http://serc.carleton.edu/research_education/nativelands/nezperce/geology.html

3.2.1 Appalachian Basin Region

The Appalachian Basin region forms a northeast-southwest trending belt, 90 to 370 miles wide, which can be subdivided into four physiographic provinces. From east to west these are: the Piedmont, the Blue Ridge, the Valley and Ridge, and the Appalachian Plateau provinces (See Figure 3.2-2). Coal-bearing strata occur primarily in the Appalachian Plateau and Valley and Ridge provinces.

The Appalachian Basin region (a depositional lowland) encompasses the coal-bearing areas of Pennsylvania, Ohio, Maryland, Georgia, West Virginia, Virginia, eastern Kentucky, Tennessee, and Alabama (See Figure 3.2-2). During the geologic time period known as the Pennsylvanian, (See Figure 3.2-1) streams flowed from minor uplands in the east toward an open marine environment to the west. The Appalachian Basin, located between these two regions, existed in a depositional setting marked by river flood plains, migrating streams, coastal swamps, marshes, peat bogs, sand bars, and lagoons. The shallow swamps were populated by abundant trees and plants that dominated the landscape. As plants died, vegetation accumulated in the widespread swamps and bogs, slowly decomposing to form peat. Periodic river flooding covered the swamps with sands, further compressing the organic debris. As the peat became denser and its moisture content reduced, the process of conversion to lignite (the lowest rank of coal) began. From time to time, the western sea encroached over the land and covered the swamps with marine sands and mud. As the Appalachian Basin subsided repeatedly throughout the Pennsylvanian, this sequence of events was repeated many times, ultimately giving rise to the present-day extensive coal deposits.

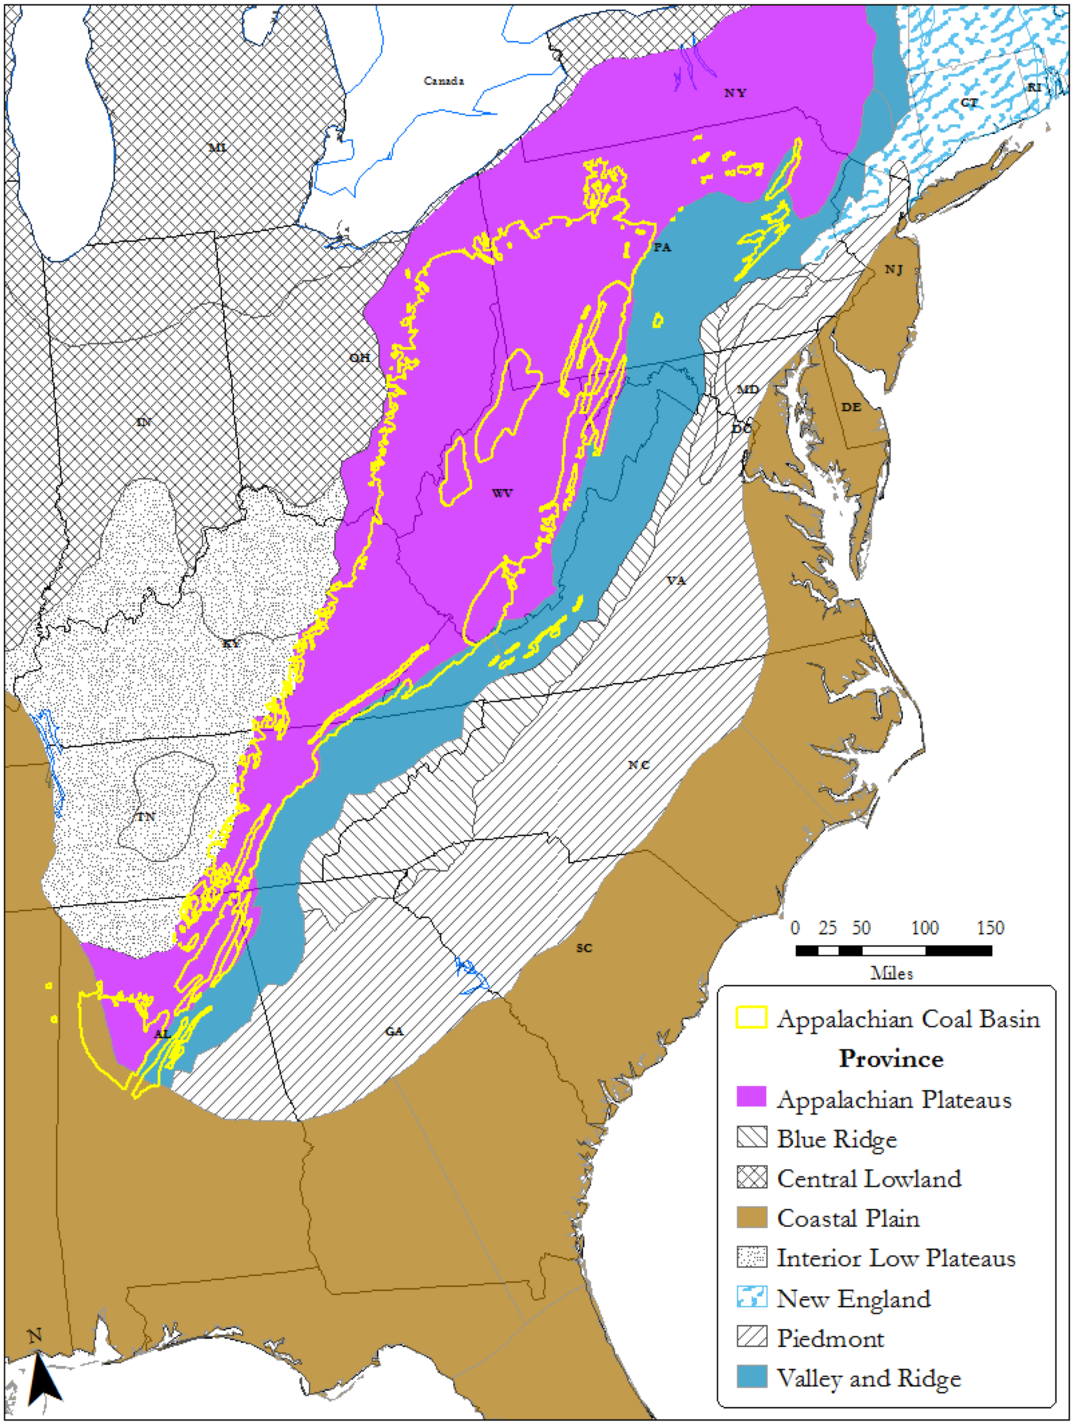
Formation of coal deposits ceased when the Appalachian Basin was destroyed as a result of uplift and mountain building in the east. This mountain building occurred as a result of tectonic plate movement during the post-Pennsylvanian, Permian period. Coal, formed earlier in the eastern part of the Basin, was compressed, folded, and faulted to create the harder, less-volatile, and more steeply inclined anthracite coal. In the western part of the basin, deformation was less intense giving rise to the softer, more volatile, and more gently inclined bituminous coal.

3.2.1.1 West Virginia Geology

West Virginia is basically composed of two areas: the western two-thirds are relatively flat-lying rocks containing minable coal, and the eastern one-third is comprised of folded and faulted rocks with no minable coal. The former area is the Appalachian Plateau Province, the latter is the Valley and Ridge Province, and they are separated by the Allegheny Front (see Figure 3-2.2).

The Valley and Ridge Province in the east is composed of folded and faulted rocks that range in age from late Precambrian to early Mississippian. This topographically comparatively flat area is composed of complex folded and faulted Cambrian and Ordovician limestones and dolomites as well as a single prominent Ordovician shale (the Martinsburg Shale). The Great Valley ends at North Mountain and from there to the Allegheny Front, a distance of about 50 miles, is a series of northeast-trending mountains and valleys. The rocks in this part of the Valley and Ridge Province range in age from late Ordovician to early Mississippian. The valleys are primarily composed of less-resistant shale and siltstone, while the mountain ridges are mainly more resistant sandstone and limestone. The structural geology of the Valley and Ridge Province is complex with extensive thrust faults and folds that contribute to the repetition of all the rock formations. In addition, three major thrust sheets have displaced the surface and subsurface rocks westward from 30 to 50 miles.

Figure 3.2-2. The Physiographic Provinces of the Appalachian Basin Region



Source: Data- USGS, 2004, Physio, U.S. DOI, http://water.usgs.gov/GIS/metadata/usgswrd/XML/physio.xml

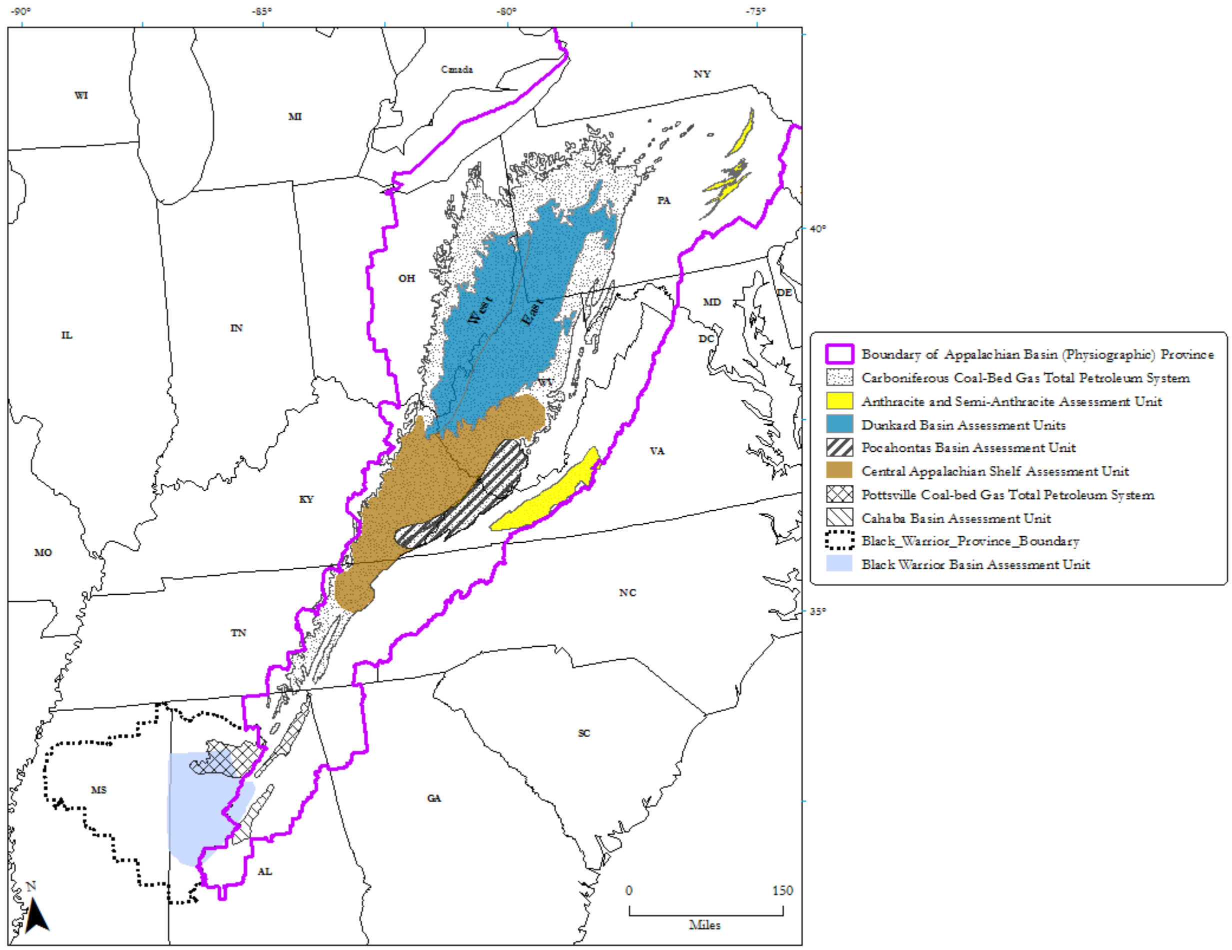
The Appalachian Plateau Province covers the western two-thirds of the state where the rock formations are relatively flat, except for several distinct folds and faults on the eastern side of the province. The oldest rocks are located in these eastern fold sequences and range in age from late Ordovician up through the Mississippian Period. The majority of the Appalachian Plateau Province is comprised of Pennsylvanian and Permian strata, where the majority of the minable coal is located. The rocks exposed in the northern part of the Appalachian Plateau Province are younger than those exposed in the southern part. This is also reflected in the age of the minable coal seams; i.e., younger to the north and older to the south. The boundary between the two provinces, the Allegheny Front Province, is a complex and rather abrupt change in the topography, stratigraphy, and structure. This boundary extends southwestward across the eastern part of the state, passes through Virginia, and reenters southeast West Virginia.

Coal-bearing rocks underlay much of central West Virginia, extending into Ohio, Pennsylvania, and Maryland. One structural fold known as the Hinge Line separates the Dunkard and Pocahontas geologic sub-basins of West Virginia (See Figure 3.2-3). These sub-basins are characterized by differences in the total thickness of their strata, as well as by the distribution of their ancient depositional environments: swamp, lacustrine, marine, and alluvial (Arkle, 1974). The Dunkard and Pocahontas sub-basins coincide approximately with the northern and southern coal fields (younger and older mining districts, respectively) of West Virginia. The various formations of sedimentary rocks exhibit local differences in strata north or south of the Hinge Line in response to different depositional environments. For example, the Allegheny and Conemaugh formations in the Dunkard sub-basin represent a sequence of marine and coastal environments, including deltaic, offshore, and alluvial depositional conditions. In the Pocahontas sub-basin, these formations predominantly include the alluvial facies of sandstones, shales, and channel deposits that generally include only limited coal seams. Additionally, higher sulfur content coal seams occur north of the Hinge Line, while lower sulfur content coal seams occur south of the Hinge Line. A more detailed discussion of coal characteristics is found in Section 3.1.

3.2.1.2 Kentucky Geology

Bituminous coal occurs in Kentucky in two regions: the eastern Kentucky coal field and the western Kentucky coal field. The two fields are separated by a structurally raised area of older rocks known as the Cincinnati Arch (See Figure 3.2-4). Strata of the eastern field, the larger of the two, were deposited in the Appalachian Basin, whereas strata of the western field were deposited in the Illinois Basin. The coal-bearing strata of western Kentucky are associated with the Illinois Basin and discussed further in 3.2.4.

Figure 3.2-3. Location of Pocahontas and Dunkard Basins in West Virginia

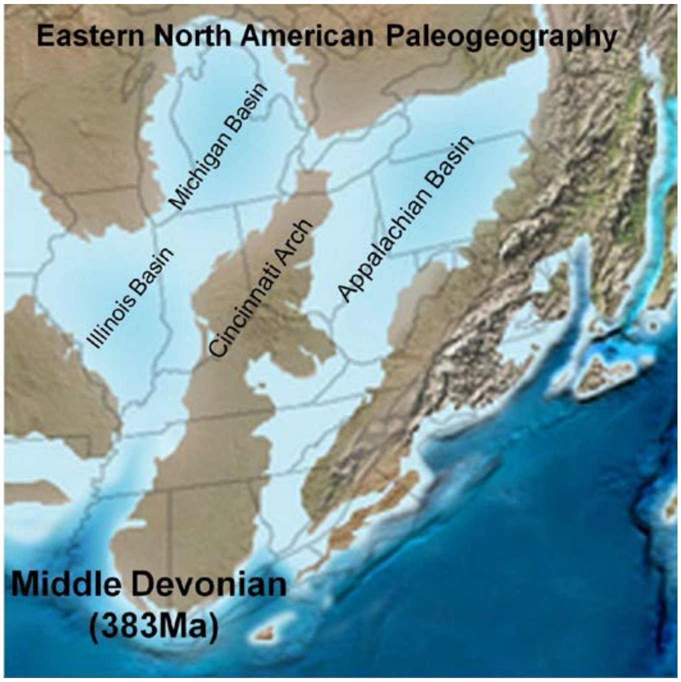


Source: USGS, 2002, *Figure 1: Appalachian Basin and Black Warrior Provinces*, U.S. DOI, http://pubs.usgs.gov/fs/2004/3092/fs2004-3092.html

Area and mountaintop-removal mining operations historically have been the most common methods of surface mining in the southern portion of the state. Contour and multiple-seam mining operations occur in both southern and northern West Virginia.

West Virginia coal-bearing formations include from youngest to oldest: the Dunkard Group, the Conemaugh Group, the Kanawha Formation, the New River Formation, and the Pocahontas Formation. Each contains multiple coal beds that are either surface mined or underground mined or both. The more predominantly surface mined coal beds in the state include: the Stockton-Lewiston zone (Upper Kanawha Formation); the Coalburg zone (Upper Kanawha Formation); the Upper Kittanning, the Middle Kittanning, and the Lower Kittanning zones (Allegheny Formation); and the Dunkard Basin Clarion zone (Allegheny Formation) (Fedorko and Blake, 1998).

Figure 3.2-4. Pre-Carboniferous Depositional Basins of Kentucky



Source: Dr. Ron Blakey, 2011, *Pre-Carboniferous Depositional Basins of Kentucky,* Northern Arizona University, http://jan.ucc.nau.edu/rcb7/namD385.jpg

Coal is mined from approximately 45 different seams in eastern Kentucky and from about ten seams in western Kentucky (Kentucky Geological Survey, 2006). Eastern coal-bearing rocks underlay approximately 25 percent of the eastern part of the state and form a broad, synclinal basin (Kiesler et al., 1983). Bedrock is essentially flat-lying throughout the trough (Kiesler et al., 1983). Upper Mississippian and Pennsylvanian coal-bearing rocks thicken towards the southeast, reaching their maximum thickness at the basin's southeastern margin. This margin is marked by the Pine Mountain Thrust Fault, a structure which disrupts and offsets the coal beds. Mining methods in eastern Kentucky consist of mountain top mining (steep slope); area surface mining; contour mining; and multiple-seam mining. The Pennsylvanian rocks of the eastern Kentucky coal field consist largely of sandstone, siltstone, and shale. Coal beds and thin marine shale and limestone units are also widespread and occur in most parts of the stratigraphic section. These deposits indicate that during the Pennsylvanian period, Kentucky was near sea level, alternately covered by lakes, extensive swamps, shallow bays, and estuaries.

Eastern Kentucky coal-bearing stratigraphic nomenclature (or rock naming convention) and correlation is not consistent with other Appalachian Basin states. For example, northwest of the Pine Mountain thrust fault on the Cumberland over thrust sheet, coal beds equivalent to the Lower Elkhorn coal zone (within the Pikeville Formation) are identified also as the Eagle coal zone, Pond Creek coal zone, and the Blue Gem coal bed. Southeast of the Pine Mountain thrust fault, still in eastern Kentucky, equivalent coals in this same interval are known as the Imboden and Rich Mountain. This same interval of coal is identified as the Blue Gem coal in Tennessee, the Imboden coal bed or Campbell Creek or Pond Creek coal zones in

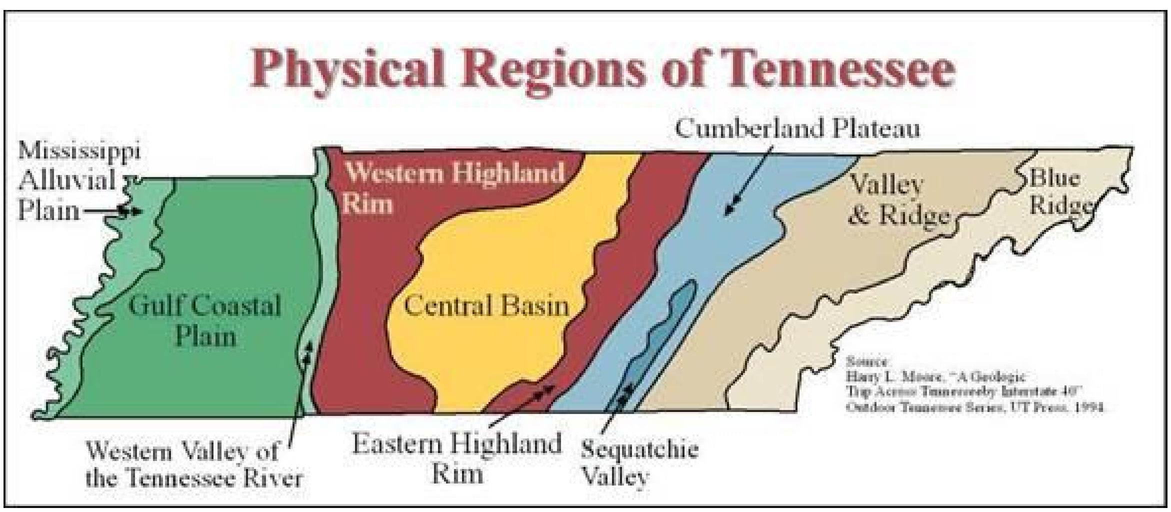
Virginia, and the Eagle coal zone in West Virginia (Ruppert et al., 2010). It is not in this FEIS's scope to standardize nomenclature or attempt to correlate stratigraphy across the coal-bearing region. For that reason, a generalized discussion of eastern Kentucky Pennsylvanian age stratigraphy and coal beds/zones are presented based from the works of Ruppert et al. (2010). In eastern Kentucky, coal-bearing units are the Lower Pennsylvanian-aged lower Breathitt Group (including the Warren Point, Bottom Creek Formation, Sewanee Sandstone, Alvy Creek Formation, Bee Rock Sandstone, and Grundy Formation); the Middle Pennsylvanian-aged middle and upper parts of the Breathitt Group (including the Pikeville, Hyden, Four Corners, and Princess Formations) and the Upper Pennsylvanian aged Conemaugh Group and Monongahela Groups.

In recent years, within the Breathitt Group, the Pikeville and Hyden Formations, (specifically the Upper Elkhorn No. 3, the Lower Elkhorn (or Pond Creek), and the Hazard No. 4 (or Fire Clay) coal zones), have been prominent coal producers in eastern Kentucky.

3.2.1.3 Tennessee Geology

The Tennessee coal fields occur in the east-central portion of the state, forming a northeast- southwest trending outcrop belt from Kentucky to the Alabama border. As with Kentucky, these coal fields form a broad, synclinal basin that is bounded on the west by the Highland Rim escarpment and on the east by the Valley and Ridge Province (See Figure 3.2-5). These coal fields are generally divided between the northern steep-slope areas of the Cumberland Mountains and the southern, flatter Cumberland Plateau, where area mining historically has dominated. Bedrock units primarily have a shallow southeasterly dip and thicken to the southeast near the basin's trough adjacent to the Valley and Ridge Province (Gaydos et al., 1982).

Figure 3.2-5. Physical Geologic Regions of Tennessee



Source: Moore, H.I., 1994, *A Geologic Trip Across Tennessee by Interstate 40*, Outdoor Tennessee Series, UT Press.

The geology and depositional settings for the coal-bearing strata southeast of the Pine Mountain Thrust (eastern Tennessee) are similar to that of Kentucky. Notable geological differences are: (1) the absence of the Princess Formation, the Conemaugh Group and the Monongahela Group; and (2) differences in coal bed/coal zone nomenclature.

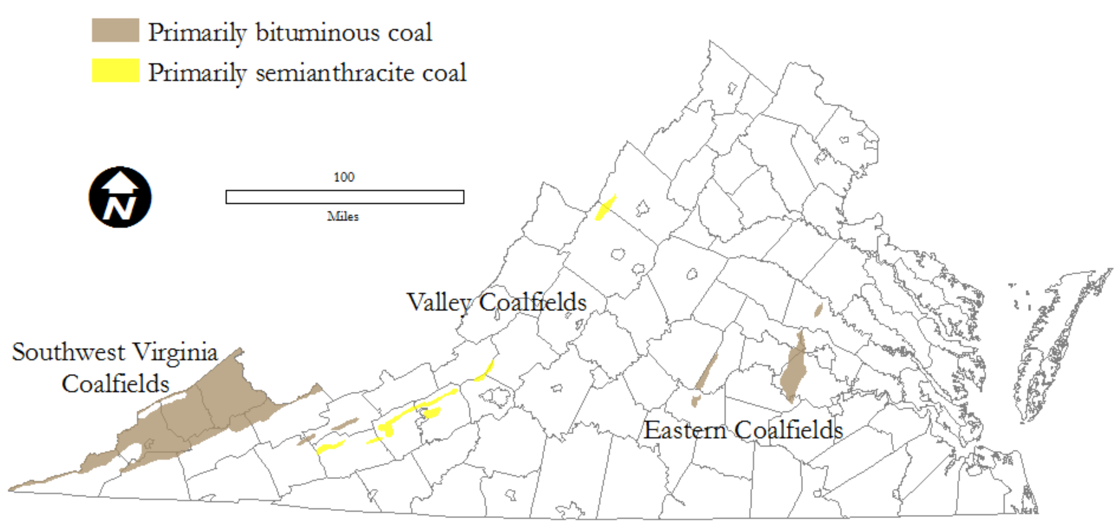
In eastern Tennessee, coal-bearing units are the Lower Pennsylvanian-aged Lower Breathitt Group (including the Warren Point, Bottom Creek Formation, Sewanee Sandstone, Alvy Creek Formation, Bee Rock Sandstone, and Grundy Formation); and the Middle Pennsylvanian-aged Breathitt Group (including the Pikeville, Hyden, and Four Corners Formations).

The reader is referred to the eastern Kentucky coal field discussion for details on geology and stratigraphy.

3.2.1.4 Virginia Geology

Coal occurs in three distinct areas in Virginia: the eastern coal fields; the valley coal fields; and the southwest Virginia coal field (See Figure 3.2-6). Since the 1950s, virtually all of Virginia's coal production has come from the southwest Virginia coal field.

Figure 3.2-6. Coal Fields of Virginia



Source: Virginia Division of Geology and Mineral Resources, 2006a, *Figure 1: Distribution of coal areas* Virginia Department of Mine Minerals and Energy, http://www.dmme.virginia.gov/Dgmr/coal.shtml

The eastern coal fields occur in five Triassic-Jurassic aged basins which were down-faulted into the crystalline rocks of the Piedmont physiographic province. These basins formed when Africa separated from North America to create the Atlantic Ocean. The Culpepper basin in the western Piedmont near the Blue Ridge province is the largest, but numerous smaller basins (including the Richmond, Farmville, and

Danville) are scattered throughout the Piedmont (Fichter and Baedke, 2000). The depositional environments within which the coal beds formed include lakes, rivers, alluvial fans, and mudflats.

The valley coal fields comprise eleven long, narrow Early Mississippian-age coal-bearing areas in the Valley and Ridge physiographic province situated in the western part of the state (VA Division of Geology and Mineral Resources, 2006a). Semi-anthracite coals were mined here primarily from 1748 to the early 1900s; however, sporadic operations continue today.

The southwest Virginia coal field is located in the Appalachian Plateau Province. The coal field consists of relatively flat-lying rocks bounded on the northwestern and southeastern basin margins by thrust-faulted and uplifted rock units (Rader and Evans, 1993; Harlow and LeCain, 1993). Along the northwestern coal field margin is the Pine Mountain Thrust fault. The southeastern margin is bounded by a series of thrust faults. The Russell Fork fault divides the basin into two regions: (1) the relatively flat-lying rocks northeast of the fault; and (2) the gently folded and faulted rocks located southwest of the fault, which were moved as part of the Pine Mountain thrust sheet (Harlow and LeCain, 1993). The rocks of both regions are nearly flat-lying and have an average northwesterly regional dip of 1.4 percent.

The primary coal-bearing formations in Virginia are, from oldest to youngest, the Pocahontas, Lee, Norton, Wise, and the Harlan Formations (See Figure 3.2-7). These geologic formations make up a stratigraphic interval that varies in thickness from 800 feet up to 5,150 feet. The coal beds are Pennsylvanian in age, low- to high-volatile bituminous in rank, and generally of a very high quality (less than one percent sulfur, less than ten percent ash, and high BTU). Although quality parameters vary locally, volatile matter generally increases from east to west and up section from older to younger coals beds (Wilkes et al., 1992).

Ordovician System	Trenton Formation

Source: Virginiaplaces.org, 2011, *Figure 11: Generalized Stratigraphic Column,* Virginia Department of Mines Minerals and Energy (original source), http://www.virginiaplaces.org/geology/naturalgasresources.html

Southwest Virginia coal field stratigraphic nomenclature and correlation is not consistent with other Appalachian Basin states. Some coal beds such as the Splash Dam, Upper Banner, and Lower Banner have been correlated very consistently within the southwest Virginia coal field and have few local or secondary names. Conversely, the Imboden coal zone, an important historic and regional producer that extends beyond Virginia into Kentucky and West Virginia, has more than 20 local and secondary names in Virginia alone (VA Division of Geology and Mineral Resources, 2006b). In the 1980s, in order to provide more detailed geologic base maps and ensure consistent stratigraphic correlation, Virginia completed the mapping and publication of 7.5 Minute Geologic Quadrangle Maps for the southwest Virginia coal fields. A coal bed's mapped geologic name is required in permitting; however, historic local names are also still commonly used by surface and mineral owners due to the use of these names in deeds, leases, and contracts.

Each coal field contains coal resources with different coal quality and physical properties. Coals range from high-volatile bituminous to natural coke in the Richmond basin area of the eastern coal fields (Wilkes, 1988), medium-volatile bituminous to semi-anthracite in the valley coal fields (Brown et al., 1952), and low- to high-volatile bituminous in the southwest Virginia coal field (Wilkes et al., 1992; VA Division of Geology and Mineral Resources, 2006a).

Mining in the southwest Virginia coal field began in the 1880s. While mountaintop removal (steep slope) and area surface mining operations occur in southwest Virginia, other surface mining methods such as contour and multiple-seam also occur.

3.2.1.5 Pennsylvania Geology

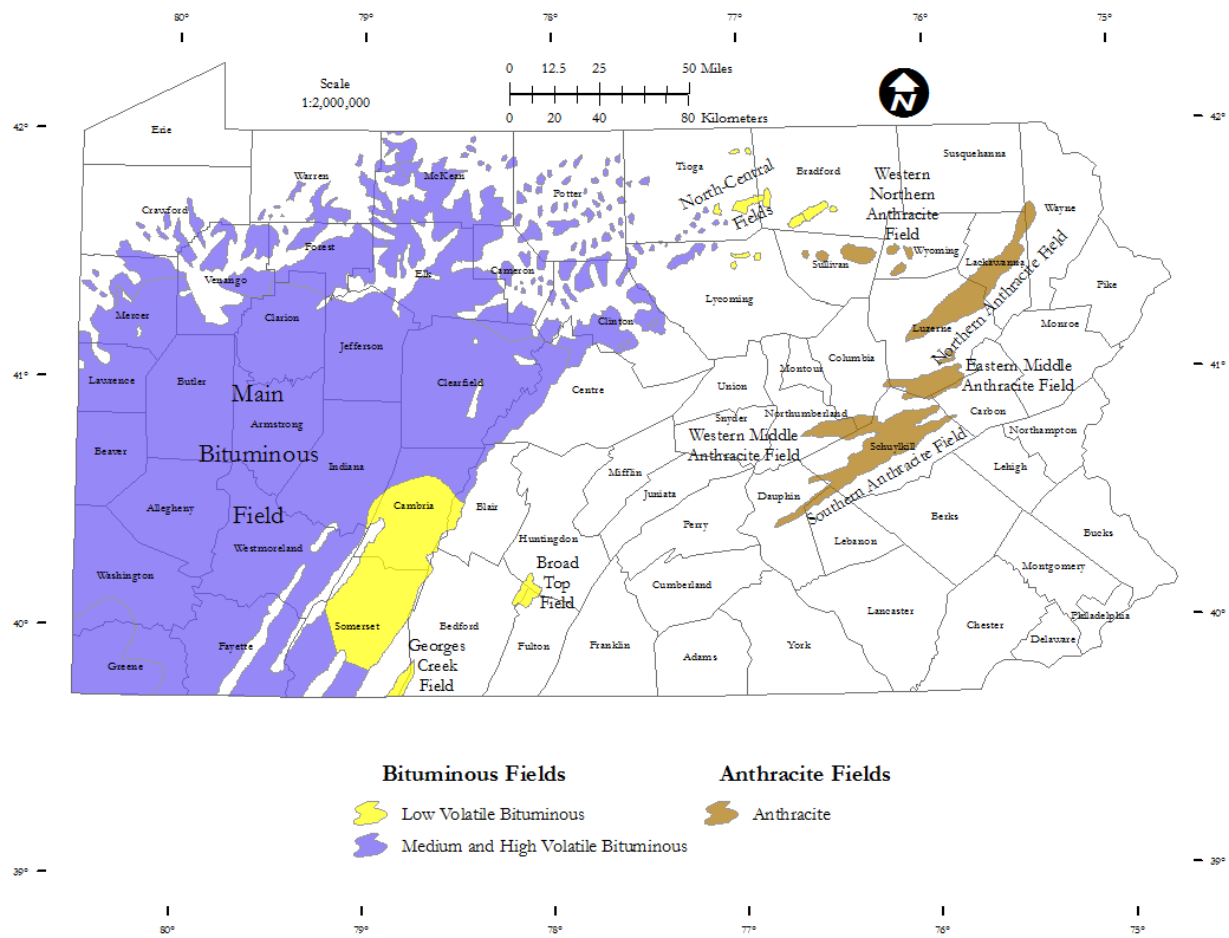
The two Pennsylvanian coal-bearing areas can broadly be discussed as the Anthracite Region located in the east and northeastern part of the state, and the Bituminous Coal Region located in the western part of the state (See Figure 3.2-8). Additional discussion of Pennsylvania coal-bearing sub-basins is found in the earlier subsection on West Virginia geology.

Pennsylvania's Anthracite Region is located in the eastern part of the state in the Valley and Ridge Province of the Appalachian Mountains. Coal-bearing strata are Pennsylvanian-aged. Lithologies consist of shales, weathered limestones, and dolomites which underlie the valleys; the more resistant sandstones and conglomerates support the surrounding ridges. This contrast in rock types results in a series of parallel valleys and ridges for which the province is named. The complex folding and faulting in the province is responsible for the higher temperatures and pressures required to create anthracitic coal.

The Anthracite Region consists of four major coal fields that are situated in synclinal basins surrounded by sandstone ridges. These fields are the northern anthracite field, the eastern middle anthracite field, the western middle anthracite field, and the southern anthracite field.

The primary coal-bearing units in the Anthracite Region, from oldest to youngest, are the Pottsville and Llewellyn Formations. The Pottsville Formation ranges in thickness from a maximum of approximately 1,600 feet to less than 100 feet. The Pottsville Formation is subdivided into three members; from oldest to youngest, these are the Tumbling Run Member, the Schuylkill Member, and the Sharp Mountain Member. The Tumbling Run and Schuylkill Members are absent to the north. The formation contains up to 14 coal beds in some areas, but most are relatively discontinuous. The Lykens Valley Coal, Numbers four through seven, are within the Tumbling Run Member; the Lykens Valley Coal, Numbers one through three, are within the Schuylkill Member; and the Scotty Steel and Little Buck Mountain Coals are within the Sharp Mountain Member of the Pottsville Formation.

Figure 3.2-8. Distribution of Pennsylvania Coals



Source: PA Department of Conservation and Natural Resources, 2008, *Map 11: Distribution of Pennsylvania Coals*, Commonwealth of Pennsylvania,
http://www.dcnr.state.pa.us/cs/groups/public/documents/document/dcnr_016203.pdf

The Pottsville Formation in eastern Pennsylvania, consisting predominantly of sandstones and conglomerates, was laid down entirely in non-marine depositional environments (Edmunds et al., 1999).

The Llewellyn Formation, up to 3,500 feet thick, consists of gray, fine to coarse-grained clastic rocks (sandstones, shales, conglomerates) and anthracite coal seams in repetitive sequences. The formation contains up to 40 mineable coal seams. The thickest and most persistent coal beds occur in the lower part of the Llewellyn Formation, particularly the Mammoth Coal zone. The Mammoth Coal zone typically contains 20 feet of coal, and thicknesses of 40 to 60 feet are not unusual. The thickest coal beds tend to be situated in the trough of the syncline. The nomenclature and stratigraphy of the coal-bearing rocks of the Llewellyn Formation are not consistent throughout the state.

The dominant lithologies of the Llewellyn Formation are sandstones and conglomerates. In the north part of the state, the formation contains one known marine bed, the Mill Creek Limestone. Combined with the Cannal and Hillman Limestones (both non-marine), these units constitute an appreciable amount of calcareous material in the uppermost 850 feet of the formation.

The Pennsylvania Bituminous Coal Region is located in the western part of the state in the Appalachian Plateau Province (See Figures 3.2-8 and 3.2-2). The Plateau consists of relatively flat lying strata, largely absent of the complex faulting and intense folding that characterize the Anthracite Region. Given the lack of significant tectonic deformation, the Pennsylvanian-aged peat deposits of the Plateau were never subjected to high temperatures and pressures. Thus, unlike eastern Pennsylvania, the coals of this area are a bituminous grade coal. Coal-bearing rocks of the Bituminous Region include (from the oldest to youngest) the Pottsville, Allegheny, Conemaugh, Monongahela, and Dunkard Groups (See Figure 3.2-9).

The Pottsville Group is variable in thickness. For the most part, it is dominated by sandstone, and the coal beds are discontinuous. Because of the discontinuous nature of these coals, and the fact that they are often thin and split with numerous partings, mining has not been common in the Pottsville Group. The Pottsville Formation can range from 20 feet to at least 250 feet in thickness with the principal coal mined being the Mercer.

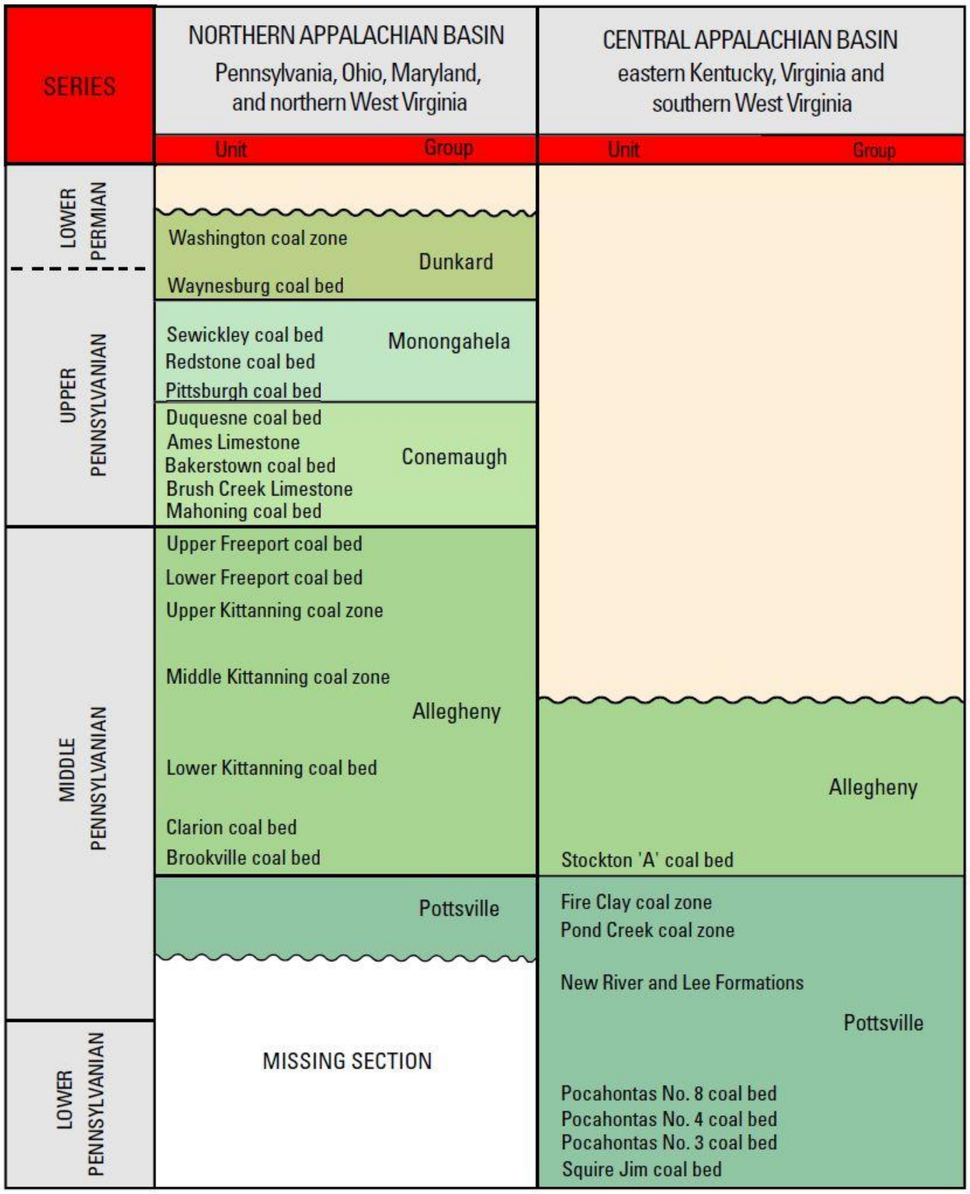
The Allegheny Group is one of two groups that contain the majority of economically mineable coals (See Figure 3.2-9). The Group contains six major coal zones with each zone taking one of three forms: a single, more-or-less continuous sheet; a group of closely related individual lenses; or a multiple-bed complex. The major coal zones are, from oldest to youngest, the Clarion, Lower Kittanning, Middle Kittanning, Upper Kittanning, Lower Freeport, and Upper Freeport.

The Lower Allegheny extends from the base of the Brookville Coal to the base of the Johnstown Limestone (or Upper Kittanning Coal where the limestone is absent). The Upper Allegheny extends from the base of the Johnstown Limestone to the top of the Upper Freeport Coal. The thickness of the Allegheny Group formation ranges from 270 to 330 feet in western Pennsylvania. The group consists of a repeating succession of coal, limestone, and clastic units which range in particle size from claystone to coarse sandstone. The Conemaugh Group contains two formations, the older Glenshaw Formation and the overlying Casselman Formation. The Glenshaw contains several widespread marine units, the most prominent of which are the Brush Creek, Pine Creek, Woods Run, and Ames Limestone. The Glenshaw is thickest in Somerset and southern Cambria Counties, where it reaches 400 to 420 feet and is thinnest near the Ohio border where it is about 280 feet thick. The mineable coals of the Glenshaw Formation, from oldest to youngest, typically are the Mahoning, Brush Creek, and Lower and Upper Bakerstown.

With the exception of the marine shales above the Ames Limestone, the Casselman Formation is made up exclusively of fresh water sedimentary rocks. Coal beds are nearly absent or very thin in the west but increase in quantity eastward. The coal beds of the Casselman Formation, typically include, from oldest to youngest, the Duquesne (or Federal Hill), the Barton (or Elk Lick), Wellersburg, Little Clarksburg (or Franklin), and the Little Pittsburgh.

The Monongahela Group extends from the base of the Pittsburgh Coal to the base of the Waynesburg Coal. It is divided into the Pittsburgh and Uniontown Formations at the base of the Uniontown Coal and is about 270 to 400 feet thick, generally increasing in thickness from the western edge of the state to western Fayette County. The Monongahela Group is entirely non-marine and dominated by limestones, dolomitic limestones, calcareous mudstones, shales, and thin-bedded siltstones and laminites. The only sandstone of significant thickness within the formation lies directly above the Pittsburgh Coal complex. The Pittsburgh Coal is continuous, covering thousands of square miles and is four to ten feet thick. The other major coals found in the Group are the Redstone and Sewickley.

Figure 3.2-9. Generalized Stratigraphic Column of the Pennsylvanian and Lower Permian in the Northern and Central Appalachian Basin Coal Regions



Source: Ruppert and Rice, 2000, Figure 10: Generalized Stratigraphic Column of the Pennsylvanian and Lower Permian in the Northern and Central Appalachian Basin Coal Regions, USGS, U.S. DOI, http://pubs.usgs.gov/pp/p1625c/CHAPTER_B/CHAPTER_B.pdf

The Permian-aged Dunkard Group is found only in the most southwestern corner of Pennsylvania in Greene and Washington Counties. It is made up of Waynesburg, Washington and Greene Formations (Berryhill et al., 1971). The Dunkard reaches a maximum thickness of about 1,120 feet in Greene County and the upper surface is the modern day erosional surface. The lower boundary of the Dunkard Group is defined as the base of the Waynesburg Coal, which is the only coal routinely mined in the Dunkard. The Dunkard is generally composed of fine-grained clastics which, in many locations, are calcareous. Thick lacustrine limestones are especially prevalent in the Washington Formation. The only significant sandstone interval lies above the Waynesburg coal.

3.2.1.6 Maryland Geology

The coal-bearing area of Maryland occurs in the westernmost portion of the state (See Figure 3.1-18). The depositional setting and geology of the coal-bearing strata are identical to that of the western Pennsylvanian Bituminous Region. Not surprisingly, the coal-bearing rock formations correlate to those in Pennsylvania. They include (from the oldest to youngest) the Pottsville, Allegheny, Conemaugh, Monongahela, and Dunkard Groups. For this reason, the reader is referred to the western Pennsylvania Bituminous Coal Region discussion provided above for details regarding geology and coal beds.

3.2.1.7 Ohio Geology

Ohio coal-bearing strata are present only in the eastern third of the state (See Figure 3.1-18). The depositional setting and geology for the coals of eastern Ohio is largely similar to that of western Pennsylvania. Not surprisingly, the coal-bearing rock formations are largely the same and are correlative with those in Pennsylvania. They include (from the oldest to youngest) the Pottsville, Allegheny, Conemaugh, Monongahela, and Dunkard Groups. The reader is referred to the western Pennsylvania Bituminous Coal Region discussion above for details regarding geology and coal beds. Additional discussion of Ohio coal-bearing sub-basins is found in the discussion of West Virginia geology.

Formation thicknesses differ somewhat from those found in western Pennsylvania. In eastern Ohio, thicknesses of the Pottsville Group range from 120 feet to approximately 470 feet. The thickness of the Allegheny Group ranges from 190 feet to approximately 260 feet. Thicknesses of the Conemaugh Group range from 350 feet to approximately 500 feet. The Monongahela Group thickness ranges from 200 feet to 500 feet. The Dunkard Group thickness is approximately 520 feet.

3.2.2 Colorado Plateau Coal-Producing Region

The Colorado Plateau region encompasses the coal-bearing areas of western Colorado, Utah, Arizona, and New Mexico (See Figure 3.1-21). The Colorado Plateau region is subdivided into several coal fields including the: Uinta Region; Tongue Mesa Field; Henry Mountains Field; Southwestern Utah Region; San Juan River Region; Pagosa Springs Field; Monero Field; Black Mesa Field; Pinedale Field; Deer Creek Field; Datil Mountain Field; Rio Puerco Field; Tijeras Field; Una del Gato Field; Cerrillos Field; Jornada del Muerto Field; Carthage Field; Sierra Blanca Field; and the Engle Field. For the purposes of this FEIS, discussion will focus on the Black Mesa Field, the San Juan Basin, the Uinta Region, and southwestern Utah since these are the most geologically extensive.

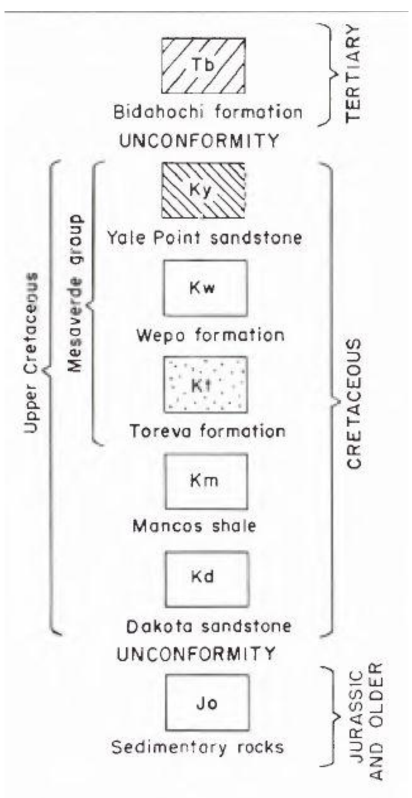
In the Paleozoic Era, the Colorado Plateau region was periodically flooded by extensive inland tropical seas. Sedimentary strata such as limestone, sandstone, siltstone, and shale were laid down in these shallow marine waters in great thicknesses. During times when the seas retreated, fluvial clastics and dune sands were deposited. Slowly, sediments accumulated over a period of 300 million years.

During the younger Mesozoic Era, the depositional environment was dominated by terrestrial sedimentation. Great accumulations of cross-bedded sandstones and eruptions from volcanic mountain ranges to the west buried vast regions beneath ashy debris. The coal beds of the Colorado Plateau were deposited during this time, specifically during the Cretaceous. For much of this period, coal forming units accumulated in coastal-plain wetlands, near-shore marine environments, and fluvial depositional settings.

3.2.2.1 Black Mesa Coal Field Geology

The Black Mesa coal field is located in northeastern Arizona. The general geology of the Black Mesa coal field consists of Cretaceous-aged units including the Dakota Sandstone, the Mancos Shale, and the Mesa Verde Group (See Figure 3.2-10). The Dakota Sandstone contains coal within its middle shale member. The thicker coal units within the Dakota are found in the southwestern part of Black Mesa and can be up to nine feet thick (O'Sullivan, 1958). Within the Mesa Verde Group are the coal-bearing Toreva and Wepo Formations. The Wepo Formation is the major coal-bearing unit of the coal field with eight coal zones measuring from four to 30 feet thick.

Figure 3.2-10. General Geology of the Black Mesa Coal Field



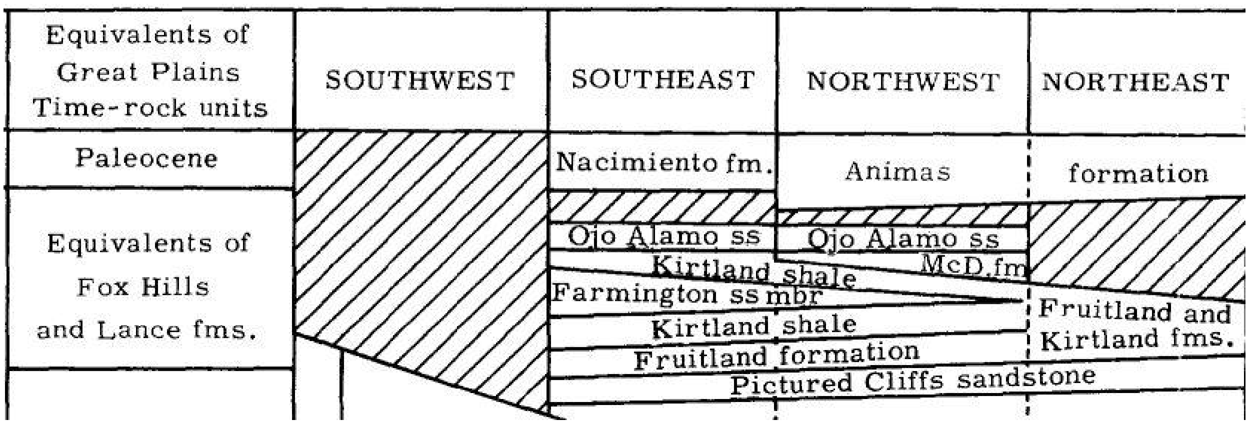
Source: R.B. O'Sullivan, 1958, *Summary of Coal Resources of the Black Mesa Coal Field, Arizona,* New Mexico Geological Society, http://nmgs.nmt.edu/publications/guidebooks/downloads/9/9_p0169_p0171.pdf

3.2.2.2 San Juan Coal Basin Geology

The San Juan Basin is an asymmetrical basin, with a gently dipping southern flank and a steeply dipping northern flank (Stone et al., 1983). It measures roughly 100 miles long in the north-south direction and 90 miles wide. The Fruitland Formation is the primary coal-bearing unit of the San Juan River Region (See Figure 3.2-11).

The Fruitland Formation coal beds are thick, with individual beds up to 80 feet thick. However, only a small percentage of the total number of coal beds is found at depths of 200 feet or less. The formation is composed of interbedded sandstone, siltstone, shale, and coal, with the thickest coalbeds always found in the lower third of the formation.

Figure 3.2-11. Generalized Stratigraphic Column for the San Juan Coal Basin



Source: Caswell Silver, 1951, *Figure 3: Generalized Stratigraphic Column for the San Juan Coal Basin*, New Mexico Geological Society, http://nmgs.nmt.edu/publications/guidebooks/downloads/2/2_p0104_p0118.pdf

3.2.2.3 Uinta Coal Basin Geology

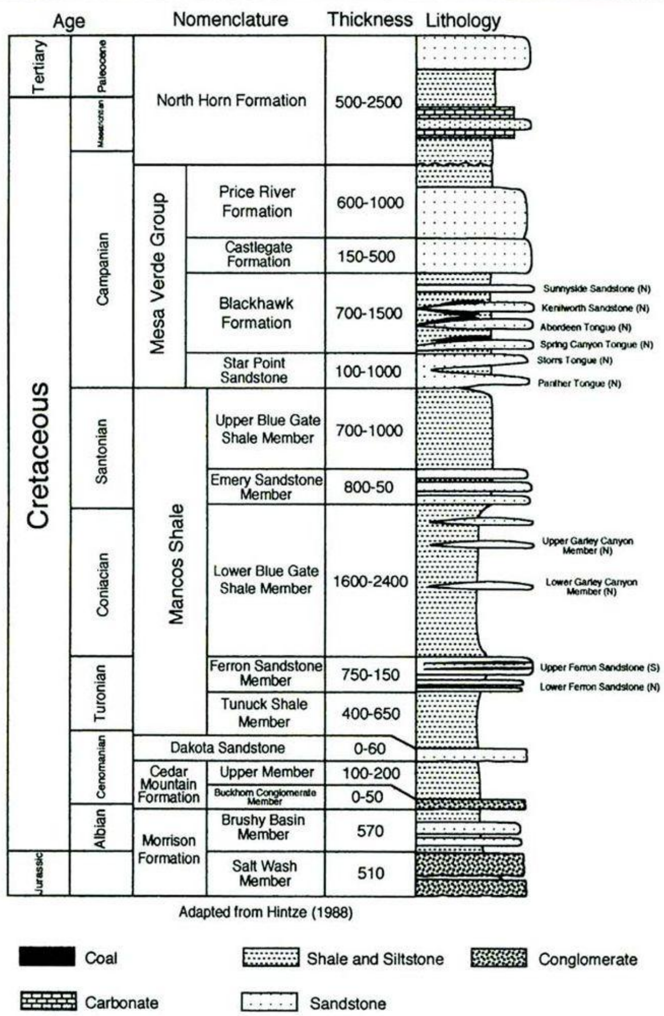
The Uinta Coal Basin, approximately 14,450 square miles in area, is located in eastern Utah and northwestern Colorado (See Figure 3.1-21). Most of the coal mines currently operating in Utah are located in the western end of the Uinta Basin. Three prominent coal fields in the region include the Wasatch coal field, the Book Cliffs coal field, and the Emery coal field.

The coalbeds are present within the Cretaceous strata throughout much of the Uinta Basin (See Figure 3.2-12). The Ferron Sandstone Member of the Mancos Shale and the Blackhawk Formation of the Mesaverde Group are two important coal-bearing units currently being mined.

The Ferron Sandstone Member coalbeds and interbedded sandstone units form a wedge of clastic sediment above the Tunuck Shale Member of the Mancos Shale and below the Lower Blue Gate Shale Member of the Mancos Shale. The coal-bearing rocks are thickest to the west and south margins of the basin, nearer to the upland source of sediments. Total coal thickness in this area ranges from four to 48 feet (averaging 24 feet). Coal beds are named in ascending order of deposition, the A, B, C, D, G, I, J, L, and M.

The Blackhawk Formation consists of coal interbedded with sandstone and a combination of shale and siltstone. It ranges from 450 to 1,500 feet thick in the Book Cliffs coal field. The Blackhawk Formation is underlain by the Star Point Sandstone and overlain by the Castlegate Sandstone. In the Book Cliffs coal field, the main coal zones in the Blackhawk Formation are the Spring Canyon, the Castlegate A, B, C, D, the Kenilworth, the Gilson, the Rock Canyon, and the Sunnyside. In the Wasatch Plateau coal field, the main coal zones are also found in the Blackhawk Formation. The main coal beds are the Accord Lakes, the Axel Anderson, the Blind Canyon, the Wattis (also known as the Upper O'Conner), the Cottonwood, and the Castlegate A.

Figure 3.2-12. Generalized Stratigraphic Column for the Uinta Coal Basin



Source: U.S. EPA, 2004, *Figure A4-2: Generalized Stratigraphic Column for the Uinta Coal Basin*, EPA 816-R-04-003, http://www.epa.gov/ogwdw/uic/pdfs/cbmstudy_attach_uic_attach04_uinta.pdf

3.2.2.4 Henry Mountains Geology

The principal coal resources of the Henry Mountains, located in Wayne and Garfield counties of southeastern Utah, are found within a north to south elongated basin, approximately 50 miles long and two to 18 miles wide (Tabet, 1999).

Coal beds are present within Cretaceous strata including the Ferron Sandstone and Muley Canyon Sandstone members of the Mancos Shale (See Figure 3.2-13). Minor coal beds exist within the Dakota Sandstone but are not considered minable due to its thin and discontinuous occurrence. The Muley Canyon coals are the thickest and most continuous, and are thus the greatest potentially minable coal resource in the area (Doelling, 1972; Tabet, 1999).

Figure 3.2-13. Stratigraphy of the Henry Mountains Coal Field

Stratigraphic Units	Depositional Environment	Thickness (ft.)
Tarantual Mesa Sandstone	Continental	270 – 400
Masuk Formation	Coastal plain; major coal	600 – 750
Muley Canyon Sandstone	Nearshore marine	270
Mancos Shale		
Blue Gate Member	Marine	1,400
Ferron Sandstone Member	Nearshore marine/coastal plain; coal	150 – 300
Tununk Member	Marine	525 – 650
Dakota Sandstone	Alluvial to marginal marine; minor coal	1 - 75

Source: Mark Kirschbaum and Laura Biewick, 2008, *Stratigraphy of the Henry Mountains Coal Field*, USGS, U.S. DOI, http://pubs.usgs.gov/pp/p1625b/Reports/Chapters/Chapter_B.pdf

As previously described, the Ferron Sandstone Member coalbeds and interbedded sandstone units form a wedge of clastic sediment above the Tunuck Shale Member of the Mancos Shale and below the Lower Blue Gate Shale Member of the Mancos Shale. The areal distribution of coal within the Henry Mountains Ferron Sandstone is patchy and is best developed in the northern, central and southern parts of the field, in pods approximately one to five miles wide and three to ten miles long. The coal exists in five beds that average one to three feet in thickness and seldom exceed four feet in thickness. The aggregated coal thickness is as much as 16.5 feet. The depth to the Ferron coal varies from exposed cropping coal around the margins of the Henry Mountains to a maximum depth of 2,000 feet in the central part of the basin (Tabet, 1999).

The Muley Canyon Sandstone member overlies the Blue Gate member of the Mancos Shale. The lower part of the Muley Canyon Sandstone consists of massive laminated-to-thin-bedded, very fine to medium-grained sandstone ranging in thickness from 131 to 307 feet. The upper portion is described as more heterogeneous and interbedded with carbonaceous mudstone and coal. Thickness ranges from 92 to 120 feet. The upper portion of the Muley Canyon Sandstone contains the thickest and most persistent coal beds. Unlike the Ferron member, coal within the Muley Canyon Sandstone is distributed throughout most of the Henry Mountains field. The Muley Canyon Sandstone coal zones generally exist in four to five beds, with as many as ten beds. Thickness of coal ranges from zero to 13.4 feet but generally averages two to five feet. The aggregated coal thickness is as much as 27.5 feet. The depth to the Muley Canyon

Sandstone coal varies from 100 feet at the northern and southern extents of the Henry Mountains coal field to a maximum depth of 1,000 feet under Tarantula Mesa (Tabet, 1999).

3.2.2.5 Southwestern Utah Region Geology

The principal coal-bearing units in the Southwestern Utah Region are the Dakota Formation and the Straight Cliff Formation (Kirschbaum and Biewick, 2008) (See Figure 3.2-14). The Dakota Sandstone consists of sandstone interbedded with mudrock and the Smirl Coal bed. The Smirl Coal bed is found from ground level to 1,000 feet below surface in the Alton coal field, which is located in this region. The Smirl Coal bed reaches a maximum thickness of 18 feet.

Figure 3.2-14. Stratigraphic Summary of Upper Cretaceous and Tertiary Strata in the Southwestern Utah Coal Basin

Age	Formation	Thickness (ft)
Miocene	Osiris Tuff	0-600
Eocene and Paleocene	Wasatch Formation	1,350- 1,650
Paleocene	Pine Hollow Formation	0-450
Paleocene and Late Cretaceous	Canaan Peak Formation	0-900
Late Cretaceous	Kaiparowits Formation	600-3,000
	Wahweap Formation	900-2,600
	Straight Cliffs Formation	1,000-2,000
	Tropic Shale	600-900
	Dakota Formation	15-250

Source: Robert Hettinger, 2008, *Figure 6: Stratigraphic Summary of Upper Cretaceous and Tertiary Strata in the Southwestern Utah Coal Basin*, USGS; U.S. DOI, http://pubs.usgs.gov/pp/p1625b/Reports/Chapters/Chapter_J.pdf

Although the Straight Cliffs Formation is also a prominent coal-bearing unit in southwestern Utah, the unit is not currently being mined. The formation consists of a series of sandstone members which include the John Henry Member, a primarily sandstone with secondary amounts of mudrock and coal. The main coal-bearing units are the Alvey, Rees, Christenson, and lower zones.

3.2.3 Gulf Coast Coal-Producing Region

The Gulf Coast region encompasses the lignite coal-bearing areas of Texas, Arkansas, Louisiana, Mississippi, and parts of Missouri, Alabama, Tennessee, Georgia, and far western Kentucky (See Figure

3.1-23). As of 2010, most coal in the region was produced from Texas, with lesser amounts mined in Louisiana and Mississippi. For this reason, the following discussion will focus on the coal-bearing formations that are mined in Texas, Louisiana, and Mississippi.

In Texas, the lignite bearing formations were deposited during the Late Cretaceous through the Middle Tertiary Periods. These units, which are present as a wide northeast-southwest band across east central Texas, include: the Jackson Group, the Claiborne Group, the Wilcox Group and the Olmos Formation of the Navarro Group (See Figures 3.2-15 and 3.2-16).

Source: WR Kaiser, 1974, *Table 1: Stratigrpahic Occurrence of Texas Lignite*, The University of Texas at Austin, http://www.lib.utexas.edu/books/landscapes/publications/txu-oclc-1552275/txu-oclc-1552275.pdf

Gulf Coast lignites are interpreted as having accumulated in a variety of fluvial, deltaic, and lagoonal depositional environments. Fluvial lignite accumulated in forested, fresh-water swamps (Nichols and Traverse, 1971). Kaiser (1974) states that "[Fluvial lignite] originated as backswamp peats on broad, isolated floodplains separated by stabilized meanderbelts …. [Deltaic] lignite is associated with three sedimentation patterns: alternating distributary channel and interdistributary deposits; repetitive coarsening-upward, delta-front sequences; and stacked coarse-grained meanderbelt deposits. … The thickest, most extensive lignites are associated with delta-plain, interdistributary deposits. … [Lagoonal lignites display a sedimentation pattern] of multi-stacked progradational or coarsening-upward barrier- and strandplain-beach sequences in which the lignites are associated with inland or updip lagoonal muds."

The Jackson Group of east Texas is interpreted as having been formed under two distinct processes of lower delta plain deposition. It has been proposed that thin, discontinuous lignite seams formed in small interdistributary areas, which were frequently covered by sediment during overbank flooding and crevassing. By contrast, thick coal seams, deposited on sand platforms, are laterally continuous and likely represent lignite deposition during periods of delta lobe abandonment.

The east Texas Wilcox Formation may show the characteristics of an alluvial-plain setting. The individual seams are lenticular, where the thickest part of the bed occurs in the center of the seam abruptly decreasing in thickness at the outer margins. Adjacent to the lignite bodies are channel-like barren areas that are filled with either mud or sand. Channels are normally parallel to the individual lignite bodies. Large, irregular, and circular mud-filled areas completely surround some of the lignite seams.

Regardless of the depositional mechanism, it was during these periods that swampy, stagnant conditions prevailed and organic matter was deposited. This organic matter was subsequently buried by sediment and over time compressed into lignite.

The lignite bearing rock in Louisiana was deposited during the Middle Tertiary approximately 36 to 66 million years ago. During this time much of Louisiana existed as an alluvial plain and was characterized by low, marshy land with heavy plant growth. The heavy plant growth then started decomposing within the swampy, marshy areas and was buried by sand and mud sediments from alluvial, deltaic and coastal sediments. The northern part of the state contains lignite beds of the Wilcox Group.

The lignite bearing rocks in Mississippi were also deposited during the Middle Tertiary, approximately 36 to 66 million years ago. The lignite seams currently mined in Mississippi were formed in a fluvial environment in which several sequences of flooding and stream channel migration occurred. It was during these periods that swampy conditions dominated and organic matter was deposited. As discussed previously, over time, this organic material was buried and compressed into lignite. These lignite beds are found in the Wilcox and Claiborne Groups.

Four of the most prominent coal-bearing units in the region are the Jackson Group, the Claiborne Group, the Wilcox Group, and the Olmos Formation of the Navarro Group. Most of the coal currently mined from the Gulf Coast region is from one of these four lithological groups.

3.2.4 Illinois Basin Coal-Producing Region

The Illinois Basin region encompasses the coal-bearing areas of Illinois, Indiana, and western Kentucky (See Figure 3.1-25). The Illinois Basin itself is an oval depression covering approximately 60,000 square miles in the midcontinent area of the United States.

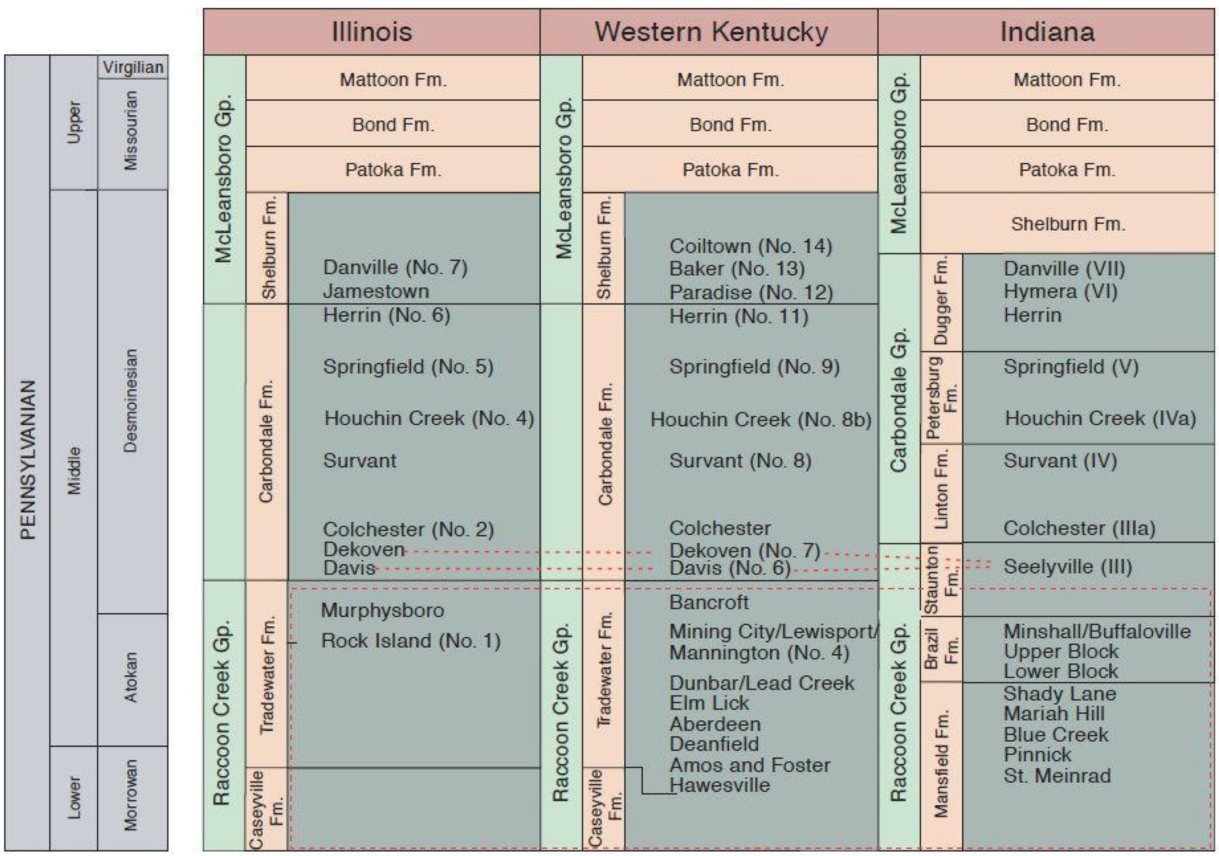
The Illinois Basin was formed as a "failed rift" related to the rupturing of an Early to Middle Cambrian supercontinent. As the continental crust was pulled apart, faulting produced a structural depression in this region. The depression evolved into an embayment that continued to subside from the Late Cambrian into the Permian.

During the Pennsylvanian, the basin filled with a thick succession of sandstone and carbonate deposits. These Pennsylvanian-aged sedimentary rocks, deposited 320 to 280 million years ago, contain the bituminous coal-bearing units which were laid down in freshwater, swamp, and rain forest environments.

No lithologic record is preserved of bedrock strata in the Illinois Basin younger than 225 million years ago. However, during the Late Cretaceous and Early Tertiary, the area immediately above the former rift subsided and filled with sediments of the Mississippi Embayment of the Gulf Coastal Plain (Leighton et al., 1990).

Due to stratigraphic discontinuity and a lack of regional key horizons, it is difficult to correlate Pennsylvanian formations basin wide. Although attempts have been made to resolve these issues (USGS, 2002a), correlation problems still exist. Generally speaking, the Pennsylvanian rocks can be subdivided into the basal Raccoon Creek Group, the overlying Carbondale Group or Formation and the McLeansboro Group. The major economic coals within the Basin are the Springfield and Herrin Coals (in the Carbondale Formation), the Danville (in the McLeansboro in Illinois), and the Baker Coal (in the McLeansboro of Kentucky) (See Figure 3.2-17).

Figure 3.2-17. Generalized Stratigraphy of Coals in the Illinois Basin



Source: J.R. Hatch and R.H. Affolter, 2002, *Figure 1; Stratigraphic chart of the Pennsylvanian System in the Illinois Basin, showing major coal members*, USGS; U.S. DOI, http://pubs.usgs.gov/pp/p1625d/Chapter_C.pdf

In addition to the Springfield, Herrin, Danville, and Baker Coals, many other coals in the Raccoon Creek Group, Carbondale Group or Formation, and the McLeansboro Group have been previously mined. Cumulative production from these other coals, however, has been much less than the production from the four principal coals (Hatch and Affolter, 2002).

3.2.4.1 Illinois Geology

The majority of the Illinois Basin lies within the state of Illinois, occupying an area of approximately 36,800 square miles (See Figure 3.1-27). The Pennsylvanian-aged coal-bearing rocks are divided into the Raccoon Creek Group, Carbondale Formation, and the Shelburn Formation (See Figure 3.2-17). Typically, sandstones are the dominant rock type of these formations, with most of the remainder made up of siltstone, shale and minor amounts of limestone.

In Illinois, the Danville Coal Member is the most prominent coal in the Shelburn Formation of the McLeansboro Group. Other McLeansboro Group coals, stratigraphically above the Danville in Illinois (and Indiana), are not as thick or as extensive as the coals in the underlying Carbondale Formation (Hatch and Affolter, 2002). The Danville has been locally measured at thicknesses reaching six feet, but generally ranging from a few inches to three feet thick (USGS, 2002a). The Danville and Jamestown coal beds in Illinois correlate to the Danville and Jamestown coals beds in Indiana and the Baker and Paradise coal beds in western Kentucky.

The Herrin Coal Member of the Carbondale Formation averages more than six feet thick over extensive areas and locally reaches 15 feet thick in Illinois (USGS, 2002a). The Springfield Coal Member ranges from an average of five feet to a maximum recorded 13 feet thick. In western and west-central Illinois, the Springfield coal exhibits claystone dikes which cut through the coal seam and the overlying strata (Hatch and Affolter, 2002).

3.2.4.2 Indiana Geology

The Indiana coal field is located in the eastern portion of the Illinois Basin and covers an area of approximately 6,500 square miles (See Figure 3.1-27). The Indiana coal field is composed of the bituminous Pennsylvanian-aged Carbondale Group (referred to as a formation in Kentucky and Illinois). The Carbondale Group consists of, from oldest to youngest, the Linton, the Petersburg, and the Dugger Formations (See Figure 3.2-17 above). Shale is the most abundant rock type of the formation with the thick gray units being interpreted as deltaic deposits (Hatch and Affolter, 2002). The Hymera and Danville Coal Members of the Dugger Formation in Indiana are correlative with the Jamestown and Danville Coal Members of the McLeansboro Group in Illinois and with the Paradise and Baker coals of the McLeansboro Group in western Kentucky. The Herrin Coal Member is not well developed in Indiana.

3.2.4.3 Western Kentucky Geology

The western Kentucky coal field covers an area of 6,400 square miles of the southeastern portion of the Illinois Basin (See Figure 3.1-25). The western Kentucky bituminous coal field comprises Pennsylvanian-aged strata that are largely alluvial or deltaic in origin, and their thicknesses are relatively consistent throughout the area (Archer, 2001).

Although the Tradewater Formation of the Raccoon Creek Group contains more than 20 mined coal beds in western Kentucky, discussion is going to focus on the Carbondale and Shelburn Formations as these are the shallower coal-bearing units (See Figure 3.2-17). The Carbondale Formation consists of siltstone, shale, and some local sandstones. It contains some thin discontinuous limestones as well as some of the most heavily mined coal beds in the region. The most prominent of the Carbondale Formation coal beds are the Herrin (No. 11) which lies at the uppermost reaches of the formation, and the Springfield (No. 9). The Herrin (No. 11) coal occurs in two distinct bodies. The thickest of these bodies is in a narrow belt along the southern edge of the western Kentucky coal field where it attains a thickness of ten feet. The second coal body occurs at the north reaches of the coal field where it is less than two and a half feet thick, or absent (Hatch and Affolter, 2002). The Springfield Coal ranges from five to six feet in thickness in the middle of the coal field, but thins to less than four feet toward the east and northeast of the coal field (Hatch and Affolter, 2002).

Also in western Kentucky, the Shelburn Formation (previously known as the Sturgis) is a coal-bearing unit which overlies the Carbondale Formation. Although the principal rock type of the Shelburn Formation is sandstone, the unit also contains interbedded siltstones, shales, limestones, and coal. The Shelburn Formation contains the Baker (No. 13) and Paradise (No.12) coal beds. The Baker Coal exhibits overlying two-foot thick coal riders that are occasionally mined, along with the main seam during surface operations.

3.2.5 Northern Rocky Mountains and Great Plains Coal-Producing Region

The Northern Rocky Mountains and Great Plains region encompasses the coal-bearing areas of Montana, North Dakota, South Dakota, and Wyoming, as well as selected coal-bearing areas in Colorado, Idaho, and Utah. This region is subdivided into many basins, regions or fields (See Figure 3.1-27). The northern Rocky Mountains are subdivided into the Green River Basin Region, the Hams Fork Region, the Jackson Hole Field, the Big Horn Basin Region, and the Wind River Region. The Great Plains are subdivided into the Blackfeet-Valier Region, the North Central Region, the Fort Union Region, the Bull Mountain Field, the Great Falls Field, and the Powder River Basin. This discussion will focus on the Powder River Basin and the Fort Union Region, as most of the coal resources occur in these areas.

3.2.5.1 Powder River Basin Geology

The Powder River Basin is an asymmetrical synclinal basin which trends from southeast to northwest. In Wyoming, the Powder River Basin is bounded by the Black Hills uplift in the northeast, the Hartville uplift in the southeast, the Laramie Mountains in the south, the Casper arch in the southwest, and the Bighorn Mountains in the west. The basin continues northward into Montana where another structural feature, the Cedar Ridge anticline, separates it from the Williston Basin (Bartos and Ogle, 2002).

Although the Powder River Basin contains one of the world's largest coal deposits, most of the coal is too deeply buried to be recovered economically. Still, the Basin is the largest coal mining region in the U.S. The Powder River Basin constitutes the single largest source of coal in the U.S., contributing about 40 percent to the national total (Luppens et al., 2008).

Some 65 million years ago, the climate of the area was subtropical, with average temperatures of 80 degrees Fahrenheit and 120 inches of rainfall per year. The region had been covered by a shallow sea which slowly retreated as the land surface began to rise. As marine conditions withdrew, lakes and marginal swamps were created. Due to the heavy rain and few rivers to carry the water away, the flat basin floor was a series of swamps and lakes for 25 million years; this was the coal forming period. The swamps were so large that no sediment could get past the outside edges leaving the central portions free to accumulate pure peat. It was this peat that would eventually produce some of the thickest, low ash coals in the world (Wyoming State Geological Survey, 2013).

Principal units of the Powder River Basin are the Fort Union (Paleocene) and Wasatch (Eocene) Formations (See Figure 3.2-18). These strata, which are buried at relatively shallow depths, are interpreted as having been deposited primarily in fluvial, lacustrine, and swampy environments (Seeland, 1992; Ellis et al, 1999). The Fort Union Formation consists of sandstones, siltstones, mudstones, limestones, and coals, including the Wyodak coal zone. Along the eastern margin of the Powder River Basin, the Fort Union Formation dips to the west at an inclination of two to three degrees (Glass, 1997). Near the western margin, the Fort Union Formation dips to the east from 10 to 25 degrees (Glass, 1997).

Most of the mining in the basin occurs within strata of the Wyodak-Anderson coal zone. This zone is known for its extreme thickness which averages 100 feet thick (University of Wyoming, 2002). Coal beds of the Wyodak-Anderson zone occur at shallow depths along the eastern margin of the Powder River Basin. Near Gillette, Wyoming, several of the individual beds merge to form a single, thick Wyodak coal bed. However, to the south, the east, and the north of Gillette, the Wyodak coal bed splits into several seams (Bartos and Ogle, 2002).

The Wasatch Formation consists of conglomerates, sandstones, siltstones, mudstones, limestones and several coal beds, including the Lake DeSmet. The Lake DeSmet coal beds are thickest in the western and central parts of the Basin, near Lake DeSmet, where they attain a thickness of 250 feet (Glass, 1980; Glass, 1997; University of Wyoming, 2002). The dip of the Wasatch Formation is shallow, generally less than four degrees (Glass, 1997).

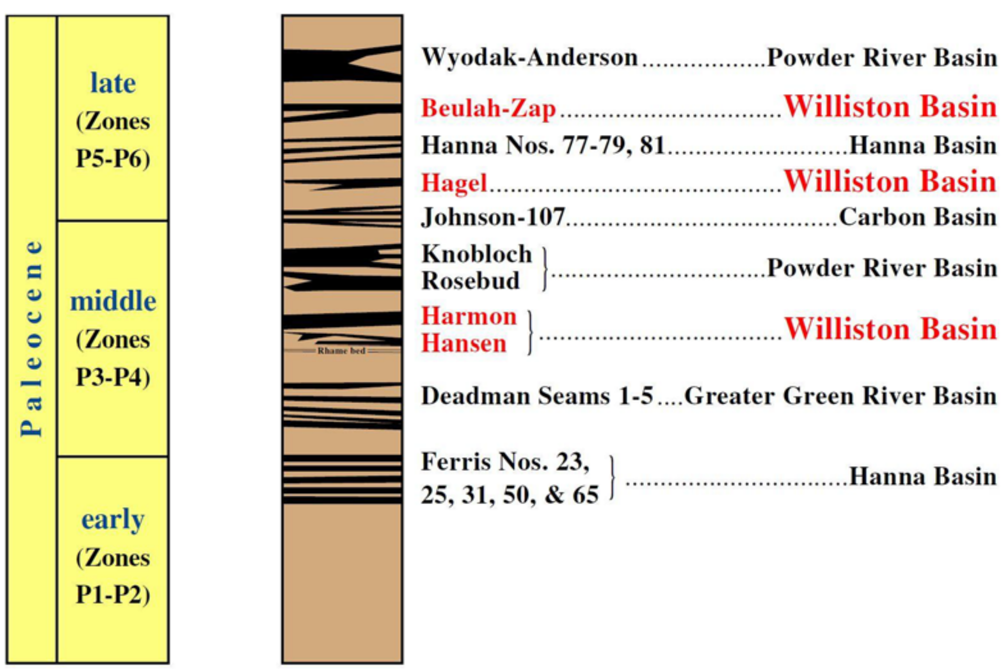
3.2.5.2 Fort Union Region Geology (Williston Basin)

The Fort Union Region in western North Dakota (the Williston Basin) is also a prominent Great Plains coal-bearing area (See Figure 3.1-27). The Williston Basin is a large geologic structural basin, though not a topographic depression, that underlies portions of Montana, North Dakota and South Dakota. The following discussion focuses on the Tertiary-aged Fort Union Formation (or Fort Union Group as it is considered by the North Dakota Geological Survey), as it is the primary coal-producing unit of the region (See Figure 3.2-18).

Strata of the Fort Union Formation are interpreted as having accumulated in the following depositional environments: fluvial and deltaic (the Tongue River and Sentinel Butte Members); tidal (the Ludlow Member); and barrier-shoreface and marine (the Cannonball Member) (Flores et al., 1999).

The Fort Union Formation is composed of, from youngest to oldest, the Sentinel Butte Member, the Tongue River Member, the Cannonball Member, and the Ludlow Member. The formation consists primarily of sandstones, siltstones, and mudstones. It also exhibits lesser amounts of carbonaceous shales, coals, and limestones. The Cannonball Member is the only non-coal-bearing member of the Fort Union Formation. Coal beds/zones include the Harmon and Hansen of the Lower Tongue Member, the Hagel of the Middle Sentinel Butte Member, and the Beulah-Zap of the Upper Sentinel Butte Member (Flores et al., 1999) (See Figures 3.2-18 and 3.2-19). The coal beds generally thicken toward the upper part of the formation with beds reaching thicknesses of 20 to 26 feet.

Figure 3.2-19. Coal Beds of the Williston Basin



Source: Romeo M. Flores et al., 1999, Figure WF-2: Composite Stratigraphic Section for the Assessment Region Showing the Studied Coal Beds and Zones with Age Relationships Based on Palynology, USGS; U.S. DOI; http://pubs.usgs.gov/pp/p1625a/Chapters/WF.pdf

3.2.5.3 Green River Basin and Hams Fork Region Geology

The Green River Basin is a large (10,500 square miles) structural and topographical basin located in southwestern Wyoming. It is one of four basins that make up the Green River Region (Figure 3.1-24). The basin was formed during the Laramide orogeny during the late Cretaceous and early Tertiary (Bartos et al., 2015). The coal beds in the Green River Basin occur in rock formations that range in age from Upper Cretaceous to Early Tertiary (Berryhill et al., 1950; Bartos et al., 2015). The Hams Fork Region, which is located, in the extreme southwestern Wyoming, west of the Green River Region (Figure 3.1-24), The structure of the Hams Fork Region is complex and includes multiple northward –trending folds and faults, resulting in coal bearing rocks that are exposed in long, narrow parallel belts. The coal beds in the Hams Fork Region occur in rock formations that range in age from Upper Cretaceous to Early Tertiary (Berryhill et al. 1950).

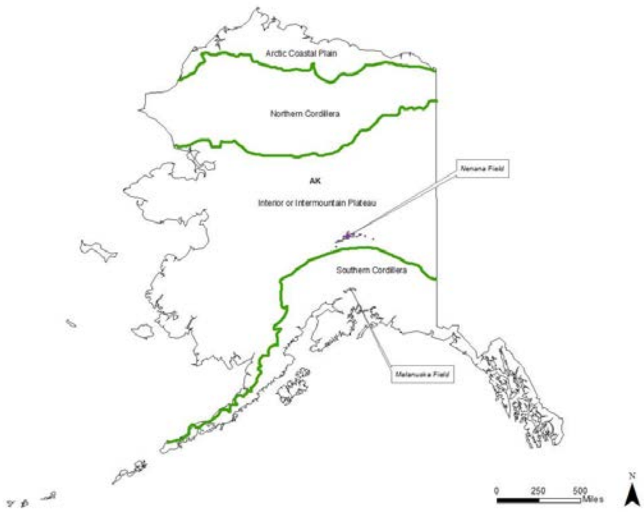
3.2.6 Northwest Coal-Producing Region

As described earlier in Section 3.1.8.6, for the purposes of this EIS the affected area for the Northwest Coal-Producing Region is limited to the Nenana and Matanuska coal fields of Alaska. Alaska is divided into four physiographic regions: Artic Coastal Plain, Northern Cordillera, Interior or Intermountain Plateau, and the Southern Cordillra. The Nenana and Matanuska coal fields are located in the Interior and southern Cordillra regions, respectively. See Figure 3.2-20.

The Interior physiographic region is between the Brooks Range on the north and the Alaska Range on the south (Plafker and Berg, 1994). Quaternary alluvial deposits sporadically cover the region from the Bering Sea to the Yukon Flats. Elsewhere the interior region is composed of plateaus, hills, and uplands, with numerous domes, ridges, and mountains at the higher elevations (Plafker and Berg, 1994). The interior region was generally free of ice during the Pleistocene glaciation. Beneath the loess and vegetation, the interior region contains pre-Cretaceous basement rocks that include displaced and rotated lithotectonic terranes of Proterozoic and Paleozoic age of miogeocline affinity (Plafker and Berg, 1994). The basement rocks also contain Devonian-Lower Jurassic terranes of oceanic affinity and Jurassic-Lower Cretaceous intraoceanic arc terranes. Mid-Cretaceous and younger plutonic and related rocks, flysch basins, and basalts conceal these rocks (Flores, et al, 2004). Tertiary coal-bearing rocks are mainly present in several synclinal basins in the northern foothills of the Alaska Range and are partly or wholly detached from each other by erosion of coal-bearing rocks from intervening structural highs (Wahrhaftig and others, 1994).

The southern Cordillera physiographic region is the northernmost extent of the Pacific Mountain system of North America that rims the Pacific Ocean margin (Plafker and Berg, 1994). The region extends from the Alaska Range on the north to the margin of the Gulf of Alaska on the south. It extends westward to the Aleutian Range and Aleutian Islands, which are a continuation of the Alaska Range. Widespread mountain glaciers and ice fields occur in the mountainous parts of the southern Cordillera region. Glaciers currently extend into tidewaters at numerous bays and fiords. The southern Cordillera region is underlain by Proterozoic to Cenozoic accreted intraoceanic arc and plateau terranes, arc-related accretionary prisms, and flysch basins (Plafker and Berg, 1994). These terranes were intruded by mid-Cretaceous to Paleogene postaccretion plutons, which are, in turn, overlapped by Upper Cretaceous-Tertiary basinal and volcanic rocks. The Tertiary coal-bearing rocks in this region are mainly found in these basins as typified by the Cook Inlet Basin (Flores, et al., 2004).

Figure 3.3-20. Northwest Region - Alaskan Physiographic Regions



Source: Flores, R.M., Stricker, G.D., & Kinney, S.A. (2004). Alaska Coal Geology, Resources, and Coalbed Methane Potential. USGS DDS-77, U.S. Department of the Interior. http://pubs.usgs.gov/dds/dds-077/pdf/DDS-77.pdf

Alaska coal resources formed in widespread deltaic and continental depositional environments during the Cretaceous and Tertiary. The younger Tertiary coals formed within sedimentary basins which were related to fault systems that controlled basin formation and influenced deposition. As discussed in Section 3.1.8.6, the Nenana and Matanuska coal reserves are located in the Central Alaska-Nenana Coal Province and the Southern Alaska-Cook Inlet Province, respectively (See Figure 3.1-29). The coal resources in the Central Alaska-Nenana and the Southern Alaska-Cook Inlet are contained in Tertiary rocks (Flores et al., 2004). The geology of these two provinces are discussed in the following sections.

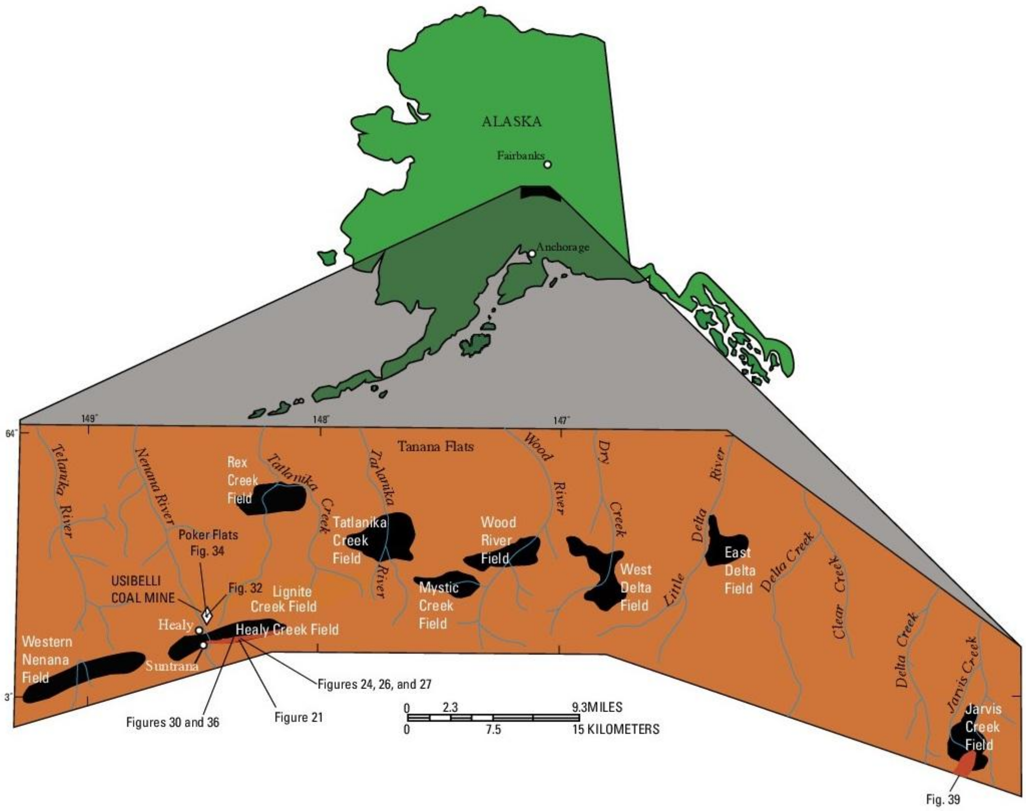
3.2.6.1 Nenana Coal Field Geology

The Nenana coal field is located in the central part of the state of Alaska with deposits trending east-west along the northern central flank of the Alaskan Range. This coal field consists of several synclinal basins partly or wholly detached from each other by erosion. As depicted in Figure 3.2-21 the fields extend as a discontinuous belt approximately 9 miles wide and 56 miles long (Flores et al., 2004).

Coal is found in the Usibelli Group (Wahrhaftig, 1987), a nonmarine sedimentary sequence of five Tertiary age formations that consists of the coal-bearing Healy Creek, noncoaly Sanctuary, coal-bearing Suntrana and Lignite Creek Formations and noncoaly Grubstake Formation (See Figure 3.2-22) overlain by Nenana Gravel. The Usibelli Group contains as many as 30 coal beds and is thought to have formed in fluvial and lacustrine environments.

The Healy Creek Formation is the oldest rock unit in the Usibelli Group. The formation may be as much as 445 feet thick, consisting of interbedded sandstones, conglomerates, siltstones, and mudstones, including carbonaceous shale and coal beds. Sandstone is the most common rock type and coal is the least common. (Flores et al., 2004)

Figure 3.2.21. Coal Fields in Central Alaska-Nenana Coal Province

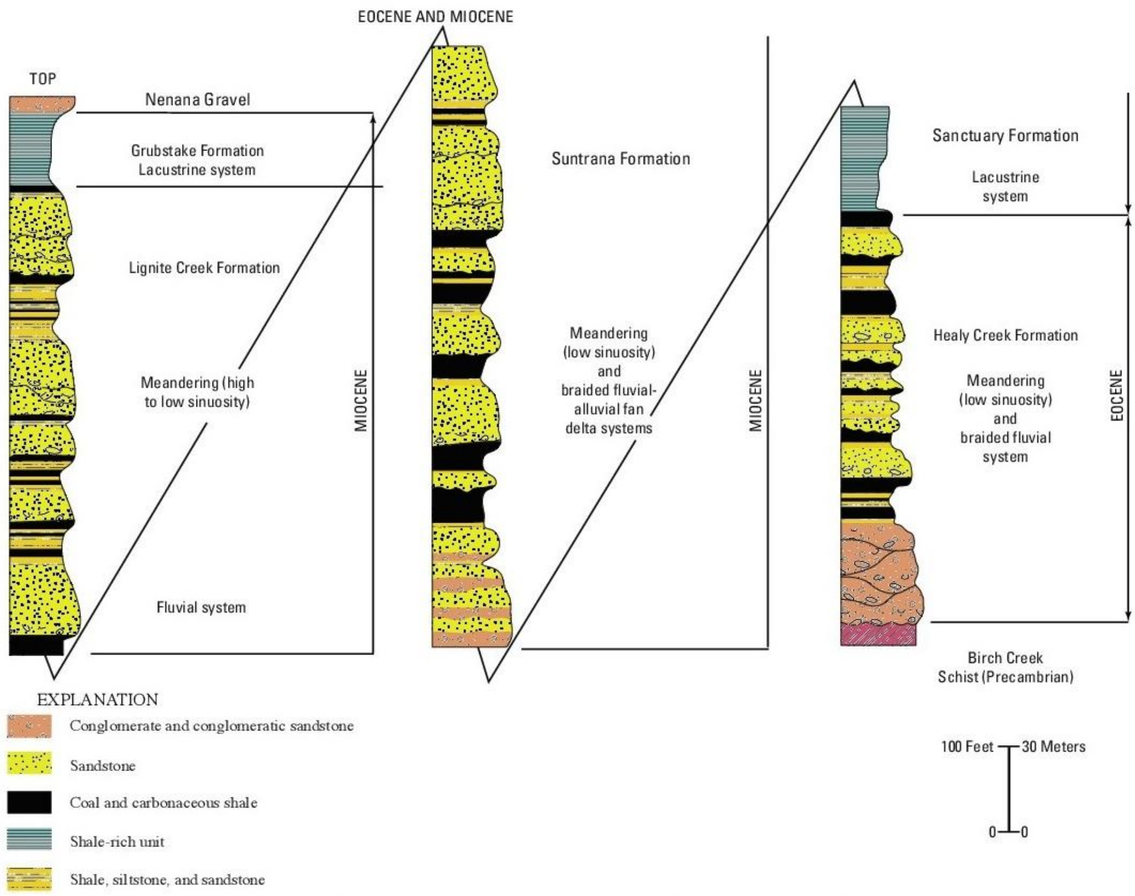


Source: Flores, R.M., Stricker, G.D., & Kinney, S.A. (2004). Alaska Coal Geology, Resources, and Coalbed Methane Potential. USGS DDS-77, U.S. Department of the Interior. http://pubs.usgs.gov/dds/dds-077/pdf/DDS-77.pdf

The Suntrana Formation unconformably overlies the Sanctuary Formation and is as thick as 1,310 feet (400 m). The Suntrana Formation is an important coal-bearing sedimentary unit of the group. It consists of interbedded sandstones, siltstones, mudstones, carbonaceous shales and coal. Shallow coal seams generally are encountered at depths less than 100 feet below ground surface and in seam thicknesses that can range up to 32 feet. Coal beds are interbedded with carbonaceous shales and have a combined thickness ranging from 1.6 to 65 feet. The Suntrana Formation lies directly on metamorphic basement rock in this area.

The Lignite Creek Formation ranges from 490 to 790 feet thick and overlies and is gradational with the Suntrana Formation. The Lignite Creek consists of interbedded sandstones, siltstones, mudstones, carbonaceous shales, and coals. The sandstones and mudstones are the most dominant. The coal beds are thin, generally less than three feet thick, woody, and relatively lenticular and interbedded with coarsening upward mudstones, siltstones, and silty sandstones. (Flores et al., 2004)

Figure 3.2-22. Usibelli Group Generalized Stratigraphic and Lithofacies



Source: Flores, R.M., Stricker, G.D., & Kinney, S.A. (2004). Alaska Coal Geology, Resources, and Coalbed Methane Potential. USGS DDS-77, U.S. Department of the Interior. http://pubs.usgs.gov/dds/dds-077/pdf/DDS-77.pdf

3.2.6.2 Matanuska Coal Field Geology

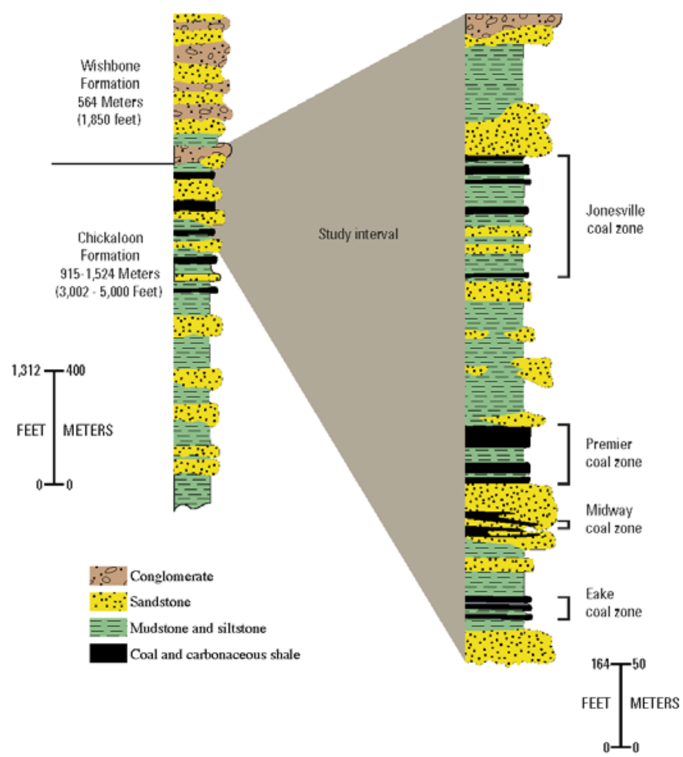
The Matanuska Coal Field is located in the Southern Alaska-Cook Inlet coal province. The province extends approximately 100 miles wide and 225 miles long, covering an area of about 22,500 square miles of which half is beneath the waters of Cook Inlet. Many of the Tertiary coal-bearing rocks in the province lie beneath the Cook Inlet, Susitna Lowland, Broad Pass Depression, Matanuska Valley, and Kenai Peninsula.

The Tertiary coal-bearing rocks in the Southern Alaska- Cook Inlet coal province accumulated in the subsiding Cook Inlet Basin, which was probably drained by a large, fluvial, trunk-tributary and alluvial fan system that flowed into the Pacific Alluvial fans drained the basin margins, and the trunk stream drained a broad alluvial plain now occupied by the Cook Inlet. Two major tributary streams of the trunk river extended northward through the present Susitna Lowland and Broad Pass Depression and eastward through the present Matanuska Valley. All the coal deposits in the Central Alaska-Nenana and Southern

Alaska-Cook Inlet coal provinces are thought to have accumulated in mires related to a large, integrated fluvial drainage system. (Flores, et al., 2004)

There are four on-shore tertiary-aged coal fields identified in the Southern Alaska -Cook Inlet province, including the Susitna-Beluga, the Kenai, the Broad Pass, and the Matanuska that border the Cook Inlet (Flores, et al., 2004). The bulk of the coal in the Southern Alaska-Cook Inlet coal province is of Oligocene to early Pliocene age. The late Tertiary coals are distributed in the Susitna-Beluga, Broad Pass, and Kenai coal fields. However, early Tertiary (Paleocene and early Eocene) coal occurs in the Matanuska Coal Field. The Matanuska Coal Field contains more than 20 coal beds with thicknesses ranging from three to 23 feet. These beds occur primarily in the Chickaloon Formation and Wishbone Formation, along with sandstones, siltstones, mudstones, and minor conglomerates (See Figure 3.2-23).

Figure 3.2-23. Generalized Stratigraphic Column of the Chickaloon and Wishbone Formations in the Matanuska Coal Field area



Source: Flores, R.M., Stricker, G.D., & Kinney, S.A. (2004). Alaska Coal Geology, Resources, and Coalbed Methane Potential. USGS DDS-77, U.S. Department of the Interior. Figure 45. http://pubs.usgs.gov/dds/dds-077/pdf/DDS-77.pdf

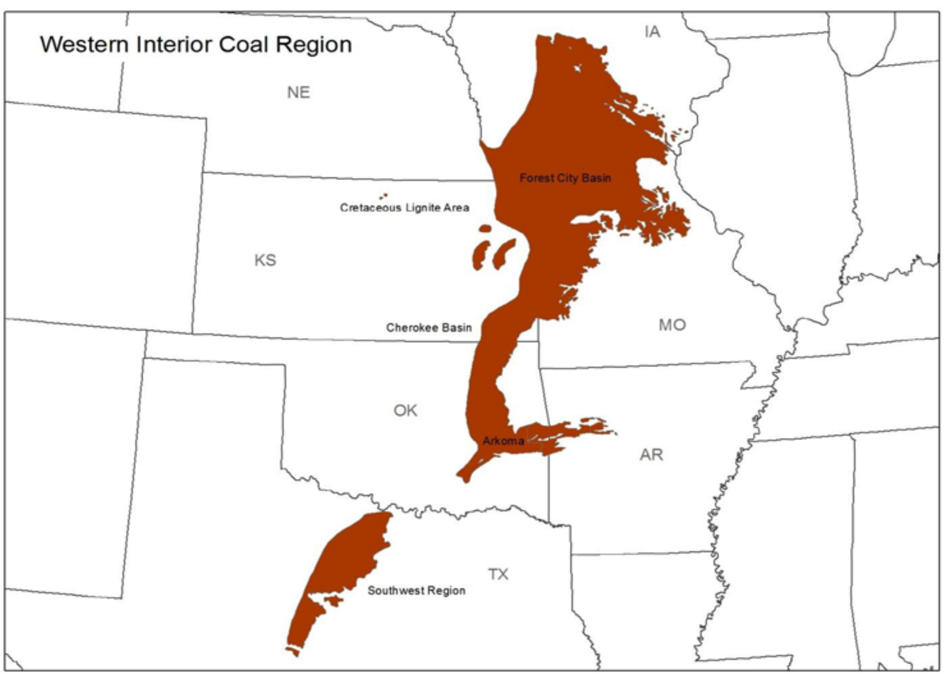
The Tertiary rocks include the Paleocene-Eocene Chickaloon Formation and Eocene Wishbone Formation. The Chickaloon Formation is a 3,280 to 4,920 feet thick Paleocene to lower Eocene sequence of mudstones, siltstones, and sandstones, with minor conglomerates and coal beds. The formation rests unconformably on the Cretaceous Matanuska Formation, which is a sequence of marine sandstone and shale and is overlain unconformably by the Eocene Wishbone Formation.

The Wishbone consists of 2,950 feet of thick, massive conglomerates and sandstones containing clasts derived from the Talkeetna Mountains to the north. The formation at the east end of the Matanuska coal field is unconformably overlain by flatlying Tertiary basalt. Gabbro sills and dikes and other Tertiary volcanic rocks also intrude the coal-bearing Chickaloon Formation and increase the coal rank along the intrusive contact. The intensity of deformation and abundance of igneous dikes and sills in the Chickaloon Formation increase eastward along the Matanuska coal field (Flores et al., 2004).

3.2.7 Western Interior Coal-Producing Region

The Western Interior region encompasses the coal-bearing areas of Iowa, Nebraska, Kansas, Oklahoma, Arkansas, Missouri and central Texas (See Figure 3.2-24). The most productive coal fields of the Western Interior region occur in three coal basins: Arkoma, Cherokee, and Forest City. The Arkoma Basin covers about 13,500 square miles in Arkansas and Oklahoma. The Cherokee Basin is part of the Cherokee Platform Province which covers approximately 26,500 square miles in Oklahoma, Kansas, and Missouri. The Forest City Basin covers about 47,000 square miles in Iowa, Kansas, Missouri, and Nebraska. For the purpose of this study, discussion will focus on these basins due to their importance to coal production.

Figure 3.3-24. Western Interior Region



Source: Data- USGS, 2011a, *Coal Fields*, U.S. DOI, http://nationalatlas.gov/atlasftp.html?openChapters=chpgeol#chpgeol

The Arkoma basin was depositionally part of a broad, stable shelf along a passive continental margin during much of its geologic history. The depositional patterns on the shelf varied greatly, with strata accumulating in both marine carbonate and terrestrial clastic environments. There is evidence of a limited source of sediments from the Ouachita fold belt in Arkansas during the deposition of the Pennsylvanian-aged Hartshorne Sandstone, an important coal-bearing formation in the basin. However, the western side of the basin in Oklahoma was apparently quiet and presumably stood at or near sea level throughout that time.

The Cherokee Basin is the central basin of the Western Interior Coal region. It is bounded on the east and southeast by the Ozark Dome, on the west by the Nehama Uplift, and on the north by the Bourbon Arch. The Cherokee Basin was formed by the downward warping of a post-Mississippian peneplain (a regional, flat, erosional surface). The basin was united with the similarly formed Forest City Basin when the low divide separating them was covered by the accumulated deposits of the Cherokee Shale. The Cherokee shale represents the oldest Pennsylvanian-aged formation in Kansas (Lee, 2005).

The Forest City Basin extends from southwestern Iowa and northeastern Kansas to central Missouri. The basin is approximately 240 miles long (north-south) by 195 miles wide (east-west). The basin exists today as a relatively under-formed Pennsylvanian-aged structural basin. A series of northwest-southeast trending folds and faults have been reported in the Missouri portion of the Arkoma Basin.

Sedimentary rocks in the Arkoma Basin range in thickness from 3,000 to 20,000 feet and consist primarily of pre-Mississippian carbonate shelf deposits, organic-rich Mississippian marine shales, and Pennsylvanian fluvial deposits. The Krebs Group, which contains the Hartshorne, McAlester, Savanna, and Boggy Formations, is a prominent coal-bearing unit of the basin. The Lower Hartshorne coal bed is the thickest and the most extensive coal bed in Arkansas and the Arkoma Basin. The Lower Hartshorne has been, and will continue to be, the most economically important coal bed in Arkansas (Arkansas Geological Survey, 2010). The Arkoma Basin contains approximately 40 named coal beds, as well as several unnamed coal beds.

3.2.7.1 Cherokee Basin Geology

The primary coal seams in the Kansas Cherokee Basin are the Riverton Coal of the Krebs Formation and the Weir-Pittsburg and Mulky coals of the Cabaniss Formation. These Pennsylvanian-aged formations consist primarily of shales, some sandstones, and minor amounts of limestone. The Riverton and Weir-Pittsburg coal beds, about three to five feet thick, are the thickest and most widespread of the units. The Mulky Coal can attain thicknesses of two feet. However, the Weir-Pittsburg coal beds and the Mulky Coal both occur at depths of several hundred feet and are mineable only by underground methods.

3.2.7.2 Forest City Basin Geology

In the Forest City Basin, coal-bearing strata are present in the Pennsylvanian-aged Riverton Formation and the Cherokee, Marmaton, and Pleasanton Groups. The coal-bearing units are cyclothems made up of shale, sandstone, limestone, and coal. More than 40 individual beds have been identified, and many have been mined for more than 100 years by both underground and surface methods. Some of the important coal beds which correlate across state boundaries are Riverton, Weir-Pittsburg, Mineral, Scammon, Fleming, Tebo, Croweburg, Bevier, Summit, Mulky, Mystic, and Mulberry. The coal beds are relatively widespread and commonly deep. As a result, many parts of the basin are underlain by multiple, unmined coal beds. The cumulative thickness of the coals may be as much as 25 feet with individual beds as thick as ten feet; however, many of the beds are less than two feet thick.

Depths to the top of the Cherokee Group coals range from surface exposures in the shallower portion of the basin in southeastern Iowa, to about 1,200 to 1,600 feet in the deeper parts of the basin in southwestern Iowa and northeastern Kansas (Bostic et al., 1993). Generally, Pennsylvanian coal rank increases with depth and westward location, where greater depths of sediment burial exist.

3.3 Soils

This section examines soil resources potentially affected by the Action Alternatives under consideration.

3.3.1 Introduction

Soil is a natural body comprised of solids (minerals and organic matter), liquid, and gases that occurs on the land surface, occupies space, and is characterized by horizons (layers) that are distinguishable from the initial material (bedrock or other parent material) as a result of additions, losses, transfers, and transformations of energy and matter or the ability to support rooted plants in a natural environment (NRCS, 1999). Soil consists of the horizons near the earth's surface that, in contrast to the underlying parent material, have been altered by the interactions of climate, topography, and living organisms over time (NRCS, 1999). The upper limit of soil is the boundary between soil and air, shallow water, live plants, or plant materials that have not begun to decompose (NRCS, 1999). Commonly, soil grades at its lower boundary to unfragmented rock or to earthy materials virtually devoid of animals, roots, or other marks of biological activity (NRCS, 1999). However, the lowest depth of biological activity is difficult to discern and is often gradual. Therefore, for purposes of classification, the U.S. Department of Agriculture, Natural Resources Conservation Service (NRCS) considers the lower boundary of soil in indistinct situations to be 200 cm (approximately 6.5 feet) (NRCS, 1999). Areas are not considered to have soil if the surface is permanently covered by water too deep for the growth of rooted plants (typically, more than 2.5 meters—approximately 8 feet) (NRCS, 1999).

Factors that contribute to soil development include parent material, climate, topography, biological factors, and time. Parent material is generally bedrock, glacial till, colluvium (material moving in response to gravity), or alluvium (material deposited by rivers and streams) on which a soil forms (U.S. EPA et al., 2003). Climate affects soil composition by freeze/thaw action and by controlling the rate at which physical and chemical weathering take place. Wind and water both remove and deposit soil materials. Soils undergo continual development because of the cumulative effects of all these factors. The time required for soil to form from parent materials ranges from hundreds to tens of thousands of years. Well-drained mine spoils have been observed to begin the process of A-horizon formation in as few as 10 to 20 years after mining.

Physical, chemical, and biological properties of soils determine their productivity and susceptibility to compaction and erosion. The potential for plant growth depends on the ability of the soil to accept, hold, and release nutrients and moisture. Soil provides the environment for root growth and development. It provides habitat for microorganisms that control processes related to plant nutrition, nutrient cycling, and the biological control of pests. The condition of the soil determines the effectiveness of these functions.

In the U.S., soil scientists recognize twelve basic types of soils known as orders. These orders reflect the environment in which soils form, their age, and the ecosystems they support. Of the 12 soil orders, the 11 listed below are present in the coal-producing regions:

- Andisols – dark soils formed from volcanic activity;
- Alfisols – brown forest soils;
- Aridisols – arid region soils;
- Entisols – very young soils that show little weathering;
- Gelisols – frozen soils of tundra areas;
- Histosols – organic soils in marshy or montane areas;
- Inceptisols – young soils;
- Mollisols – dark, rich soils of the plains (mostly grasslands);
- Spodosols – ashy soils of wet, sandy areas;
- Ultisols – highly weathered soils of mostly temperate areas; and
- Vertisols – soils with shrink-swell clays.

Soils are further divided by similar characteristics into suborder, great group, subgroup, family, and soil series. There are more than 19,000 soil series in the U.S. (NRCS, 2011). Throughout this section, certain soil suborders and great groups (italicized) are included with the soil orders to provide a more detailed description of soils within the various regions.

Soil productivity is the ability of a soil to produce vegetation, either in general or in terms of a specific crop. The physical (texture and structure), chemical (organic matter decomposition and nutrient release), and biological (nutrient cycling and nitrogen fixation) properties of soil supply the required air, water, and nutrients the plants require for plant growth (BLM, 2008).

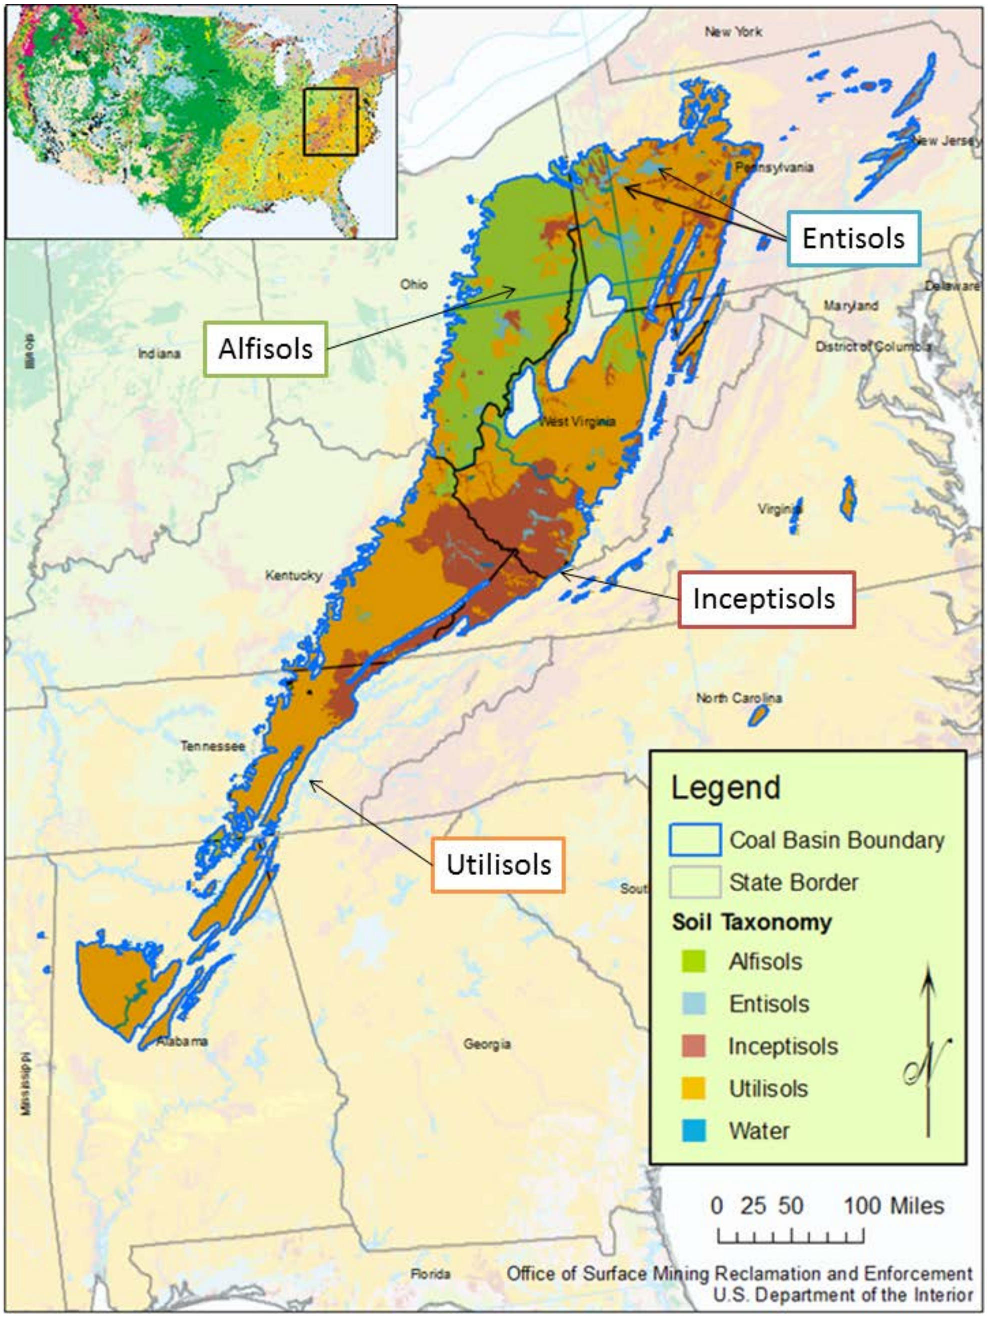
To describe the soil resources potentially affected by the Action Alternatives, this section briefly discusses the dominant soil orders, suborders, and soil associations of the ecoregions (McNab and Avers, 1994) in each coal region. Soil distribution can be very heterogeneous, creating a mosaic of soil types over small areas.

3.3.2 Appalachian Basin Region

3.3.2.1 Description of Soils in Region

The Appalachian Basin region (see Figure 3.3-1) features soils that are predominantly colluvial in nature, i.e., soils that occur on mountain slopes formed on residuum from acidic sandstone, siltstone, and shale. These associations/complexes typically occur on steep side slopes at higher elevations. They form on residuum or creep material from acidic sandstone, siltstone, and shale. These soils are very thin—typically 0-3 inches of topsoil and 1.5-5 feet of subsoil underlain by bedrock. Logging methods may adversely affect topsoil thickness (U.S. EPA et al., 2003).

Figure 3.3-1. Soil Orders of the Appalachian Basin Region



Source: NRCS, 2011, *U.S. General Soil Map (STATSGO2) - Soil Data Mart*, U.S. Department of Agriculture (USDA), downloaded from: http://www.nrcs.usda.gov/wps/portal/nrcs/detail/soils/survey/geo/?cid=nrcs142p2_053629

The presence of deeper colluvial and residual weathered deposits on southwest slopes that receive higher precipitation amounts than slopes with other aspects make slopes with a southwest aspect susceptible to landslides.

The most extensive soils in the Appalachian Basin region are Ultisols. Ultisols are generally deep to moderately deep, leached, acidic, and highly weathered. They have a low nutrient content and their ability to retain minerals is moderate to low. Inceptisols are immature soils that occur on steep slopes and in depressions in the region. They form from highly resistant parent material or in alluvial floodplains. Inceptisols are predominantly found on slopes and in depressions in warmer temperature regimes. These soils are generally thin but can be deep in places. They are better able to retain minerals than the Ultisols. Alfisols, which are moderately deep, are also present. Typically, xeric shallow soils are present along the tops of cliffs and rock outcrops, while thin rocky soils accumulate in crevices, on ledges, and along rock margins.

Ecological areas, referred to as ecoregions, in the Appalachian Basin are the Southern Unglaciated Allegheny Plateau, Allegheny Mountains, Northern Cumberland Mountains, and Northern Cumberland Plateau. Soil descriptions of the ecological areas can be summarized as follows (OSMRE, 2008):

- Southern Unglaciated Allegheny Plateau ecological area soils consist mostly of Ultisols (Udalfs, Udults, and Ochrepts). Soil conditions are moist for most of the growing year and the soils have a mixed-clay or primary-clay mineralogy. These fine-loamy or clayey soils are frequently in a reducing environment.
- Soils in the Allegheny Mountains ecological area are predominantly Ultisols, Inceptisols, and Alfisols and are moist for most of the growing year. They are derived from heavily weathered shales, siltstones, sandstone residuum, colluvium, and limestone residuum. Spodosols with frigid temperature regimes and reducing environments occur in isolated pockets at the highest elevations.
- Northern Cumberland Mountains ecological area soils are mainly Ultisols, Inceptisols, and Alfisols. These fine- to coarse–loamy soils are moist for most of the growing year. They are derived from heavily weathered shales, siltstones, sandstone residuum and colluvium, and limestone residuum. Ultisols and Inceptisols (Dystrochrepts, Hapludults, and Fragiudults) on plateaus and upper slopes are fine-loamy to loamy with a siliceous or mixed mineralogy.
- Ultisols dominate side slopes and ridges in the Northern Cumberland Plateau ecological area. Inceptisols are found on slopes and Entisols on floodplains. These medium- to-fine-textured, shallow to deep soils with a siliceous or mixed mineralogy are moist for most of the growing year.

3.3.2.2 Productivity and Reclamation Potential

Throughout much of the Appalachian Basin, reclaimed soils are frequently very thin. Excessive grading caused by the need to restore appropriate slopes as well as additional grading to redistribute soil has resulted in over-compaction. This compaction of soil and root zone media makes revegetation with species other than grasses difficult and has historically inhibited the reestablishment of desired hardwood forests after mining. However, more recent efforts at reestablishing hardwood forests on mined lands in the Appalachian Basin, based on current research indicating that trees grow well in uncompacted mine spoil, have been successful (Burger et al., 2005). In partnership with industry, universities, and the states, OSMRE has developed the Appalachian Region Reforestation Initiative to promote reclamation and reforestation using the Forestry Reclamation Approach. This approach minimizes grading and compaction, thus facilitating successful tree root development and vigorous tree growth, with a high potential for successful forestry postmining land uses.

3.3.3 Colorado Plateau Coal-Producing Region

3.3.3.1 Description of Soils in Region

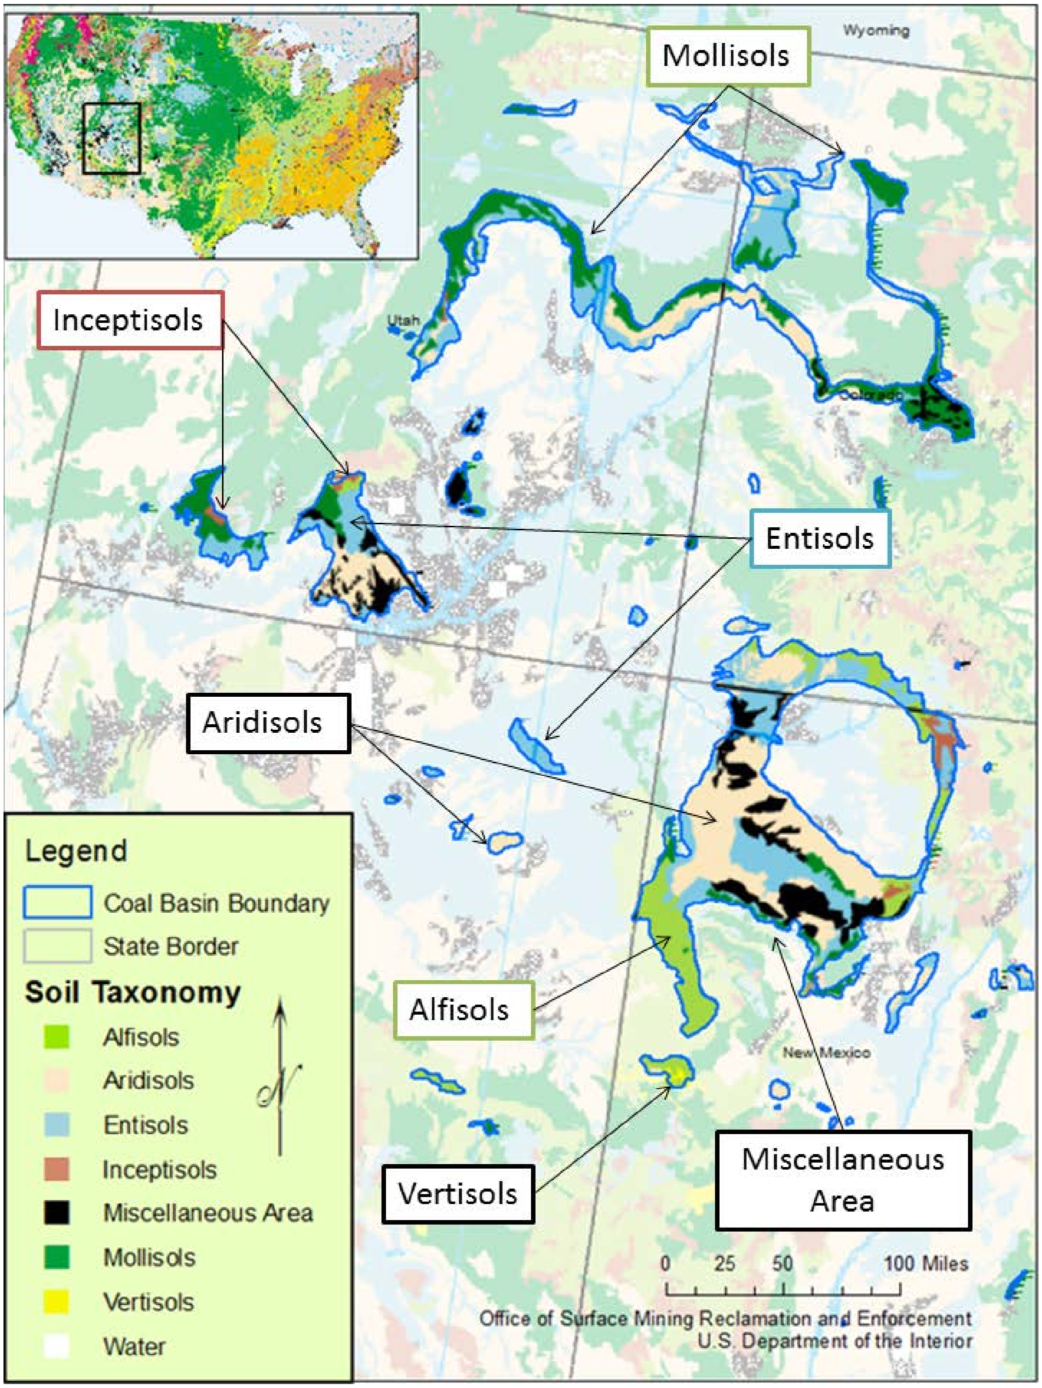
The Colorado Plateau (see Figure 3.3-2) is predominantly composed of Alfisol, Aridisol, Entisol, Inceptisol, and Mollisol soils. Alfisols are predominant in forested areas at high elevations. Aridisols are a common soil series in the western U.S. and are formed in areas that are dry for long periods of time. Entisols of the western U.S. are generally Orthents found on recent erosional surfaces. These soils support rangeland, pasture, and wildlife. Inceptisols in this region occur mostly at high elevations where the vegetation is mostly conifers or mixed conifers. Mollisols form in grasslands and are the dominant soils of the plains and high-elevation plateaus and ridgetops.

Colorado Plateau soils are generally cool soils with dark-colored, organic-rich surface horizons in moderately sloping areas and shallow, poorly developed soils in steeper areas and on rock outcrops. Soils on upper slopes have a thin organic-rich surface horizon and soils on the lower slopes range from shallow to moderately deep. These soils are generally formed in colluvium, with a few formed in residuum derived from shales and sandstone. Some are formed from eolian (wind-deposited) material. Biological crusts, a complex mosaic of blue-green algae, green algae, lichens, mosses, microfungi, and other bacteria (Belnap et al., 2001) are also present. These fragile crusts affect water retention and infiltration and surface runoff and may reduce soil erosion.

Ecological areas in the Colorado Plateau region are the Navajo Canyonlands, Tavaputs Plateau, and Southern Parks and Ranges. Soil descriptions of the ecological areas can be summarized as follows (OSMRE, 2008):

- Soils in the Navajo Canyonlands ecological area are mostly Aridisols with some Inceptisols, Alfisols, and Entisols. Soils are fine- to coarse-loamy, generally dry, and shallow, especially along slopes. Entisols can be rocky or gravelly.
- The Tavaputs Plateau ecological area soils include Entisols and Aridisols with moderate moisture, cold soil temperature regimes, and arid soil moisture regimes (dry for at least half the year). Entisols are generally fine-loamy, but can be clayey. Most soils contain calcium. Many soils (Entisols, Aridisols, and the less common Inceptisols) are shallow-rocky or loamy-skeletal with cold temperature regimes.
- Soils in the Southern Parks and Ranges ecological area are Alfisols and Mollisols. Fine, kaolinitic, and fine-loamy Alfisols are present, along with fine-grained Mollisols.

Figure 3.3-2. Soil Orders of the Colorado Plateau



Source: NRCS, 2011, *U.S. General Soil Map (STATSGO2) - Soil Data Mart*, USDA, downloaded from: http://www.nrcs.usda.gov/wps/portal/nrcs/detail/soils/survey/geo/?cid=nrcs142p2_053629

The NRCS identifies more than 580 soil associations in the ecological regions in the Colorado Plateau region. While not technically a soil, rock outcrops are part of the soil mapping scheme. These outcrops are extensive throughout the Colorado Plateau.

3.3.3.2 Productivity and Reclamation Potential

Most of the Colorado Plateau is arid to semiarid, although some areas are forested. Precipitation is a limiting factor when revegetating mined land. Elevated soil salinity levels can limit productivity. To establish vegetation, soil substitutes and supplements are commonly used, particularly in areas with shallow or rocky soils. Seed mixes of native and non-native species are tailored to the individual environment. Seeding is done during seasons with the best chance for precipitation.

3.3.4 Gulf Coast Coal-Producing Region

3.3.4.1 Description of Soils in Region

The Gulf Coast region (see Figure 3.3-3) consists of lignite fields that spread from southern Texas northeastward into northern Louisiana and southern and south-central Arkansas. A separate lignite field stretches north from the Mississippi Embayment area into parts of far western Tennessee and Kentucky and east into southern Alabama. Although lignite is present in all of these states, it is only mined in Texas, Louisiana, and Mississippi. For this reason, the following discussion focuses on the lignite-mining portions of these three states.

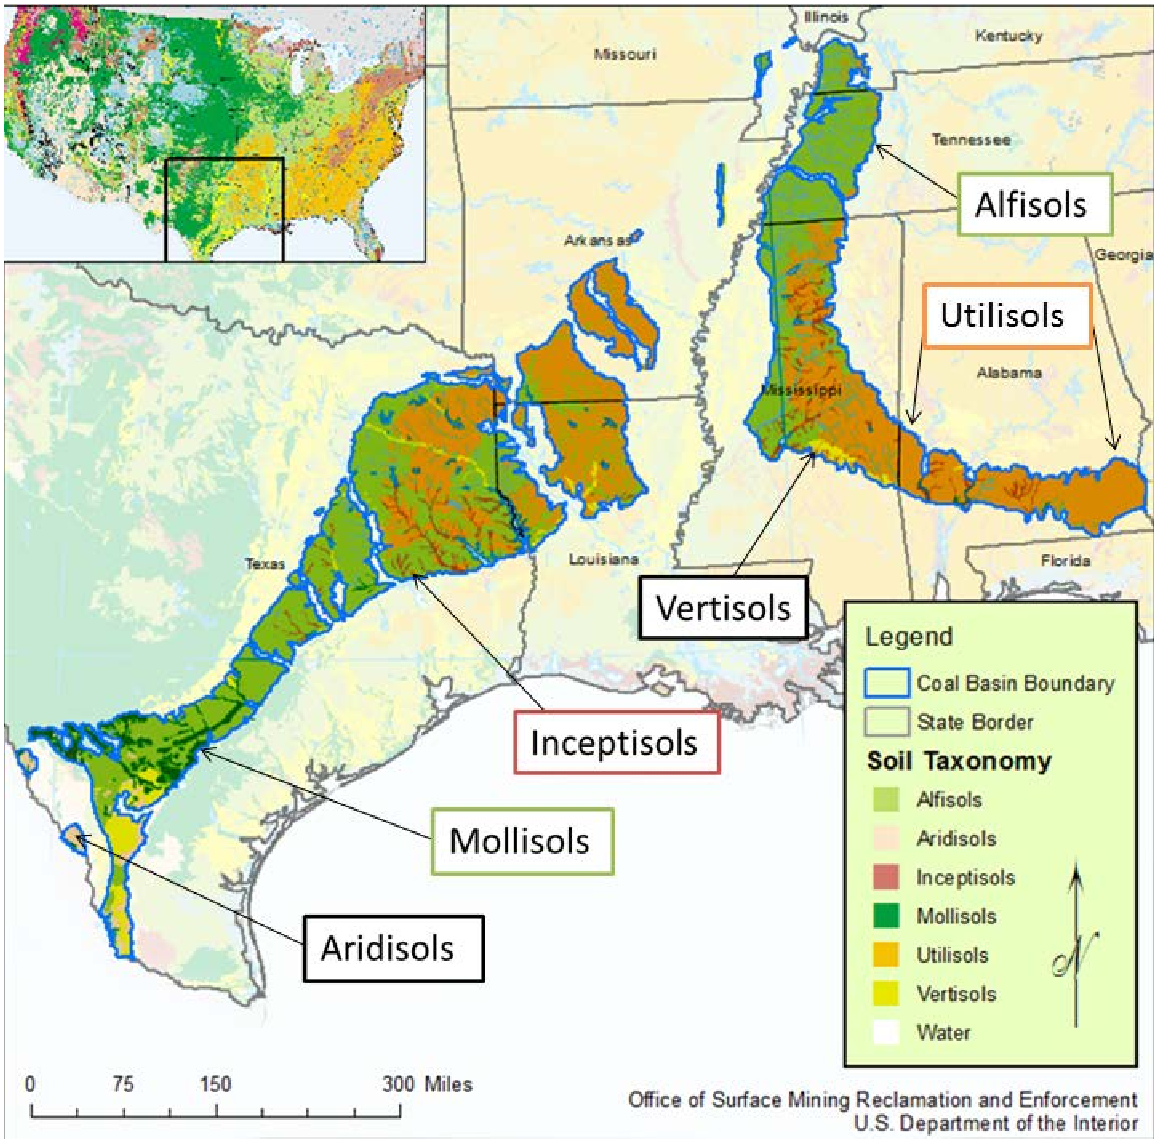
Soils in the Gulf Coast region are predominantly Alfisols, Inceptisols, Mollisols, Ultisols, and Vertisols. Alfisols occur in dry areas of the southern Great Plains, mostly in Texas. They support savanna and grassland vegetation. Entisols in the Gulf Coast region are present along the coast and on floodplains, fans, and small streams. Inceptisols, Mollisols, and Vertisols occur in temperate subhumid or semiarid regions. Ultisols occur in wet environments and support cropland and forests.

Gulf Coast region soils range from dry (as in south Texas) to wet (as in eastern Texas, Louisiana and Mississippi) and most soils are on flat to gently rolling plains dissected by streams. Soils in the major coal areas of eastern Texas are generally well-developed clayey or loamy soils. They tend to have high shrink-swell properties. Soils further east in the more humid environment of Louisiana and Mississippi are rich organic Entisols, Vertisols, and Ultisols.

Ecological areas in the Gulf Coast region are the Rio Grande Plain; Oak Woods and Prairies; Coastal Plains and Flatwoods – Western Gulf; Mid-Coastal Plains – Western; Coastal Plains – Middle Section; and Lower Coastal Plains and Flatwoods. Soil descriptions of the ecological areas are as follows (OSMRE, 2008):

- Rio Grande Plain ecological area soils consist of Usterts, Torrerts, and Ustalfs. Pellusterts, including Calciustolls and Calciorthids are found on plains over clayey marine sediments. Torrerts, Haplustolls, Calciustolls, Paleustalfs, and Haplustalfs are found on plains. Soils have a hyper thermic temperature regime, an ustic or aridic moisture regime, and mixed mineralogy. Soils are mostly deep, fine- to coarse-textured, well-drained, and have limited soil moisture for use by vegetation during the growing season.

Figure 3.3-3. Soil Orders of the Gulf Coast



Source: NRCS, 2011, *U.S. General Soil Map (STATSGO2) - Soil Data Mart*, USDA, downloaded from: http://www.nrcs.usda.gov/wps/portal/nrcs/detail/soils/survey/geo/?cid=nrcs142p2_053629

- In the Oak Woods and Prairies ecological area, soils are predominantly Ustalfs. Paleustalfs and Albaqualfs are found on uplands and other areas with thick sandy surfaces. Pelluderts, Pellusterts, and Hapludolls are found on floodplains and clayey terraces along major rivers. These soils have a thermic temperature regime, an ustic moisture regime, and montmorillonitic mineralogy. Soils are deep, medium-textured, and generally have a slowly-permeable, clayey subsoil. Moisture may be limiting for plant growth during parts of the year.
- Soils of the Coastal Plains and Flatwoods – Western Gulf ecological area are mostly siliceous fine clays and fine silty clay Alfisols with lesser amounts of coarser siliceous Entisols and

Ultisols. Ultisols (Udults, Paleudults, and Hapludults) and Alfisols (Hapludalfs, Paleudalfs, and Albaqualfs) occur on uplands. Entisols (Fluvaquents, Udifluvents) and the less common Inceptisols occur along major streams. Soils are mostly derived from weathered sandstone and shale and of siliceous or mixed mineralogy. Soils are deep, coarsely-textured, moist, and mostly well-drained.

- The Mid-Coastal Plains – Western ecological area soils are predominantly Ultisols. Alfisols and some Ultisols are found on uplands. Entisols, Inceptisols, and Alfisols are found on bottomlands along major streams. Soils are generally fine-grained, but some coarser soils are present. Siliceous mineralogy is prevalent with lesser amounts of clayey and kaolinitic soil series.
- Coastal Plains – Middle Section soils are mostly Ultisols characterized by fine to fine-loamy siliceous material with lesser amounts of coarser Entisols, Inceptisols and wetter Alfisols. Ultisols are on level to strongly sloping uplands and occur on less sloping, moderately well-drained areas. Small but significant areas of Alfisols and Entisols are present in localized areas and bottomlands. Ultisols are found in low-elevation wetlands. Soils are deep and loamy, clayey, or sandy with poor to good drainage.
- Soils of the Lower Coastal Plains and Flatwoods ecological area are predominantly Ultisols with fine to fine-loamy clays with a thermic temperature regime and a moist moisture regime. Soil texture ranges from fine-silty to fine-loamy to sandy. Mineralogy ranges from quartzitic to arkosic to clayey to micaceous. Soils are deep, moderately-permeable, and well-drained.

3.3.4.2 Productivity and Reclamation Potential

Productivity and reclamation potential vary throughout the Gulf Coast region. Soils in the lignite areas of Louisiana and Mississippi typically possess high productivity and reclamation potential. However, in the immediate area of current coal production, soils have more substantial limitations, which commonly result in the use of topsoil substitutes. Climate and water availability can influence productivity. Soils in Texas are more variable with productivity and reclamation potential ranging from poor in the dry south to fair in the wetter east. All current coal-producing areas contain certain soil types with one or more of the following limitations: (1) poor parent materials (residuum), (2) less than ideal soil texture, (3) extreme weathering, and (4) acidic soil chemistry.

Operators commonly use topsoil substitutes in the Gulf Coast region to achieve an increase in productivity over the highly eroded and weathered native soils. The NRCS has developed mapping units for many mined areas in Texas that have been reclaimed using soil substitute materials. Although limited in acreage, two postmining soil substitute mapping units within the state have been classified as prime farmland soils (Bigbrown and Grayrock) (Bearden, E.D., 1997; NRCS, 2013).

3.3.5 Illinois Basin Coal-Producing Region

3.3.5.1 Description of Soils in Region

The Illinois Basin (see Figure 3.3-4) contains the southern two-thirds of Illinois, southwestern Indiana, and part of western Kentucky. Soils in the Illinois Basin are Mollisols, Alfisols, Inceptisols, and Entisols. Mollisols, predominant in the northern half of the region, reflect their prairie origins and are mostly freely-draining. Originally dominated by tallgrass prairie, these soils are now used primarily as cropland and pasture/hayland, with some grazing land. A high percentage of these soils are designated as prime farmland. Alfisols predominate in the southern half of the basin and are present over much of the area near the Mississippi and Ohio Rivers. Entisols occur in the vicinity of rivers and streams in the Illinois Basin coal region. These soils support vegetation that tolerates permanent or periodic saturation.

Soils in key ecological areas can be described as follows (OSMRE, 2008):

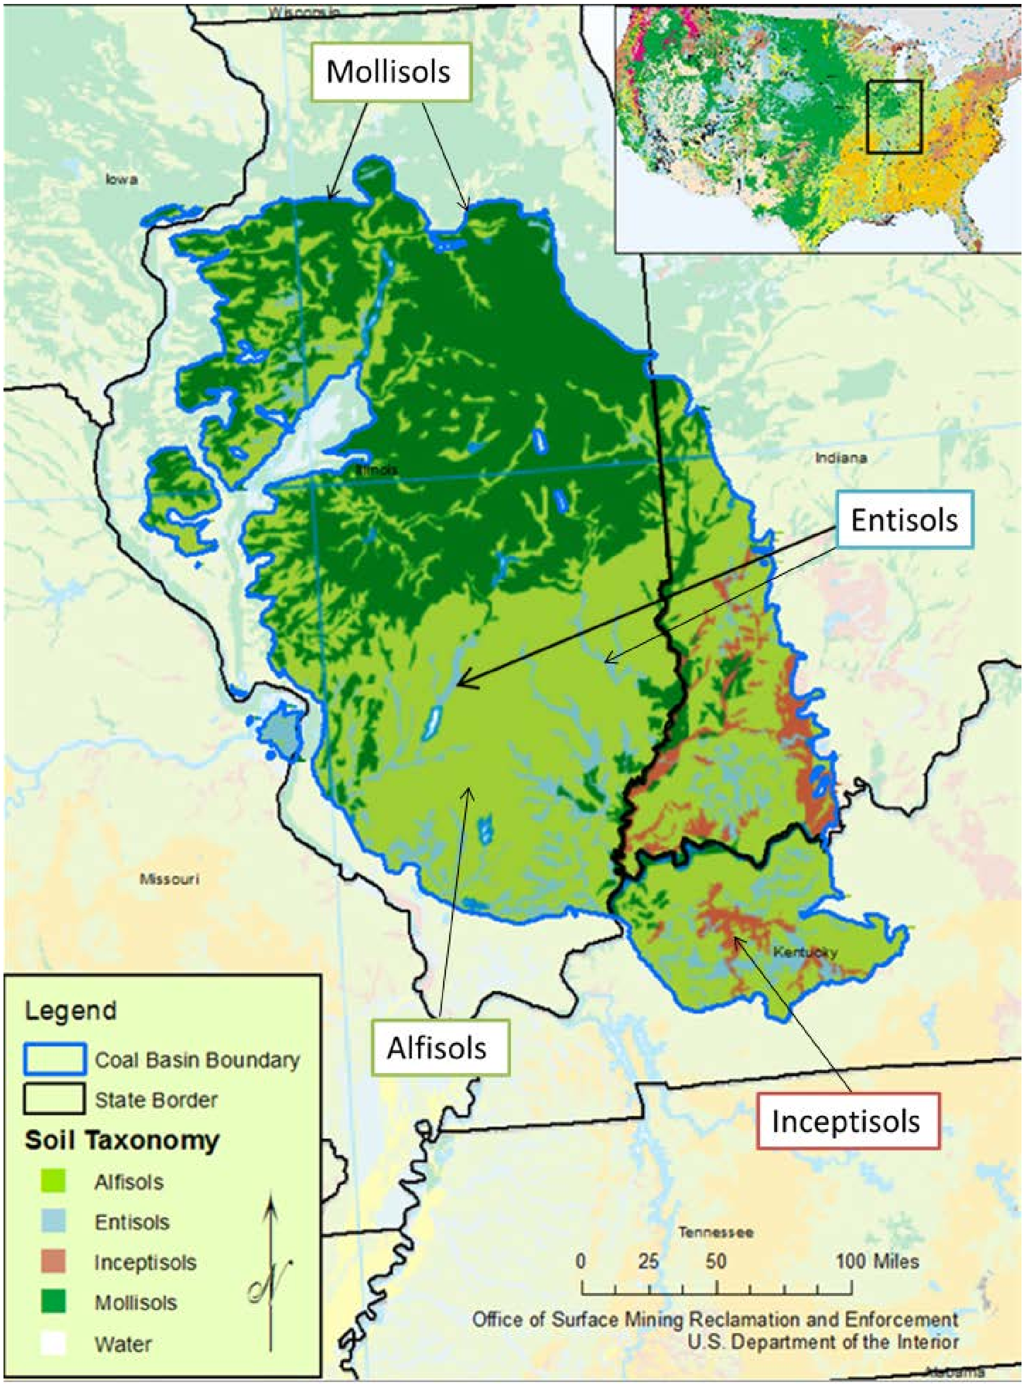
- Central Till Plains - soils are mostly Ultisols and Alfisols, but Inceptisols and Mollisols are also present. Soils tend to have relatively thick upper horizons that are darkened by decomposed organic matter. They are very productive for agricultural crops and are predominantly designated as prime farmland soil types. Located on floodplains and till plains, these soils are commonly poorly-drained, with fine-silty to coarse-silty textures.
- Interior Low Plateau - Shawnee Hills soils formed from loess, residuum, and alluvium. The area is dominated by Ultisols and Alfisols with Inceptisol inclusions. These fine-silty and fine-loamy soils are generally well-drained to moderately well-drained.

3.3.5.2 Productivity and Reclamation Potential

Soils in the Illinois Basin coal region are highly productive, supporting primarily agricultural land uses of cropland and pastureland. The thickness, texture, and high organic content of these soils afford good handling characteristics and promote rapid revegetation after disturbance. This region’s flat to rolling topography and overall lack of steep slopes also contribute to excellent reclamation potential. Prime farmland soils reclaimed after mining have experienced 100 percent restoration of agricultural productivity.

Proper soil handling and replacement techniques are essential in the reclamation of these prime farmland soils to avoid compaction and a reduction in agricultural crop productivity. The region’s less fertile native soil types generally are reclaimed to non-agricultural postmining land uses, frequently fish and wildlife or forestry. When compaction is avoided, these soils can readily support excellent forestry and wildlife postmining land uses.

Figure 3.3-4. Soil Orders of the Illinois Basin



Source: *U.S. General Soil Map (STATSGO2) - Soil Data Mart*, USDA, downloaded from: http://www.nrcs.usda.gov/wps/portal/nrcs/detail/soils/survey/geo/?cid=nrcs142p2_053629

3.3.6 Northern Rocky Mountains and Great Plains Coal-Producing Region

3.3.6.1 Description of Soils in Region

Soils in the Northern Rocky Mountains and Great Plains region (see Figure 3.3-5) have generally developed from residual material (residuum) and alluvium in a climate of cold winters, warm summers, and low precipitation. The upland soils are derived from both residual material (flat-lying, interbedded sandstone, siltstone, and shale) and stream alluvium. Valley soils have developed from unconsolidated stream sediments, including silt, sand, and gravel (BLM, 2003b). Exposed bedrock is present on steep slopes.

The most extensive soils are Entisols, which occur mainly on sloping topography. The physical and chemical characteristics of Entisol soils largely depend on the soil parent materials and the bedrock on which they occur. These soils generally are low in plant nutrients and commonly have clay textures.

The coal-rich Powder River Basin has large areas of gently sloping to nearly flat topography with Aridisol soils. These soils have low to moderate organic matter content and plant nutrients in the surface horizons. They also have moderate to strong structural development within the surface and subsoil horizons. This results in a more fertile rooting zone, particularly when soil textures are loamy rather than sandy or clayey.

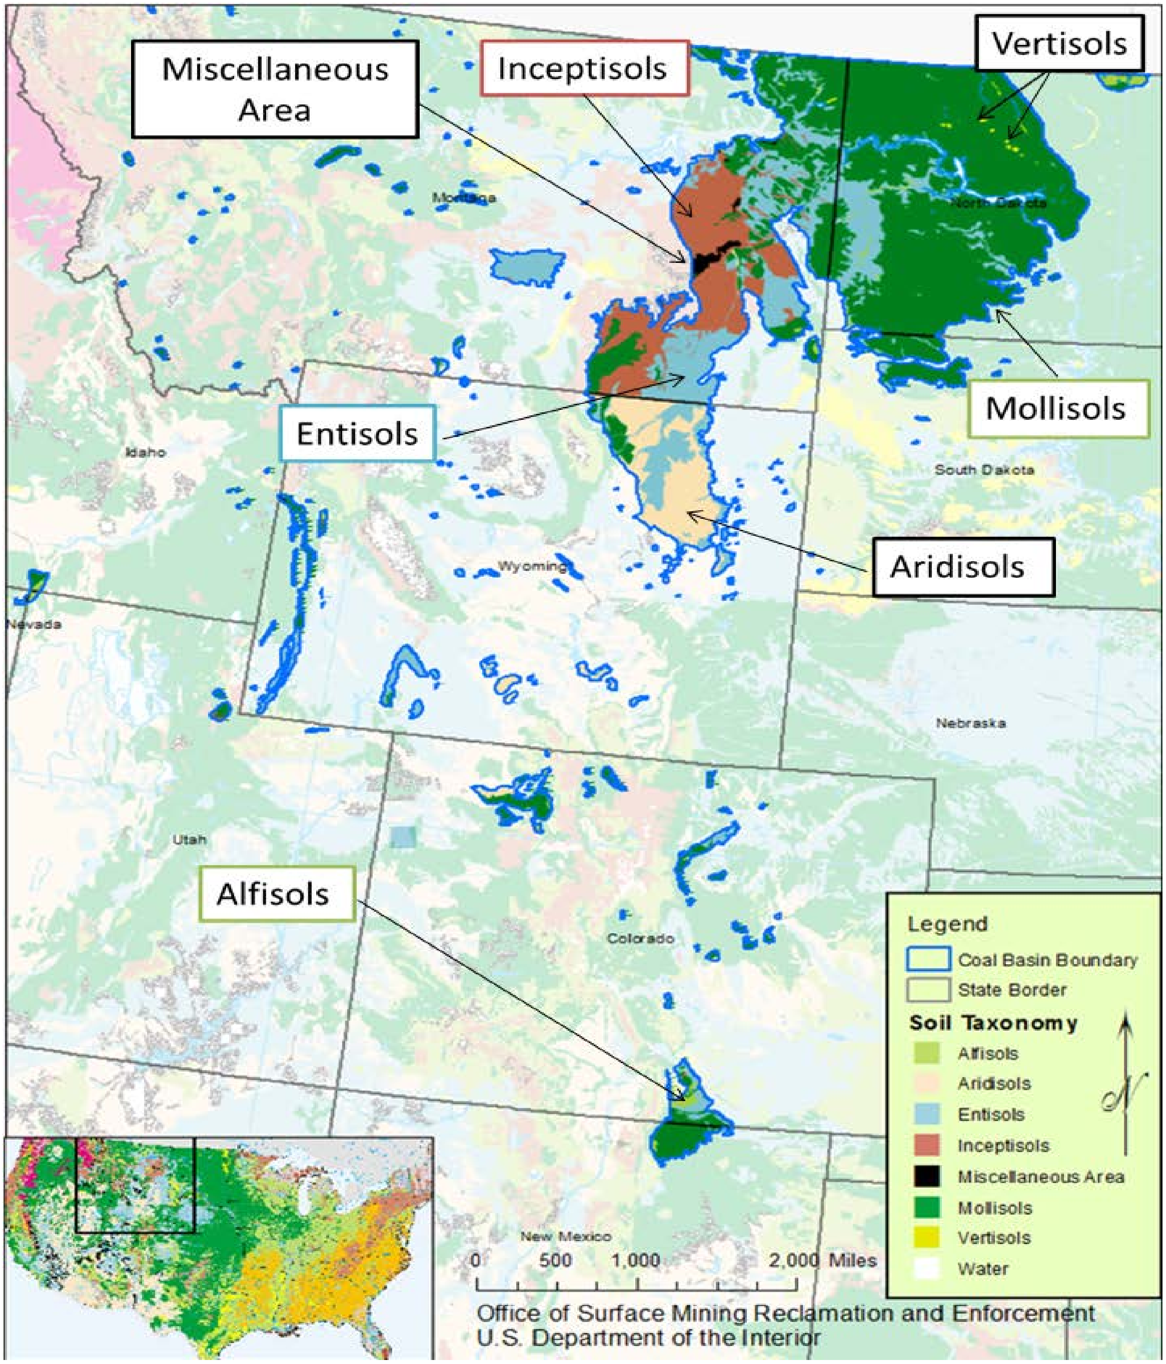
Mollisol soils occur mainly in western North Dakota. These fertile soils contain high levels of organic matter and nutrients. They are commonly classified as prime farmland.

Soils in rolling to steep mountainous terrain are generally formed from residuum and transported material from bedrock. Soils are shallow to deep, well-drained, and moderately-permeable (Lowham et al., 1985). Runoff potential is moderately low to high and erodibility is low to moderate. The most abundant soils are found on alpine slopes and meadows and are generally classified as Cryoboalfs (Gaggiani et al., 1987).

Plains soils are derived from transported and residual materials. They generally contain organic material, are fine-grained, and are more alkaline than mountain soils (Lowry et al., 1983). The low to moderate permeability of these soils can result in moderate to high surface runoff from precipitation events (Lowry et al., 1983). Additionally, soils on the Plains are subject to wind erosion. Biological crusts, a complex mosaic of blue-green algae, green algae, lichens, mosses, microfungi, and other bacteria (Belnap et al., 2001) are also present in the Northern Rocky Mountains and Great Plains region. These fragile crusts affect water retention and infiltration and surface runoff and may reduce soil erosion.

Fluvial soil types are found on gently sloping to flat drainage bottoms in the Powder River Basin. Fluvial soils vary considerably in fertility, depending on the source of alluvium. When low in salts and sodium, these soils tend to be very fertile and are the most productive in the Basin (BLM, 1984).

Figure 3.3-5. Soil Orders of the Northern Rocky Mountains and Great Plains



Source: NRCS, 2011, *U.S. General Soil Map (STATSGO2) - Soil Data Mart*, USDA, downloaded from: http://www.nrcs.usda.gov/wps/portal/nrcs/detail/soils/survey/geo/?cid=nrcs142p2_053629

3.3.6.2 Productivity and Reclamation Potential

Reclamation potential varies, depending on soil type, depth, and slope. On the Great Plains, precipitation is the main factor in determining reclamation success, especially for native species. The North Dakota lignite area receives greater precipitation than the Powder River Basin. Reclamation of these soils is successful when best management practices are applied, including use of the appropriate seeding mixture (native and non-native species) and soil substitutes and supplements. Reclamation potential in mountainous areas is generally poor because of the soil type, limited depth of soil, slope, and dry conditions, except in mountain meadows.

3.3.7 Northwest Coal-Producing Region

3.3.7.1 Description of Soils in Region

The soils of Alaska are primarily in one soil order, the Inceptisols. Therefore, the discussion below provides information down to the next lower soil taxonomic levels of the Group and Subgroup based on soils information provided for each ecoregion of Alaska in USGS Professional Paper 1567 titled "Ecoregions of Alaska" by Alisa Gallant, Emily Binnian, James Omernik and Mark Shasby, referred to from here forward as Gallant et al., 1995. The Nenana and Matanuska coal fields of Alaska are located within three ecoregions: the Interior Forested Lowlands and Uplands ecoregion, the Alaska Range ecoregion, and the Cook Inlet ecoregion. Soils are extremely diverse, ranging from areas containing little to no soil in rugged terrain to deep glacial deposits in lowland areas. Soils containing permafrost and peat also are found within this area.

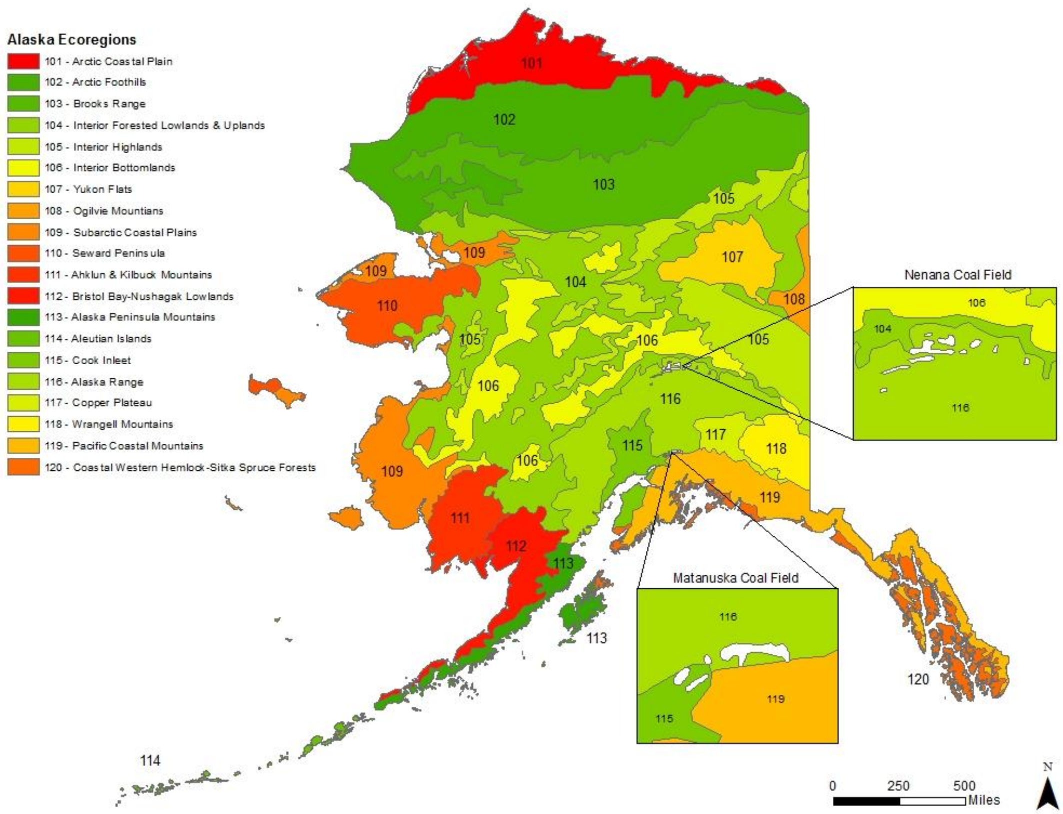
The Cook Inlet ecoregion is underlain by deep glacial deposits. Upper soil horizons are formed from loess and from windblown volcanic ash. This ecoregion contains peat deposits, but is generally free from permafrost. The dominant soils are Haplocryands, Sphagnic Borofibrists, Terric Borosaprists, Typic Borohemists, Andic Haplocryods, and Andic Humicryods (Gallant et al., 1995).

The dominant soils within the Alaska Range ecoregion are Typic Haplocryands and Typic Vitricryands. Glacial deposits are the predominant soil parent material, with some soils forming in deposits of ash and cinder. The soils are highly erodible. Steep slopes and mountain peaks have little or no soil cover (Gallant et al., 1995).

Upland soils within the Forested Lowland and Upland ecoregion formed from loess and colluvial material. Some upland soils formed from residual rock parent material. Lowland soils formed from loess and alluvium. They tend to be shallow and underlain by permafrost. The dominant soils within this ecoregion are Histic Pergelic, Cryaquepts, Pergelic Cryaquepts, Aquic Cryochrepts, Pergelic Cryochrepts, Typic Cryochretps, Typic Cryorthents, and Pergelic Cryumbrepts (Gallant et al., 1995).

Figure 3.3-6 below is adapted from Gallant et al., 1995 and depicts each of the ecoregions in numeric codes as follows: 104 for the Forested Lowland and Upland ecoregion, 115 for the Cook Inlet ecoregion and 116 for the Alaska Range ecoregions. Additional information about each of these ecoregions as well as for the other ecoregions not described above can be found in the source document.

Figure 3.3-6. Alaska Ecoregions



Source: Derived from spatial data downloaded August 2016 from https://www.epa.gov/eco-research/level-iii-and-iv-ecoregions-continental-united-states, original data contained in Gallant et al., 1995.

3.3.7.2 Productivity and Reclamation Potential

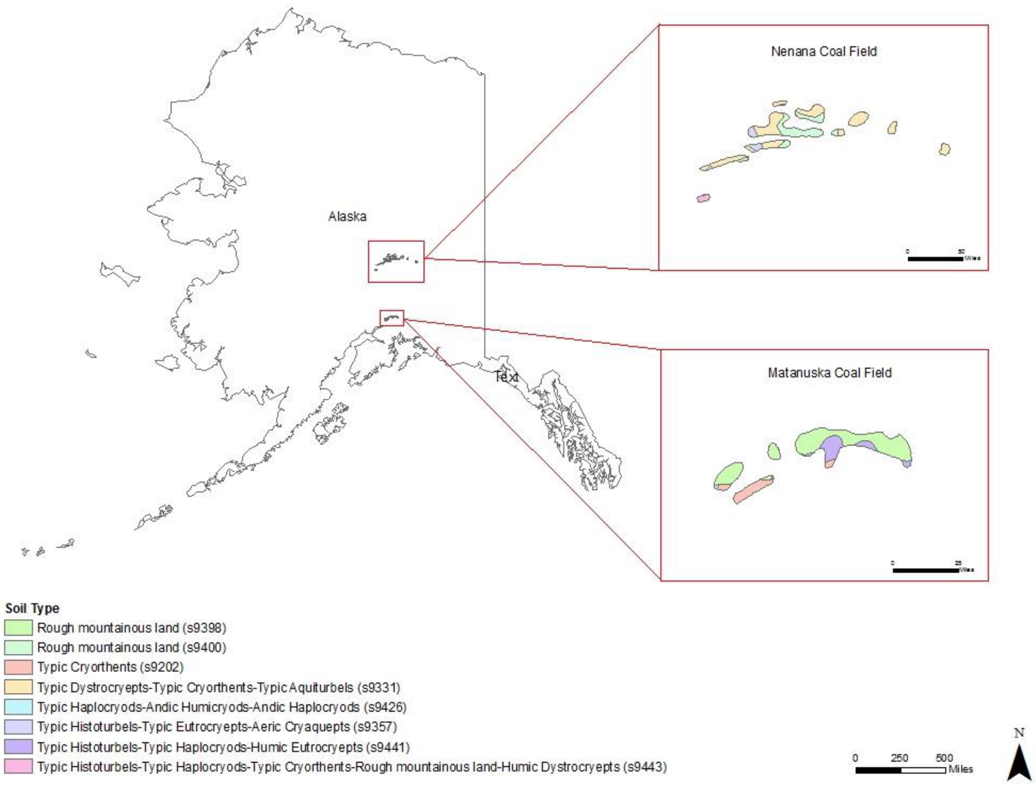
Productivity and reclamation potential of soils in the coal fields of Alaska are low because of the harsh climate.

3.3.8 Western Interior Coal-Producing Region

3.3.8.1 Description of Soils in Region

The Western Interior coal region includes the bituminous coal reserves of central and southern Iowa, northwestern and central Missouri, southeastern Nebraska, eastern Kansas, eastern Oklahoma, and west-central Arkansas. The limited bituminous coal reserves in north-central Texas are not included in this discussion because these reserves are not currently mined (see Figure 3.3-6).

Figure 3.3-7. Soil Orders of the Northwest Coal-Producing Region



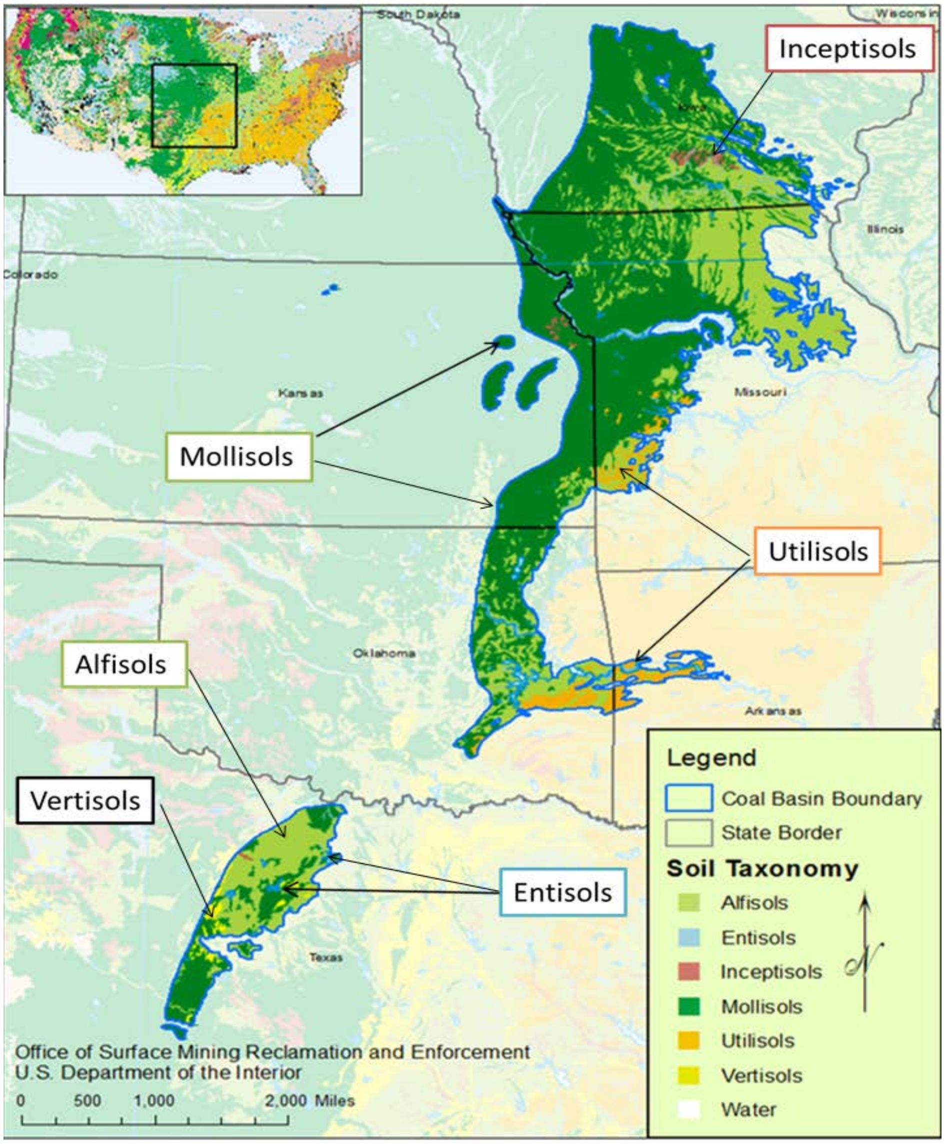
Source: NRCS, 2011, *U.S. General Soil Map (STATSGO2) - Soil Data Mart*, USDA, downloaded from: http://www.nrcs.usda.gov/wps/portal/nrcs/detail/soils/survey/geo/?cid=nrcs142p2_053629

Soils in the Western Interior coal region are predominantly Mollisols, which have a favorable texture and high levels of organic matter. Alfisols are present, especially in Oklahoma and Arkansas, with minor amounts of Entisols occurring near rivers. Mollisols are the dominant soils of the Plains. They form in grasslands and are used mainly as cropland and pasture/haylands. Alfisols in this region occur in areas with moderate rainfall and support grassland and forest vegetation. Entisols are generally sandy. They are among the most productive rangeland soils, especially along rivers, and are used as rangeland or pasture. These soils may be subject to wind erosion.

3.3.8.2 Productivity and Reclamation Potential

In the Western Interior coal region, soils are generally productive and support a range of agricultural land uses (primarily cropland and pasture/haylands). The overall lack of steep slopes on the Plains improves reclamation potential.

Figure 3.3-8. Soil Orders of the Western Interior



Source: NRCS, 2011, *U.S. General Soil Map (STATSGO2) - Soil Data Mart*, USDA, downloaded from: http://www.nrcs.usda.gov/wps/portal/nrcs/detail/soils/survey/geo/?cid=nrcs142p2_053629

3.4 Topography

3.4.1 Introduction

Topography refers to the general configuration of the surface of the land. In common usage it is the landscape and it can be described generally by terms such as mountainous, hilly, undulating, upland, lowland, plain, etc. Topography includes the concepts of relief (high vs. low areas) and compass orientation of natural or manmade features (American Geological Institute, 1997). Topography is intimately related with the science of geomorphology which attempts to explain the origin and evolution of topographic features.

3.4.2 Regional Topography

The earth's surface can be subdivided into natural regions that display internal uniformity. A physiological province is a geographic area that exhibits such a similarity among its topographic features, and is distinct from those of surrounding areas. Each physiographic province is a broad region with a uniformity of character regarding the geomorphology, relief, and environment. In most instances the type and boundaries of any physiographic province are determined by the nature and structure of the underlying rocks. However, any one physiographic province may contain within its borders more than one type of topographic feature. That is, a single province may contain both ridges and valleys, or basins and mountains, or high plateaus and low level areas, etc., so long as the province is distinct from surrounding areas.

Major physiographic provinces may further be subdivided into either sub-provinces or sections based on additional geographic distinctions or changes in topographic characteristics within the major province. As an example, the Gulf Coast Physiographic Province contains the East Gulf Coastal Plain Section and the West Gulf Coastal Plain Section, a differentiation based on geographic location (See Figure 3.4-9). The Illinois Basin Province contains the two sub-provinces of the Central Lowlands and the Interior Low Plateaus, the former having been glaciated and the southern limit of glaciation marking the boundary between the two (See Figure 3.4-10).

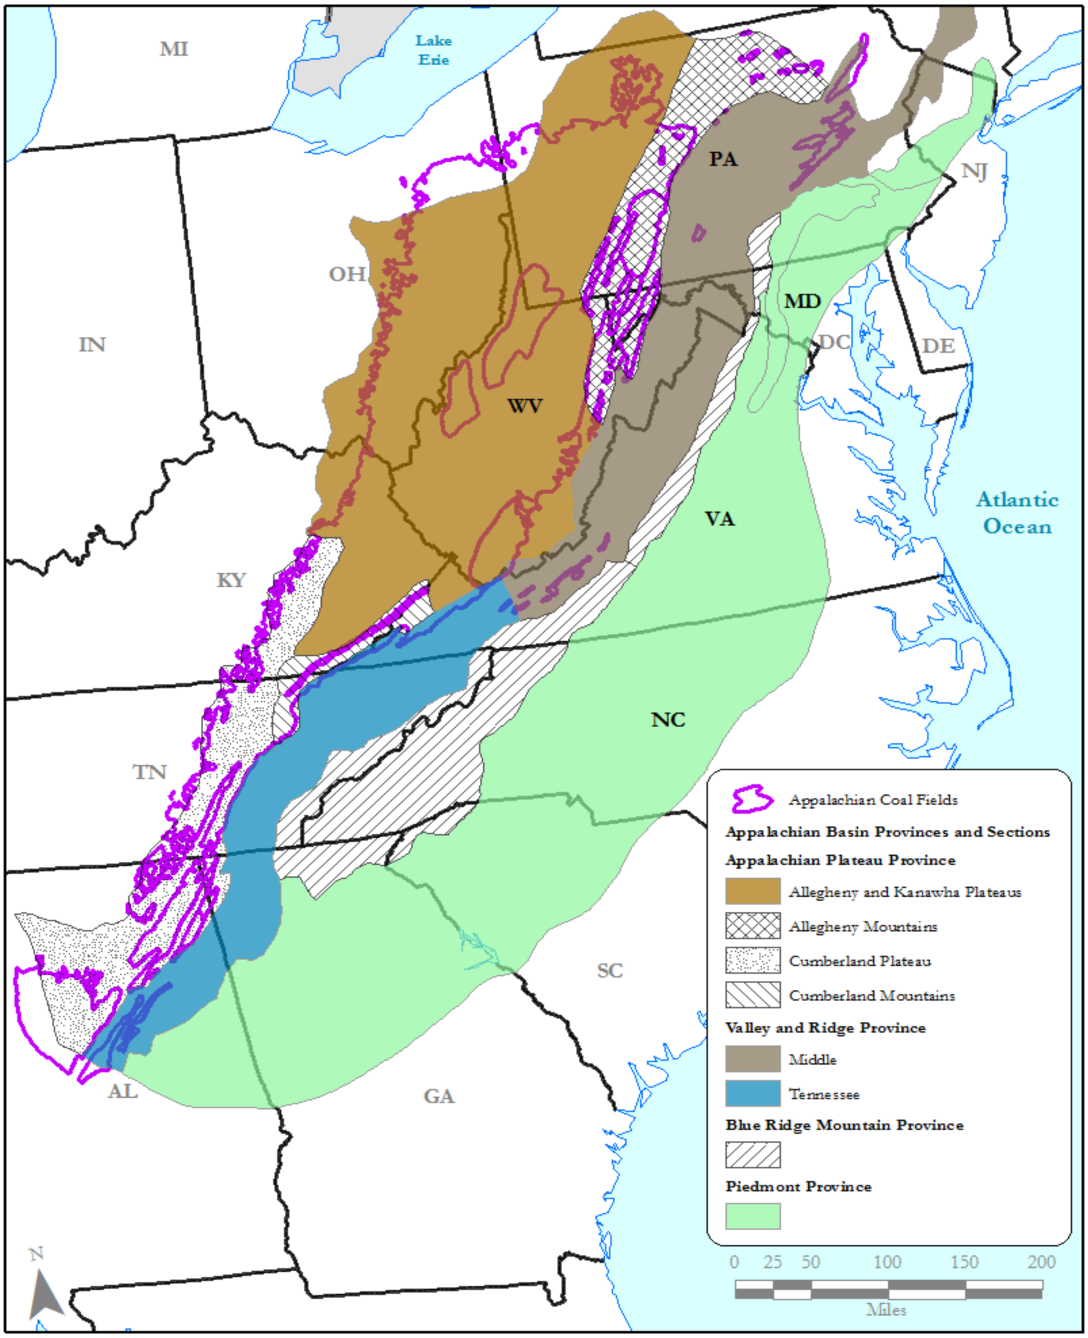
The next sections will describe in further detail the geomorphology of the following seven U.S. coal-bearing regions:

- Appalachian Basin;
- Colorado Plateau;
- Gulf Coast;
- Illinois Basin;
- Northern Rocky Mountains and the Great Plains;
- Northwest (including Alaska);
- Western Interior

3.4.2.1 Appalachian Basin Region

During the Paleozoic sediments were laid down in a broad, northeast-southwest trending lowland along the eastern portion of the U.S. This area of accumulating strata is termed, in common parlance, the Appalachian Basin. Here the term basin is used in the physiographic sense to indicate a low area within which sedimentary deposits accumulate. Over time, and under pressure from overlying strata, these deposits became lithified or converted to rock. It is within the swamps and lagoons of the Appalachian Basin that carbon-rich deposits amassed, eventually forming the strata of the Appalachian coal beds. Due to multiple episodes of tectonic plate collisions and mountain-building from the early Paleozoic to early Mesozoic (i.e., from about 450 to 220 million years ago) the region was raised into what is now termed the Appalachian Highlands. Folding, faulting and uplift of these lithified strata was followed by periods of erosion and weathering. These Earth forces created the distinctive topography that characterizes the Appalachian physiographic provinces (see Figures 3.4-1, and 3.2-2). Currently, uplifted and rejuvenated streams continue to cut downward through the ancient bedrock.

Figure 3.4-1. Physiographic Provinces and Sections of the Appalachian Basin Region



Source: USGS, 2004, *Physio*, U.S. DOI, http://water.usgs.gov/GIS/metadata/usgswrd/XML/physio.xml

The Piedmont and Blue Ridge Provinces do not concern us as these areas are composed of crystalline (igneous and metamorphic) rocks and contain no known deposits of coal. Conversely, the Valley and Ridge Province, and the Appalachian Plateau Province contain significant thicknesses of sedimentary rocks (sandstones, siltstones, shales, conglomerates and limestones) within which are included numerous beds of coal. The coal accumulated most significantly during a period of time termed the Pennsylvanian, however lesser widespread deposits were formed at other times. Coals in these two physiographic provinces are of both the bituminous (medium rank) and anthracite (high rank) types.

The difference in the topography between the Appalachian Plateau and Valley and Ridge provinces is determined primarily by the structure of the underlying bedrock. The Plateau is underlain by sedimentary strata that are either horizontal or gently folded. Consequently, the topography is typified by relatively flat, concordant (equal elevation) upland surfaces, carved by stream erosion into steep-sided, relatively narrow river valleys. By contrast, the strata of the Valley and Ridge Province have been folded and faulted into complex structures producing a topography of long linear ridges and broad valleys.

Figure 3.4-2. View of the Allegheny Mountains

Source: OSMRE, 2015a. Photograph Archive. U.S. Department of the Interior.

The Appalachian Plateau marks the western part of the Appalachian Highlands, stretching from New York to Georgia and Alabama. The surface of the Plateau is highest in the east and slopes gently to the northwest where it merges into the Interior Plains. The province is divided into several physiographic sections, which include the Allegheny Mountains, Cumberland Mountains, and the Kanawha Plateau and Cumberland Plateau (See Figure 3.4-1). Most of the lateral extent of the Appalachian bituminous coal seams is located within the Kanawha and the Cumberland Plateaus; lesser deposits occur in the Allegheny and Cumberland Mountains.

The “plateau” and “mountain” sections of the Appalachian Plateau differ from each other primarily according to local relief. The Allegheny Mountains run for about 400 miles from north-central Pennsylvania, through western Maryland and eastern West Virginia, to southwestern Virginia (See Figure 3.4-2). They rise to approximately 4,860 feet above mean sea level (MSL) in northeastern West Virginia. Local relief ranges from approximately 1,000 to 2,000 feet. In the east, the mountains are dominated by a high, steep escarpment known as the Allegheny Front. In the west, they grade down into the closely associated Allegheny Plateau. The Allegheny Mountain Section differs from the Allegheny Plateau in that dissection is so advanced that the topography no longer resembles a plateau, even a dissected one. This section also differs in that mild folding and erosion on anticlines and synclines have produced linear ridges. As a result, the section includes trellis as well as dendritic (radial branching) drainage patterns.

The Allegheny Plateau is a large dissected plateau area in western and central New York, northern and western Pennsylvania, northern and western West Virginia, and eastern Ohio. It is divided into the glaciated Allegheny Plateau and the unglaciated Allegheny Plateau (where bituminous coal seams are located). In the unglaciated Allegheny Plateau in southeastern Ohio and westernmost West Virginia, relief is typically in the range of 200 to 400 feet. Locally, the highest elevations in this area are often in the range of 900 to 1,500 feet. Along the plateau's eastern border however, at the Allegheny Front, elevations may reach well over 4,000 feet above MSL, with relief of up to 2,000 feet. Generally the section's stratigraphy includes more shale than the Allegheny Mountains (where sandstone is more common); consequently its slopes tend to be smoother. The general drainage pattern in this section is dendritic.

The Cumberland Mountains section represents the southern counterpart of the Allegheny Mountains (See Figure 3.4-1). It occupies a strip about 150 miles long and 25 miles wide in Virginia, Kentucky, and Tennessee. Its geology is dominated by the Cumberland thrust block which is 125 miles long and 25 miles wide. The Cumberland Mountains are higher than the adjacent Cumberland Plateau to the west because the thrust brought resistant rock to the surface at a relatively high elevation. Peak elevations range from 2,000 to 2,600 feet above MSL and local relief varies from 100 to 200 feet. Similar to the Allegheny Mountains, this section contains trellis as well as dendritic drainage patterns.

The Cumberland Plateau constitutes the southernmost part of the Appalachian Plateau Province (See Figures 3.4-1 and 3.4-3). It includes parts of eastern Kentucky and Tennessee, and a small portion of northern Alabama and northwest Georgia. Elevations range from 1,270 to 2,000 feet above MSL and local relief averages 200 feet but can reach 1,000 feet along the eastern edge where the land transitions to the Ridge and Valley Province (Gaydos, 1982; Hollyday, 1983). The general drainage pattern is dendritic. The terms "Allegheny Plateau" and "Cumberland Plateau" stem from historical usage rather than geological difference. There is no strict dividing line between the two. Two major rivers share the names of the plateaus, with the Allegheny River rising in the Allegheny Plateau and the Cumberland River rising in the Cumberland Plateau.

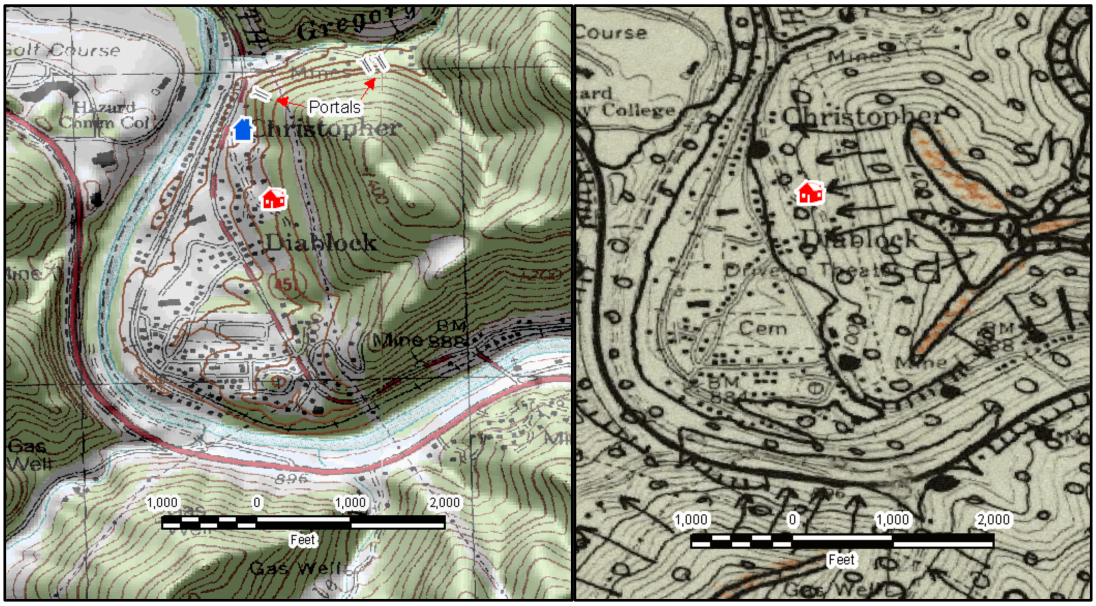
Owing to steep slopes, an abundance of weak mudstones (claystone, shale, and siltstone) in the geologic section, and a temperate-to-humid climate, the Appalachian Plateau is an actively erosional landscape prone to mass movement processes, including rock falls, slope wash, soil creep, landslides, mudflows, and debris flows (See Figure 3.4-4). The active nature of the slopes in these mountains and hills is well documented on soil maps of the U.S. Natural Resources Conservation Service; in regional slope-instability mapping by Lessing et al. (1976) and Outerbridge (1979, 1982); and in numerous geotechnical investigations of natural landslides and other types of major mass movements. Gray and Gardner (1977) provide the following summary of how unstable slopes can form from the accumulation of rock and debris:

Figure 3.4-3. View of Cumberland Plateau Topography in Eastern Kentucky

Source: OSMRE, 2015a. Photograph Archive. U.S. Department of the Interior.

Weathering of rock and formation of soil is most active in the upper portions of the hillside where slopes are steep and rock occurs at the surface or at shallow depths. The soil particles derived from weathering of the near surface rock are transported downhill through mass wasting processes such as sheet wash and creep. A short distance down the slope, the transported soil begins to encounter conditions where downhill movement is retarded and soil accumulation occurs. Areas of accumulation usually occur where the slope angle decreases and/or where the volume of soil entering the area is greater that the capacity of mass wasting processes to remove it. Two basic zones of accumulation can be identified: the first involves accumulation on flatter slopes above ledges and on benches; the second involves accumulation within swales and small gullies on the hillside.

Figure 3.4-4. OSMRE Landslide Investigation in Perry County, Kentucky



Source: Michael, P. et al., 2010, *Figure 11*, U.S. Department of the Interior. (Modified from U.S. EPA, 2005)
http://www.techtransfer.osmre.gov/ARsite/Publications/0610-Michael-PA.pdf

Left: site topography; Right: 1979 USGS survey of landslides and related features surrounding the site. Area covered with small circles represents colluvial slopes with landslides. Arrows delineate zones of debris flows and debris avalanches. Orange shading represents rock and soil susceptible to landslides.

Loose rock debris can accumulate at ledges, in swales, or at the toe of slopes. Ledges and benches form where more resistant rocks, such as sandstones and limestones, jut out of the slope farther than the surrounding, more easily eroded softer shales. Swales are smooth, broad indentations or concavities in a slope which form due to concentrations of weak or fractured rock. Another zone of accumulation occurs at the base or toe of a slope where the rate of colluvium introduction exceeds the rate of its erosion by fluvial processes. (Rock fragments pile up faster than streams can carry them away.)

It is important to note that even where thick accumulations of colluvium are naturally stable, their modification via human construction practices can destabilize them. Common forms of human-induced destabilization include:

- Over-steepening of a slope by removal of colluvial material (See Figure 3.4-5);
- Overloading the slope with fill; and
- Increasing pore-water pressure in the colluvial material through disruption or redirection of natural drainage.

Figure 3.4-5. Destruction of a Residential Structure by a Landslide Caused by Human Activities (Excavation) into a Slope, Eastern Kentucky.

Source: OSMRE, n.d., *Landslide in Eastern Kentucky*, U.S. Department of the Interior

The common occurrence of potentially unstable slopes in the Appalachian Plateau and its effect on the long-term stability of excess spoil fills has long been recognized within the mining industry and among government regulators. Emphasis is placed on the identification of "landslide topography" to avoid construction on unstable foundation slopes. Four key elements related to Appalachian Plateau topography that affects the stability of excess spoil fills are summarized below. More detailed discussions are available in OSMRE (2002) and, Michael and Superfesky (2007):

Steep fill foundation slopes: Fill failures are a relatively uncommon occurrence in the Appalachian Plateau; those that have been reported have foundation slopes in excess of twenty percent. Contributing to failure potential is the use of weak, non-durable rock in the construction of excess spoil fills. West Virginia, Kentucky and Virginia have implemented fill minimization provisions. These provisions require that: operations are conducted such that more spoil material is placed within the mined area and, less material be placed in excess spoil fills. Following this procedure avoids the placement of fill material in the proximity of intermittent and perennial streams. One potential outcome of these provisions is that the toe, or bottom of the fill, is often located at higher elevations in the hollows (i.e. to prevent or limit burial of streams), which, as a consequence, result in the toe resting on steeper foundation slopes. This aforementioned scenario can negatively impact the stability of the fills if proper design and construction techniques are not followed. The effect of steep foundation slopes must be off-set by proper foundation preparation and placement of underdrains that can efficiently convey seepage out of the valley fill.

Potentially low shear strength of fill foundation materials: As discussed above, layers of colluvium are pervasive on the hill sides and tend to thicken downslope towards base level. However, deep soils can occur locally in higher elevations where weak rock types (e.g., mud rocks like shale and claystone) are exposed. Several studies have emphasized that the identification of soil-like material in the foundation of a proposed excess spoil fill — and the use of accurate foundation shear strength properties — is essential for a realistic valley fill stability analysis.

Ground water discharge into excess spoil fills: Sedimentary strata in the Appalachian Plateau, including aquifers, are near-horizontal in inclination; consequently, numerous water-bearing beds intersect — or crop out — into excess spoil fills. The rock strata also tend to be densely fractured near the surface due to valley stress relief. Thus ground water can flow parallel to valley side slopes as well as horizontally through aquifers. As a result, numerous excess spoil fills are constructed on top of seeps and springs, especially in locations where bounding sedimentary strata dip into the fill. The construction of fill underdrains capable of discharging subsurface drainage that has entered the fill is critical.

Figure 3.4-6 shows an example of an excess spoil durable rock fill that failed due to an inadequate underdrain (as well as placement on a steep, soil-like foundation). Underdrains in durable rock fills rely solely on the natural segregation of end-dumped durable rock material. The larger, heavier durable rock is theoretically supposed to roll downslope and form a natural underdrain. In reality, the spoil material often does not adequately segregate. Consequently, naturally occurring springs and seeps in the hillside, as well as those that may occur within the fill foundation, can be buried with non-durable rock material. This can lead to greater water infiltration into the fill material and longer contact time with toxic materials in the spoil; this in turn may result in contaminated discharges.

Figure 3.4-6. Failed Excess Spoil Fill (Specifically a Durable Rock Fill) in Eastern Kentucky

Source: Peter Michael, et al., 2010, *Figure 3 Durable rock fill in eastern Kentucky*, U.S. Department of the Interior. http://www.techtransfer.osmre.gov/ARsite/Publications/0610-Michael-PA.pdf

Erosion potential of surface drainage and timely reclamation: In the Appalachian Plateau the combination of steep slopes and abundant precipitation results in significant kinetic energy even in headwater streams. This condition necessitates that drainage be carefully controlled to minimize unchecked runoff. Such uncontrolled flow may result in: (a) dangerous sediment-laden floods or mudflows; (b) clogging of exposed parts of fill underdrain structures; and (c) heavy sedimentation and pollution of off-permit downstream waters. Effective drainage control is especially important while the excess spoil fill is still under construction as well as during the process of final grading and revegetation. Contemporaneous reclamation can lessen the severity of erosion and surface drainage that may lead to off-site damage. A worst case example of a severe, life-threatening flood from a durable rock fill into a residential area is the Lyburn incident in West Virginia in 2002 (OSMRE, 2002) (See Figure 3.4-7).

Figure 3.4-7. Property Damage in Residential Area from Storm Runoff Erosion Over an Unreclaimed Excess Spoil Fill

Source: Peter Michael, et al., 2010, *Figure 5 property damages downstream of the fill*, U.S. Department of the Interior.
http://www.techtransfer.osmre.gov/ARsite/Publications/0610-Michael-PA.pdf

The character of the Valley and Ridge Province (Figure 3.4-1) is well-described by Hunt (1967):

The Valley and Ridge Province extends the entire length of the Appalachian Highlands. It is divided into three sections: a very narrow one, only 25 miles wide, with much shale at the north along the Hudson River; a second, 75 miles wide, with varied kinds of rocks in Pennsylvania, Maryland and northern Virginia; and a third, about 50 miles wide, which is like the second but more faulted, extending from southern Virginia to the south end of the highlands in Alabama.

The Valley and Ridge Province is world famous for its fold mountains . . . which are made up of Paleozoic sedimentary formations 40,000 feet in thickness. The sediments that formed these rocks were derived from a mountain mass that lay to the east. . .. The composition of the formations changes away from the source of the sediments. Sandstone and shale formations tend to grade westward into shale and limestone. The well-known limestone caverns of Virginia are developed in Paleozoic limestone formations in the valley west of the Blue Ridge . . .

Toward the end of Paleozoic time . . . deposits like those on the Coastal Plain spread westward across the top of the older marine formations. This coastal plain contained swamps . . . [of] . . . tree-like ferns . . .. The accumulation of this woody material in the swamps produced the coal beds that are found in the anthracite fields in the Valley and Ridge Province and the bituminous coal fields of the Appalachian Plateaus farther west.

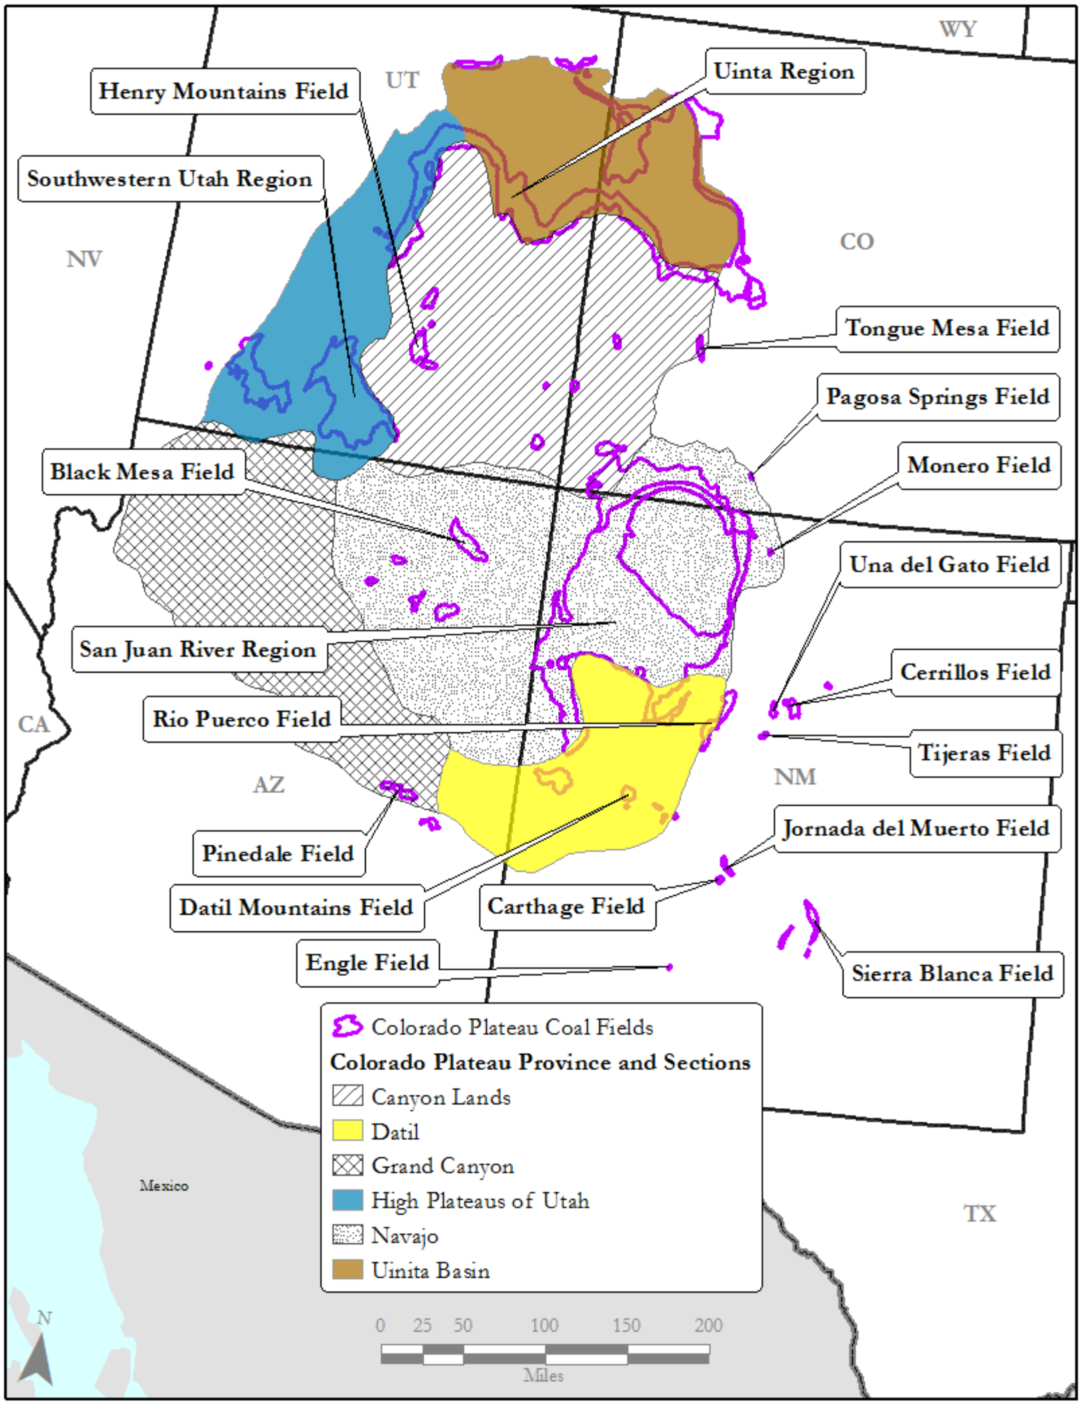
The effects of weathering and erosion on sedimentary rocks over eons of time produced the distinctive physiography to the Valley and Ridge Province. The erosion of erodible bedrock and shale provided the bedrock underlying the valleys. The sandstones and conglomerates, by contrast, are harder and appreciably more durable so they form the linear ridges that now dominate the uplands. Seen from the air, the mountains are long, linear, sinuous ridges that, in places exhibit tight s-shaped curves. This singular pattern of the hard strata is a result of post-depositional folding that largely occurred toward the end of the Paleozoic.

3.4.2.2 Colorado Plateau Region

The majority of the Colorado Plateau coal-bearing region is contained within the physiographic provinces of the same name. The province is a high-elevation region consisting of plateaus and isolated mountains that encompass parts of Utah, New Mexico, Colorado, and Arizona (See Figures 3.4-8). It is bounded on the east by the Rocky Mountains, on the north by the Uinta Mountains, and on the south by the Mogollon Rim. The most common elevation on the plateau is 5,500 to 6,000 feet MSL (OSMRE, 2008). The landscape is dominated by deep canyons, elevated plains, low plateaus, buttes, mesas, and badlands, and is largely underlain by horizontal strata of sedimentary rocks. Large scale mass wasting has changed many of the landforms in this region (Orme, 2002). The Colorado Plateau includes the Uinta Basin of northeastern Utah and the Piceance Basin of northwestern Colorado. Identified mineable coal resources exist along southern rim of these basins as well as within the north-south trending faulted anticline separating the basins, known as the Douglas Creek Arch. Along the edge of the basin, topography is characterized by a series of nearly parallel north and northeasterly trending ridges and valleys with steep bluffs. The overall aspect of the basin is northeasterly. At lower elevations to the north of the basin rim, broad open plains exist interrupted by moderately hilly land and mesas (U.S. BLM, 1985).

The central coal fields of Utah include the Wasatch Plateau (in the northeast corner of the High Plateau Section) and Tavaputs Plateau (located in the southern Uinta Basin). The Wasatch Plateau is characterized by a gently rolling dissected plateau with deeply cut ravines and alluvial valleys. The Tavaputs Plateau is characterized by rugged terrain and deeply incised canyons. The southern Utah coal fields, including the Kaiparowits, Alton, Kolob-Harmony, and Henry Mountain coal fields, exist in portions of the High Plateau and Canyon Lands physiographic sections (See Figures 3.4-8). The plateaus form a series of broad and erosion-resistant bedrock terraces or benches that have been dissected by deep canyons. Elevations above MSL range from 4,000 feet near the Utah-Arizona border to 11,000 feet in the Henry Mountains (U.S. DOI, 1979).

Figure 3.4-8. Physiographic Provinces and Sections of the Colorado Plateau



Source: USGS, 2004, *Physio*, U.S. DOI, http://water.usgs.gov/GIS/metadata/usgswrd/XML/physio.xml

The Black Mesa coal fields of northeastern Arizona and the portions of the San Juan River coal fields of northwestern New Mexico exist within the Navajo physiographic section. Geomorphic processes active in this area have resulted in significant plateau dissection and deep canyon formations. Volcanic mountains and intrusions also exist, but block-fault structural mountain ranges do not. Major landforms are canyon lands, plateaus, plains, and hills. Elevation ranges from 4,000 to 8,000 feet MSL. The San Juan Basin coal field, located in northwestern New Mexico and southwestern Colorado is located at a higher elevation and in a wetter climate. Landforms in the area of this coal field include mountains, plains, plateaus, and hills, with steeper landforms toward the inner core of the basin. Elevations range from 6,000 to over 14,000 feet MSL (OSMRE, 2008).

3.4.2.3 Gulf Coast Region

The Gulf Coast region is part of the Coastal Plains geomorphic province (See Figures 3.4-9). Mining in the Gulf Coast region is limited to the east Gulf Coastal Plain and the West Gulf Coastal Plain Physiographic Sections. The western Gulf Coastal Plain, covering portions of Texas, Louisiana, and Arkansas, comprises the Coastal Prairies, Interior Coastal Plains, and the Blackland Prairies (these subdivisions, parallel to the Gulf Coast in Texas and Louisiana, are not delineated in Figure 3.4-9). The Coastal Prairies extend inland from the Gulf of Mexico to an elevation of approximately 300 feet above MSL.

The primary topography of this area is nearly flat prairie, sloping approximately one foot per mile toward the Gulf. The Interior Coastal Plains reaches an elevation of approximately 300 to 800 feet above MSL. The primary topographic features are parallel ridges (cuestas) and valleys. The Blackland Prairies extend from approximately 450 to 1,000 feet MSL and comprises mostly low, rolling terrain (Bureau of Economic Geology, 1996). Elevations in the coal mining areas range from 80 to 1,350 feet MSL with local relief approximately between zero and 500 feet (Orme, 2002).

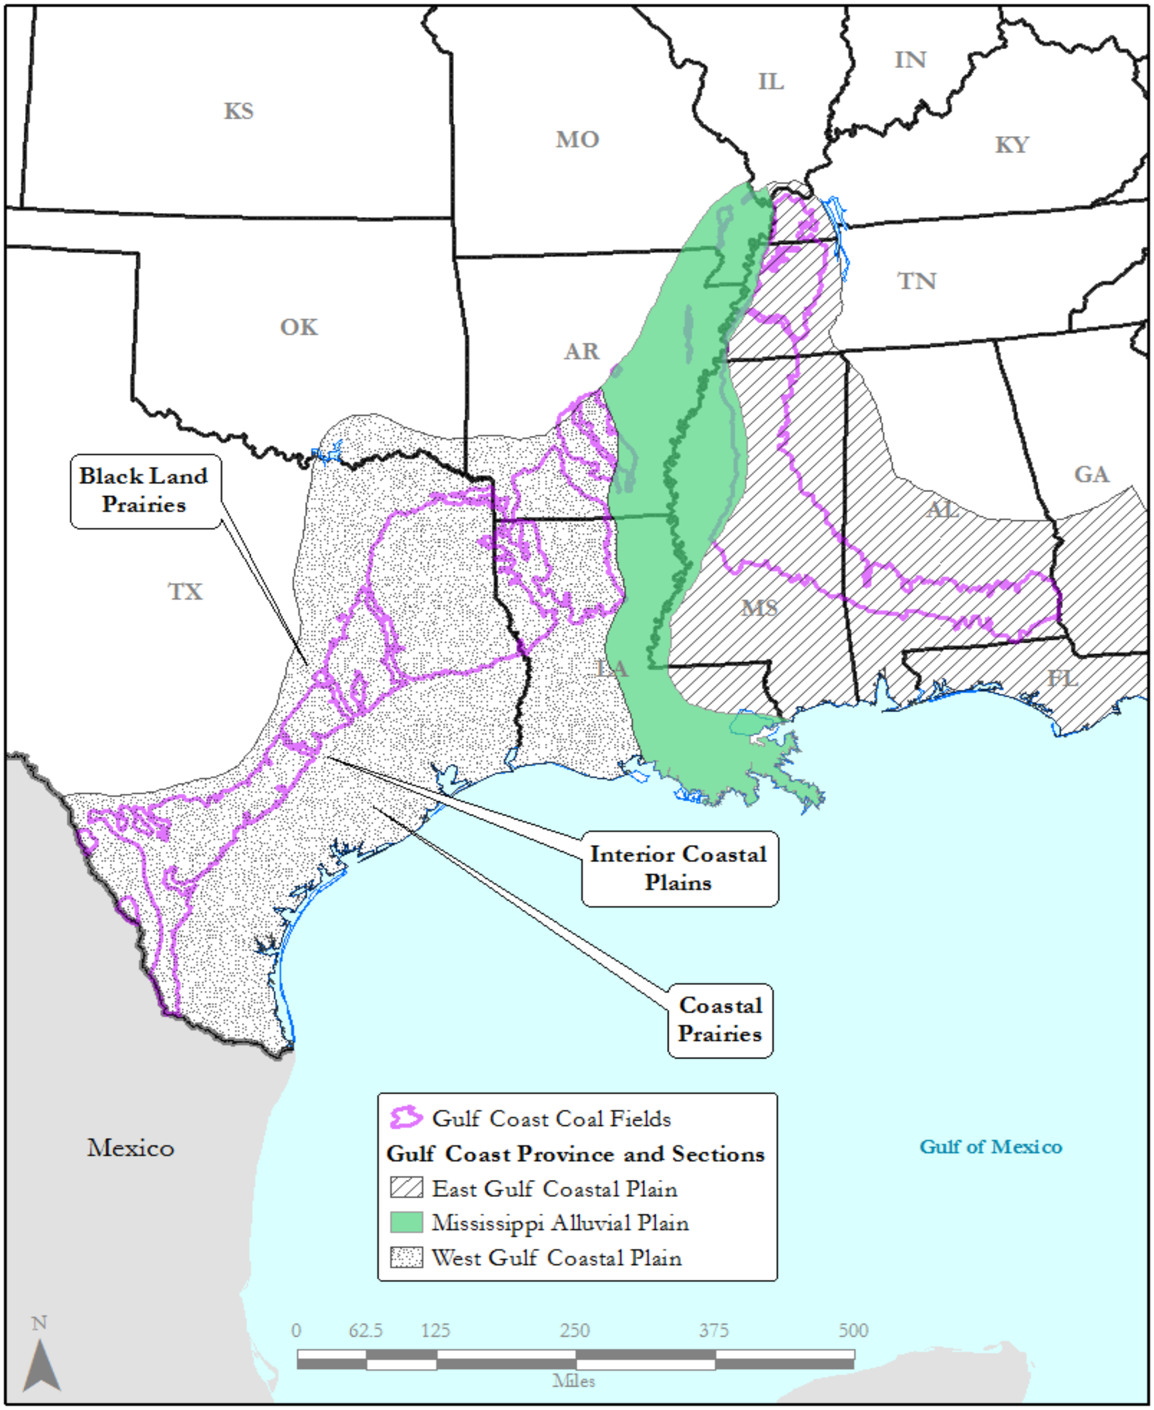
The east Gulf Coastal Plain extends from Florida to the Parishes of Louisiana over most of Mississippi, some of western Tennessee and Kentucky, the southwestern two thirds of Alabama, and the western panhandle of Florida (Ruth, 2006). Topography of the east Coastal Plains is widely varied, with areas of rounded, eroded hills, cuestas, and nearly featureless plains (Neilson, 2007).

3.4.2.4 Illinois Basin Region

The Illinois Basin is a northwest-southeast trending geologic basin which is bounded on all sides by structural arches. The Basin is located within the Central Lowlands and Interior Low Plateaus physiographic provinces; its margins are delineated by the outer limits of the coal fields (See Figure 3.4-10).

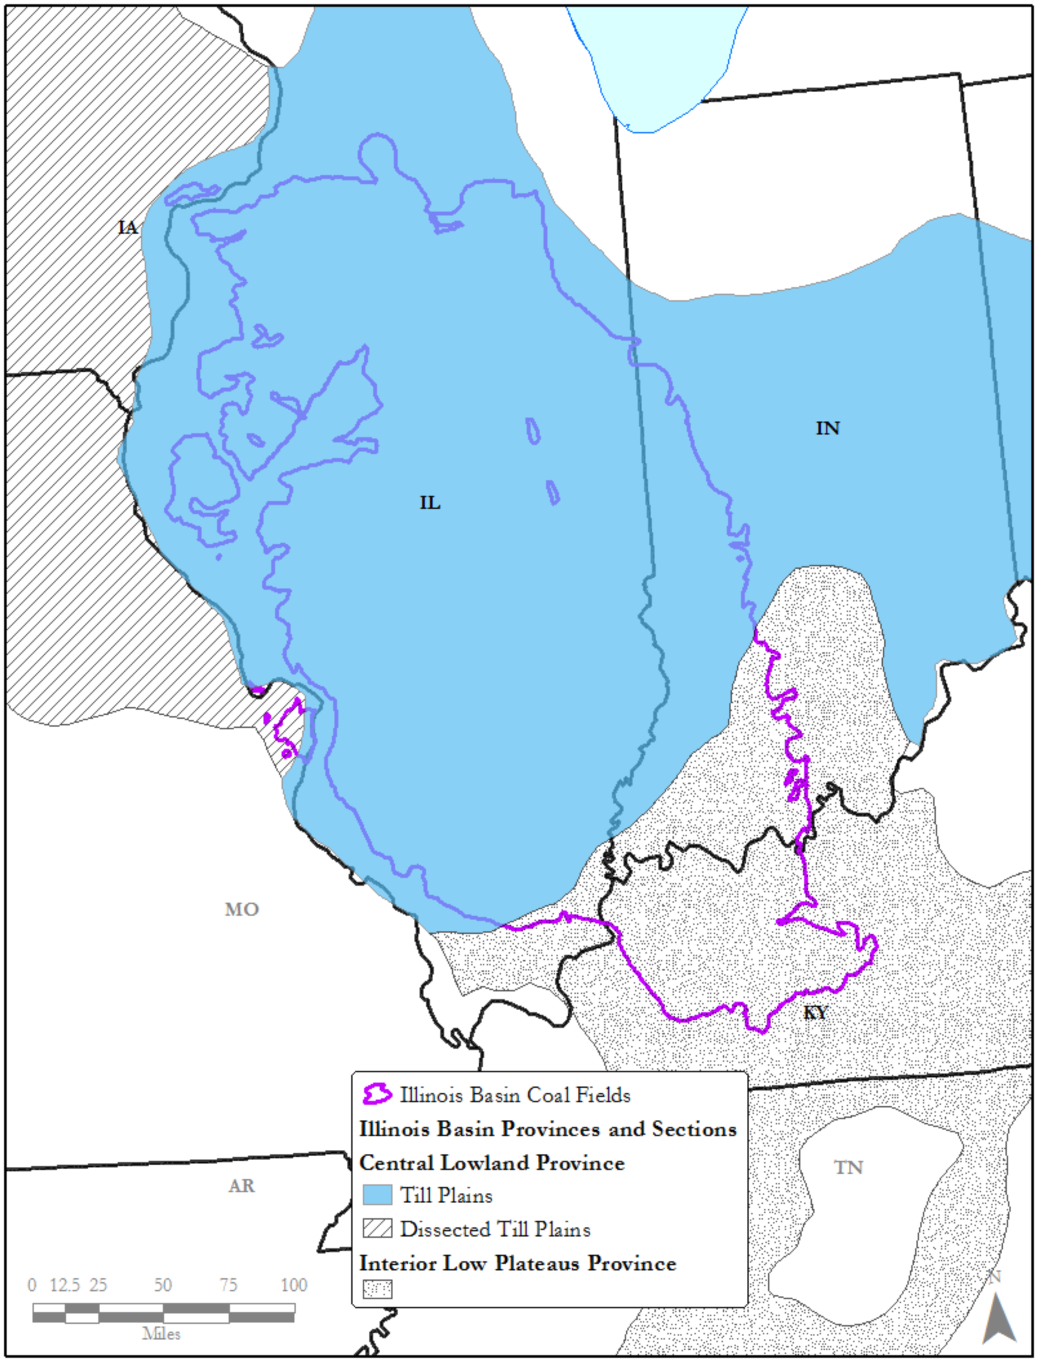
The majority of the Illinois Basin physiography is characterized by gently rolling plains with surface elevations in the coal mining areas ranging from 325 to 1000 feet above MSL. In places relief is up to one hundred feet. Vogel (1981) describes the topography as follows:

Figure 3.4-9. Physiographic Provinces and Sections of the Gulf Coast



Source: USGS, 2004, *Physio*, U.S. DOI, http://water.usgs.gov/GIS/metadata/usgswrd/XML/physio.xml

Figure 3.4-10. Physiographic Provinces and Sections of the Illinois Basin



Source: USGS, 2004, *Physio*, U.S. Department of the Interior, http://water.usgs.gov/GIS/metadata/usgswrd/XML/physio.xml

- Most of the area in Illinois and Indiana lies within the Central Lowlands physiographic province, while the portion in Kentucky and extreme southern Illinois and Indiana is in the Interior Low Plateaus. The boundary between these two physiographic provinces marks the southern limit of glaciations.
- The Central Lowlands, in the vicinity of the coal fields, consists of broad level uplands between steep sided valleys with broad floodplains. This area is covered with glacial till and loess deposits that, toward the Mississippi River, reach 30 feet in thickness.
- The Interior Low Plateaus consist of a slightly westward sloping plateau that is deeply entrenched with meandering rivers. This area has more relief than that to the north, but is still gently rolling. The low, gently rolling topography of the Illinois Basin Coal region has allowed extensive area-type surface mining and an easily developed road, rail, and river barge transportation system (Vogel, 1981).
- Geomorphic processes include fluvial erosion, transport and deposit, minor mass wasting, and in Kentucky, karst solution. Pre-law surface mined lands may exhibit hummocky or ridge-swale topography. Broad flood plains exist in the region and glacial till and loess deposits can reach up to 30 feet in thickness (Orme, 2002).

3.4.2.5 Northern Rocky Mountains and Great Plains Region

The Northern Rocky Mountains and Great Plains coal region exists within the Middle Rocky Mountain, Wyoming Basin and Great Plains physiographic provinces (see Figure 3.4-11). Southwestern Wyoming is an area of low mountains and semiarid basins. Total relief is about 3,500 feet. The Middle Rocky Mountains and Wyoming Basin physiographic provinces are divided geographically from west to east into the Overthrust Belt, Green River Basin, Rock Springs Uplift, Great Divide Basin, Washakie Basin, and Hanna Basin. [Not all of the aforementioned features are indicated in Figure 3.5-5.] The Overthrust Belt is characterized by north-south trending mountains and valleys formed from linear folds and faults.

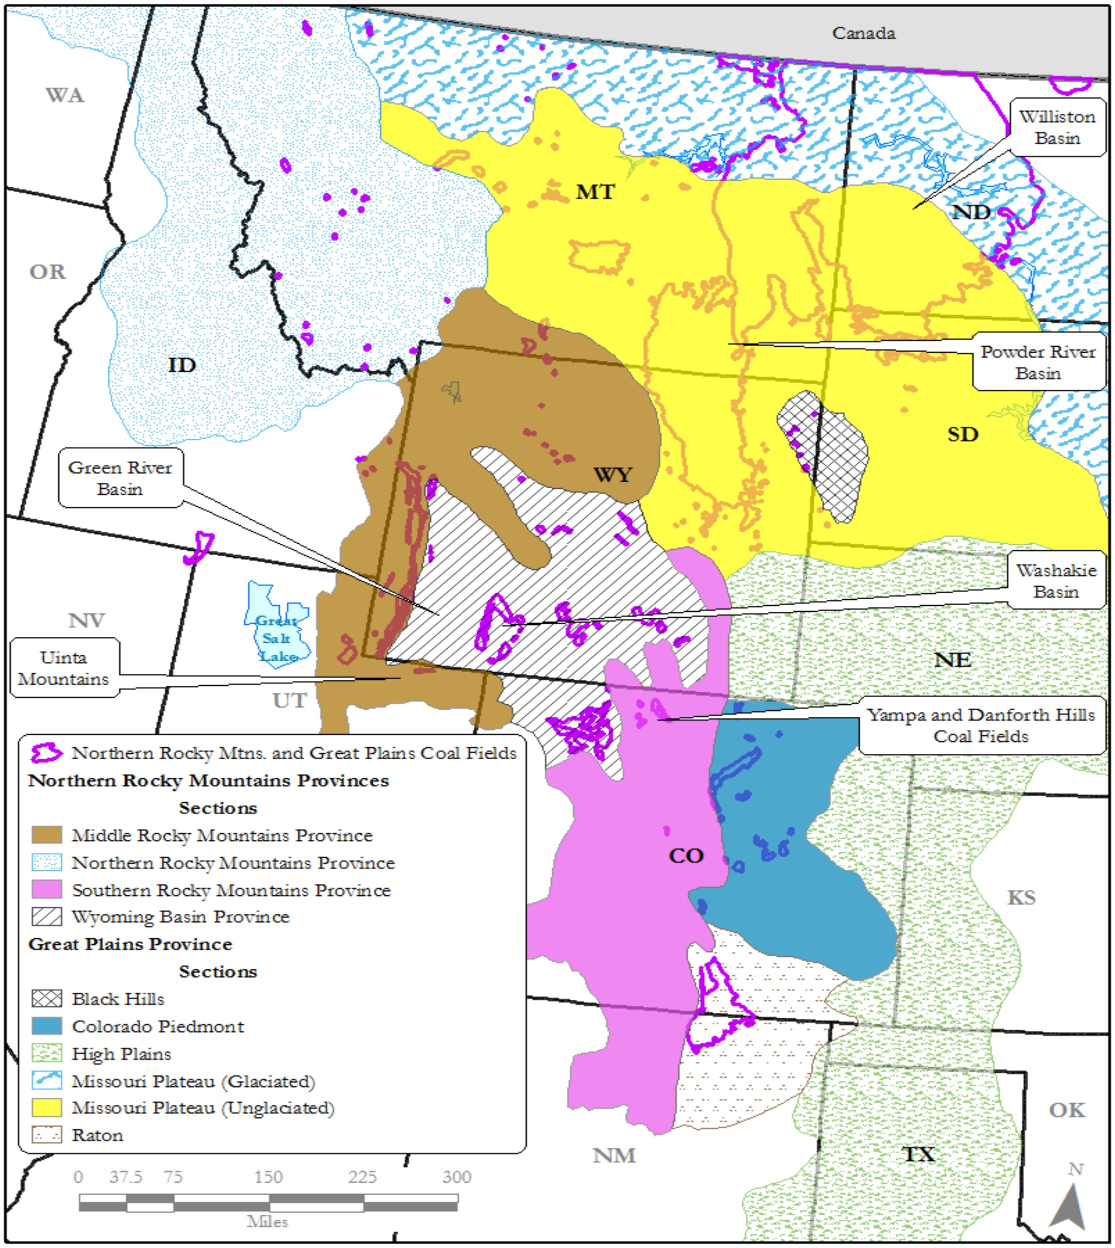
Elevations range from about 6,800 to 7,400 above MSL. The Rock Springs uplift is composed of a central basin surrounded by ridges and mountains that dip into the surrounding basins. Elevations range from about 6,400 to over 8,600 feet MSL. The Washakie Basin is characterized by low rolling hills, high rock rims on the north and southwest, and broad shallow valleys. Elevations range from about 6,000 feet to about 8,000 feet MSL. The Hanna basin is characterized by high plains that are topographically broken around the margin by low ridges composed of resistant sandstone. Elevations range from 7,000 to 8,000 feet above MSL (U.S. BLM, 1980).

The coal fields of northwest Colorado (including the Danforth Hills and Yampa fields) are located in the Wyoming Basin and Southern Rocky Mountains physiographic provinces (see Figure 3.4-11). The Dansforth Hills field is characterized by steep south facing escarpments and gentler north-facing dip slopes whereas the Yampa fields demonstrate low mountain ranges, rolling hills and broad valleys. Elevation ranges from about 6,200 to 8,700 feet above MSL.

In northeast Montana and southwest North Dakota, the Missouri Plateau is divided into the southern unglaciated and the northern glaciated sections of the greater Great Plains province (See Figure 3.4-11). Previously glaciated areas demonstrate modified bedrock topography and glacial drift erosional remnants on upland and valley fill in major drainages. The topography is characterized by wide flat alluvial valleys, rolling prairies, and low to moderate hills with local relief of 20 to 560 feet. The unglaciated

Missouri Plateau is comprised of eroded bedrock surfaces with gently rolling uplands, scattered buttes, and highly dissected badlands. Relief is comparable to the glaciated Missouri Plateau. Elevation for the area ranges from 1,600 feet to 3,600 feet above MSL.

Figure 3.4-11. Physiographic Provinces and Sections of the Northern Rocky Mountains and Great Plains



Source: USGS, 2004, Physio, U.S. DOI, http://water.usgs.gov/GIS/metadata/usgswrd/XML/physio.xml

The Powder River Basin (PRB) is a high plains environment that is bounded by the Black Hills on the east; the Big Horn Mountains on the west; the Hartville Uplift, Casper-Arch, and Laramie Mountains on the south; and the Yellowstone River on the north, including northeast portions of Wyoming and southeast portions of Montana. The basin consists of a dissected rolling upland plain with low relief, broken by low buttes, mesas, hills, ridges, buttes and plateaus capped by “clinker” or sandstone. Elevations in the PRB coal resource area range from approximately 5,000 to 6,000 feet above MSL.

Located mostly in the Missouri Plains of North Dakota and Montana (Great Plains Province), the Williston Basin is a north-south trending oval-shaped region. Measuring approximately 300 miles wide by 500 miles long, the Basin provides an excellent example of a lack of conformance between an area's surface physiography and its contrasting underlying structure. Topographically, the Basin is best characterized as being generally flat with only a gently rolling land surface. Locally, however, a topographic relief of several hundred feet has been created near the Missouri and Yellowstone Rivers, a result of erosion of the relatively soft sandstones, coals, and shales. The subsurface, in contrast, is marked by a structural down-warping of the strata to form an actual geological basin wherein all stratigraphic units are inclined toward the center. Strata of the Williston Basin are of Late Cretaceous and Early Tertiary age.

According to the USGS (Thamke, et. al.):

> The area is semiarid, with mean precipitation ranging from 12 to 20 inches per year (in/yr) and available precipitation (difference between monthly precipitation and potential evapotranspiration) ranging from 0 to 5 in/yr (Reilly and others, 2008). Pasture and hayland is the predominant land-cover category (70 percent) in the study area (Multi-Resolution Land Characteristics Consortium, 2011).

3.4.2.6 Northwest Region

The Northwest Coal region includes potentially mineable resources limited to Alaska because there is no active coal extraction occurring or reasonably expected to occur in Oregon and Washington. The Northern Alaska coal fields are also not discussed due to the questionable potential for their development and production at this time.

The primary coal resources of Alaska are associated with the Nenana and Matanuska coal fields are located within the Interior Forested Lowlands and Uplands Ecoregion and the Alaska Range and the Cook Inlet Ecoregions, respectively. (See Figure 3.3-6). The Interior Forested Lowlands and Uplands consists of rolling lowlands, dissected plateaus, and rounded low to high hills. The ecoregion lies between elevations of sea level to approximately 1,600 feet, with some hills at approximately 2,300 feet and slopes from zero to five degrees (Gallant et al., 1995).

The Alaska Range consists of steep rugged mountain ridges separated by broad valleys. Elevations are approximately 1,900 feet in lower valleys and often rising to greater than 12,500 feet – Mount McKinley is higher than 20,000 feet. Slopes are steep, almost always greater than 5 degrees on hillsides and exceeding 25 degrees on some mountains (Gallant et al., 1995).

The Cook Inlet consists of level of rolling terrain shaped by ground moraine, drumlin fields, eskers, and outwash plains, remnants of the Pleistocene glaciation. Elevations range from sea level to approximately 1,900 feet. The slopes are generally less than three degrees.

3.4.2.7 Western Interior Region

The Western Interior coal-bearing region includes Arkansas, Iowa, Kansas, Oklahoma, and Missouri (See Figure 3.4-13). The general topography of the region is very flat plain with elevations ranging from 500 to 1200 above MSL with very little local relief. The northern portion of the Western Interior region occupies the Central Lowlands physiographic province including the Osage Plains, and Dissected Till Plains Sections (See Figure 3.4-13). The portion lying primarily in Kansas and Oklahoma falls within the Osage Plains, while the Missouri and Iowa portions fall within the dissected Till Plains. The small area of the Western Interior coal region that extends into western Arkansas and parts of eastern Oklahoma falls in the Ozark Plateau physiographic province.

The Dissected Till Plains section has been glaciated and therefore is of low relief, ranging from 100 to 300 feet. The glacial till of this area is covered in the more eastern parts with up to 30 feet of loess.

The Osage Plains section lies south of the glacial limit so it has greater relief than the glaciated area of the Central Lowlands to the north. Most of the Osage area consists of upland plains with deeply entrenched rivers, some with valleys a few hundred feet deep.

The Ozark Plateaus physiographic province resembles the Appalachian Plateau Province, but elevations and relief average lower than in the Appalachians. A maximum elevation of 2,000 feet is reached in the southern part of this province (Vogel, 1981).

3.5 Water Resources

3.5.1 Introduction

Water resource considerations vary greatly across the coal-producing regions covered by this FEIS. This section presents background information on the affected environment for both the physical (flow of water) and the chemical (water quality) aspects of water resources. The discussion is organized into two major topics:

- **General Hydrology**: The General Hydrology section provides national-level information as context for understanding the affected environment descriptions of the seven coal regions.
- **Regional Hydrology**: The Regional Hydrology section describes groundwater and surface water systems for the seven coal regions, and characterizes associated water usage.

3.5.2 General Hydrology

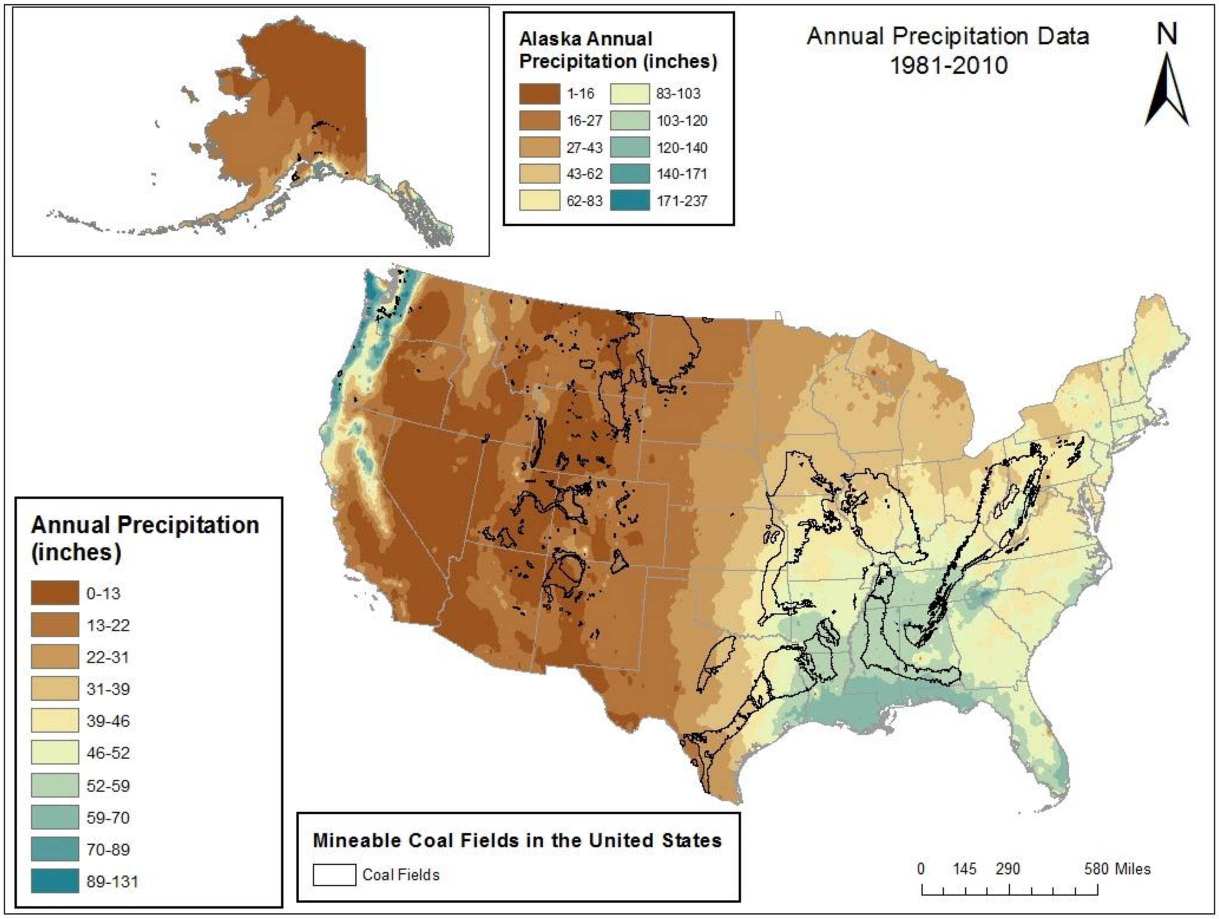
The following discussion provides background information needed to understand the regional hydrological descriptions presented in the Regional Hydrology section below. The general description of hydrology is organized in four parts:

- The Climatic and Precipitation discussion section provides basic climatic information related to climatic differences and similarities between the seven coal resource regions.
- The Groundwater discussion section provides a brief introduction to the national importance and use of groundwater.
- The Surface Water discussion section covers four topics: stream types; stream morphology; water quantity; and, water quality. This introductory information is related to information about surface water in the Regional Hydrology section.
- The Water Usage discussion section provides a national overview of how surface and groundwater is used to support a variety of domestic and industrial needs. This section also discusses how water usage by the mining industry compares to water usage by other domestic and industrial users. More detailed water usage information is also provided in the Regional Hydrology section.

3.5.2.1 Climate and Precipitation

Climatic conditions vary greatly across the seven coal-producing areas, ranging from semi-arid to humid conditions. This variability affects stream type and flow characteristics. This section presents two maps of the continental U.S. depicting the annual precipitation and annual average temperature (Figures 3.5-1 and 3.5-2). Figure 3.5-1 and 3.5-2 are reproduced from the National Oceanic and Atmospheric Administration "Climate Normals dataset" which is produced once every 10 years. The 1981–2010 U.S. Climate Normals dataset is the latest release of NCEI's Climate Normals. This dataset contains daily and monthly Normals of temperature, precipitation, snowfall, heating and cooling degree days, frost/freeze dates, and growing degree days calculated from observations at approximately 9,800 stations operated by NOAA's National Weather Service. Specific climate conditions for each of the seven coal resource regions are discussed below.

Figure 3.5-1. Annual Precipitation 1981 to 2010



Source: USGS, 2001c, *Coal Fields*, U.S. DOI, http://nationalatlas.gov/atlasftp.html?openChapters=chpgeol#chpgeol NOAA, 2010. 1981-2010 *Climate Normals- precipitation*, U.S. Department of Commerce. http://www.ncdc.noaa.gov/oa/climate/normals/usnormals.html

NOAA, 2010. 1981-2010 *Climate Normals- Temperature*, U.S. Department of Commerce. http://www.ncdc.noaa.gov/oa/climate/normals/usnormals.html

3.5.2.2 Appalachian Basin Region

The Appalachian Basin has a humid climate with abundant rainfall. Precipitation averages about 45 inches annually (Figure 3.5-1). Rainfall is greatest in the mountain areas. Precipitation is generally greatest during the spring and summer and least during the fall and winter. October is usually the driest month. Thunderstorms occur 40 to 50 days per year on average and are more frequent during June and July. These storms sometimes produce intense local rainfall and cause flooding in the narrow valley bottoms. Intense storms rarely encompass large areas but are frequent over small areas. The ten-year, 24-hour rainfall average is approximately four inches (Ehlke, et al., 1982). The mean annual rainfall ranges from 52 inches to 56 inches, with winter being the wettest season and March as the wettest month, on average. The driest months are commonly in the fall, with October being the driest month overall. It is common to have periods of no precipitation lasting longer than two to three weeks (Harkins et al., 1980).

3.5.2.3 Colorado Plateau Region

Climate classification predominantly depends on altitude with lower elevations in the east being classified as sub-humid and higher elevations in the west as semi-arid (Colorado Climate Center, 2010; Western Regional Climate Center, 2013). The climate in the four corners area of New Mexico, Arizona, Utah, and Colorado is characterized as semiarid to arid. The driest and wettest months on average are June and December, respectively. Most of the rainfall that occurs as intense thunderstorms occurs during the late summer (Colorado Climate Center, 2010). The climate changes to the north in the higher terrain areas of eastern Utah and western Colorado. Areas at higher altitudes have greater precipitation and lower temperatures than those at lower altitudes. Average annual precipitation on the Colorado Plateau, based on analysis of daily records from 97 long-term weather stations, ranges from 5.4 to 26.3 inches per year, with a median precipitation of 11.8 inches per year (USGS, 2005d). In higher altitudes for this area, the precipitation usually ranges between 25 to 35 inches per year. During summer and early fall, precipitation comes from intense, short duration, localized convective storms.

3.5.2.4 Gulf Coast Region

Generally, a maritime climate prevails along the Gulf Coast of Texas. Average annual precipitation in the coastal mining area of Texas exceeds 56 inches with some areas incurring higher amounts. There are two basic seasons: a hot summer that may last from April through October and winter that starts in November and usually lasts until March. Monthly average temperatures range from 48°F in January to 88°F in August (City-Data.com, 2010; Texas Water Development Board, 2012). Proceeding towards Oklahoma and Arkansas, the climate is characterized by a mild spring, a hot and humid summer, a mild autumn, and a mild winter. On average, July and August are the warmest months with December and January being the coldest. Average daily maximum temperatures in Oklahoma and Arkansas range from 50 degrees in January to 95 degrees in July and August.

Normal annual precipitation for the Gulf Coast coal-producing region ranges from about 36 inches in the northwestern to about 50 inches in the southeastern part of this area. In an average year, about 32 percent of the annual participation falls in the spring with 27 percent, 22 percent, and 19 percent falling in the summer, autumn, and winter, respectively. April, May, and June are the wettest months and are characterized by short-duration thunderstorms of varying intensity that make up most of the rainfall for the year. Twenty-four hour rainfall totals of up to ten inches have been recorded. In the winter, snowfall averages close to six inches per year occurring mainly in January and February (Marcher, et al., 1987).

3.5.2.5 Illinois Basin Region

In the Illinois Basin, precipitation is mainly produced by low-pressure westerly systems entraining southerly winds bearing moist, warm air from the Gulf of Mexico. Occasionally, high pressure cells from the north also create rain, snow, and sleet conditions. Average annual precipitation ranges from approximately 39 to 50 inches. Precipitation occurs about 120 days per year. Monthly precipitation averages from August through October are 20 percent to 35 percent less than monthly averages for the remainder of the year. Intense storms usually cover large areas.

3.5.2.6 Northern Rocky Mountains and Great Plains Region

The climate in this area is significantly affected by the mountains along the Pacific coast and the Rocky Mountains. Annual precipitation in the mountains exceeds 25 inches while the plains receive approximately 10 to 16 inches. Most precipitation occurs as snowfall from November through April with greater than 100 inches of snow in the mountains and 30 to 75 inches in the plains. Much of the snow in the plains is sublimated. Precipitation during the summer months primarily occurs as light showers with occasional intense thunderstorms.

3.5.2.7 Northwest Region

The climate in Southcentral Alaska is a subarctic climate due to its short, cool summers. The climate of the interior of Alaska is best described as extreme and is the best example of a true subarctic climate, as the highest and lowest recorded temperatures in Alaska have both occurred in the interior. The Matanuska Valley, although adjacent to tidewater, lies so far from the ocean that its climate is more like that of the Interior (Barnes and Payne, 1956).

The continental climate of interior Alaska has a wide range of air temperatures between summer and winter and large fluctuations around the seasonal means. The only active coal mining operation in Alaska is in the Tanana Valley. The mean annual temperatures in the Tanana Valley average 26.4°F at the Fairbanks International Airport with the warmest month, July, averaging 61.3°F, and the coldest month January averaging -10.3°F (1917 to 2000 averages). However, these averages do not present an accurate picture of either the extreme summer or winter air temperatures. For example, in the Tanana Valley, periods of extreme cold ranging in the vicinity of -40°F to -49°F are not uncommon at any time from late November through February. In contrast, daily maximum temperatures occasionally reach 90°F to 98.6°F in June and July, often with only modest night cooling because of persistent daylight (Bonanza Creek LTER, 2011).

Annual precipitation in interior Alaska is low and decreases from west to east, with a 50-year average for Fairbanks of 11.3 inches and a range from 5.6 inches in 1957 to 18.8 inches in 1990. Most summer and winter precipitation is generated from major frontal systems that cross the State, but convective storms add significantly to the summer precipitation. Precipitation events in early summer (May, June, and early July) are typically light and showery, with high spatial variability. The relatively dry summer conditions are replaced by the fall rain events which can be heavy and sustained. On average, precipitation increases through the summer.

3.5.2.8 Western Interior Region

The general climate of the Western Interior region is continental affected primarily by alternative masses of warm moist air from the Gulf of Mexico and cold, comparatively dry air from the northern polar regions. Hence, there are large variations in precipitation and temperature. Average annual precipitation ranges from approximately 34 inches in the western area, increasing to greater than 40 inches towards the east. About 70 percent of precipitation occurs in the growing season from April through October. Rainfall occurs either in intense thunderstorms of short duration or longer storms that cover greater areal extent. The ten-year 24-hour storm average is approximately five inches. The average temperature is about 56 °F in the Western Interior region. July is generally usually the warmest month with an average daily maximum of 91 °F and an average daily temperature of 69 °F. January is the coldest month with the average daily maximum and minimum of 40 °F and 21°F, respectively (NOAA, 2011; National Weather Service, 2012).

3.5.3 Groundwater Usage Overview

Groundwater is among the Nation's most important natural resources. As defined in the federal regulations (30 CFR 701.5), groundwater is "subsurface water that fills available openings in rock or soil materials to the extent that they are considered water saturated." A USGS report (USGS, 2000b) states that groundwater "… provides drinking water to urban and rural communities, supports irrigation and industry, sustains the flow of streams and rivers, and maintains riparian and wetland ecosystems. In many areas of the Nation, the future sustainability of groundwater resources is at risk from overuse and contamination. Because groundwater systems typically respond slowly to human actions, a long-term perspective is needed to manage this valuable resource."

Nationwide, fresh groundwater withdrawals of 79.6 billion gallons per day (bg/d) in 2005 were about five percent less than in 2000. Of this 79.6 bg/d, about 67.2 percent were for irrigation, 18.3 percent for public supply, 4.7 percent for domestic supply, 3.9 percent for industrial use, 2.4 percent for aquaculture, 1.6 percent for livestock, 1.3 percent for mining, and 0.6 percent for thermoelectric use. More than half (43.35bg/d) occurred in six states: California, Texas, Nebraska, Arkansas, Florida, and Idaho (Kenny, et al., 2009). Of these six major groundwater user states, only Texas is considered a significant coal producer. Appendix J includes tables listing the source and amount of groundwater withdrawals for all counties within the U.S. that produced coal in 2005. These tables can be used to compare the magnitude of mining-related withdrawals to other industries.

3.5.4 Surface Water Overview

Surface water receives direct input from precipitation, including precipitation that has traveled overland and from groundwater. Watersheds and their surrounding ecosystems are linked by the flow of water. In a watershed context, landscape hydrologic connectivity refers to the maintenance of natural hydraulic connections of surface and subsurface flow between source, headwater, or contributing areas and downstream/down-gradient receiving waters. As headwater streams occur upstream from, and may ultimately discharge into higher order perennial streams, they connect landscape processes through their influence on the supply, transport, and fate of water and solutes in the watershed (Alexander, et al., 2007; Leibowitz, et al., 2008).

3.5.4.1 Stream Types

"Stream" is a general term for a body of flowing water. In hydrology, the term is generally applied to the water flowing in a natural channel, as distinct from a canal. Stream reaches are "dynamic zones within stream networks" (Fritz, et al., 2006) meaning that the points-of-origin of streams are not static but can vary depending on factors such as precipitation, evapotranspiration, and land use (Paybins, 2003). Streams in natural channels may be classified as follows (Meinzer, 1923):

- Relation to time:
  - **Perennial**: A stream that flows continuously.

- **Intermittent or seasonal**: A stream that flows only at certain times of the year when it receives water from springs, precipitation, or from some surface source such as melting snow.
- **Ephemeral**: A stream that flows only in direct response to precipitation or snowmelt, and whose channel is at all times above the water table.

- Relation to space:
  - **Continuous**: A stream that does not have interruptions in space.
  - **Interrupted**: A stream that contains alternating reaches that are perennial, intermittent, or ephemeral.
- Relation to groundwater:
  - **Gaining**: A stream or reach of a stream that receives groundwater contributions.
  - **Losing**: A stream or reach of a stream that contributes water to groundwater.
  - **Insulated**: A stream or reach of a stream that neither contributes water to groundwater nor receives water from it. It is separated from groundwater by an impermeable bed.
  - **Perched**: A stream whose stream bed is above the water table and separated from underlying groundwater by an impermeable geologic unit in the unsaturated zone.

Table 3.5-1 contains a summary of the lengths and percentages of intermittent and perennial streams for each coal resource region. This table was generated using the USGS National Hydrography Dataset (NHD). The NHD is a comprehensive set of digital spatial data that represents the surface water of the U.S. using common features such as lakes, ponds, streams, rivers, canals, stream gages, and dams (USGS, 2011b).

Table 3.5-1. Summary of NHD Intermittent and Perennial Stream Lengths for the Coal Resource Study Areas[1]

Region	Stream Type	Length (miles)	Percent of Total Length (Perennial and Intermittent only[1])
Appalachian Basin	Intermittent	69,296	56
	Perennial	55,004	44
	Total	124,300	
Colorado Plateau	Intermittent	35,522	93
	Perennial	2,605	7
	Total	38,127	
Gulf Coast	Intermittent	175,670	75
	Perennial	47,761	25
	Total	223,431	
Illinois Basin[2]	Intermittent	71,010	75
	Perennial	23,485	25
	Total	94,718	
Northern Rocky Mountains and Great Plains	Intermittent	141,721	95
	Perennial	7,742	5
	Total	149,463	
Northwest	Intermittent	109	13
	Perennial	760	88
	Total	860	
Western Interior	Intermittent	125,066	81
	Perennial	29,984	19
	Total	155,050	

Source: Derived from USGS, 2011b, National Hydrography Dataset (http://nhd.usgs.gov/documentation.html), clipped to the boundaries of the coal resource study areas used in this EIS.

[1]The dataset is known to be incomplete for ephemeral streams. Therefore this table presents only the total of stream characterized as Perennial or Intermittent. The dataset is high resolution mapped at 1:24,000.

[2]Approximately 23 percent of the stream lengths in the dataset for this region were given no designation.

As seen in Table 3.5-1, most of the regions have intermittent stream lengths greater than perennial stream lengths, but the values vary markedly. For more arid regions such as the Colorado Plateau and the Northern Rocky Mountains and Great Plains, the lengths of intermittent streams are far greater than perennial streams. For the Illinois and Gulf Coast Basins where rainfall amounts can be notably variable, the intermittent stream lengths are greater but not as significantly as in the more arid regions. The Appalachian, and Western Interior regions have the least difference in length of intermittent versus perennial streams.

Using the NHD, the EPA has estimated that 59 percent of the streams in the U.S. (excluding Alaska) are ephemeral or intermittent (Levick, et al., 2008). The NHD also identifies start reaches as those that have no other streams flowing into them (at the 1:100,000 scale). These reaches can thus be considered headwater or first-order streams (Levick, et al., 2008; Nadeau and Rains, 2007).

One of the most common methods used to classify streams is known as the Strahler method (Strahler, 1952). Using this method, streams are numbered progressively from the headwaters or drainage basin divide to a downstream location. Streams with no tributaries are designated as first-order. When two first-order streams join to create a confluence, a second-order stream is designated. When two second-order streams create a confluence a third-order stream is designated, and so on downstream. Leopold, et al. (1964) used the Strahler method to estimate the total stream length in the U.S. (Table 3.5-2). Extrapolating from maps of 1:24,000 to 1:62,500 scale, the authors estimated that there are 3,250,000 miles of streams in the U.S. Since Leopold, et al. (1964) used a 1:24,000 scale map as their basis, the stream lengths presented in Table 3.5-2 are likely under-representative of the actual stream lengths as many ephemeral streams and some intermittent ones are likely not shown on large scale maps.

Table 3.5-2. Number and Length of Streams in the U.S.

Order	Number	Average Stream Length (mi)	Total Stream Length (mi)
1	1,570,000	1	1,570,000
2	350,000	2.3	810,000
3	80,000	5.3	420,000
4	18,000	12	220,000
5	4,200	28	116,000
6	950	64	61,000
7	200	147	30,000
8	41	338	14,000
9	8	777	6,200
10	1	1,800	1,800

3.5.4.2 Stream Morphology

This FEIS describes stream morphology using the Rosgen (1994) classification system. While all Rosgen types can be identified in all regions, discussion is limited to a generalized Rosgen Level 1 description of the characteristic stream type(s) that are likely to be impacted by surface and underground mining in their respective coal region. Further, classifications for the most part are identified as a function of the physiographic and topographic relief conditions present. The intent is to highlight the relative occurrence of Rosgen stream types across coal regions, not describe all stream types present.

The variety of stream forms or morphologies that exist in the environment are an expression of driving forces (water, gravity) and resisting forces (as influenced by lithology, vegetation, sediment load, and sediment size). The dominance of erosion or deposition is determined by the relative magnitude of the elements affecting the driving and resisting forces, and thus determines stream form and how actively streams change their morphology (Lane, 1955).

Broad morphological characterization is accomplished using descriptions of relief, local lithology, plan form, valley configuration, channel profile, and dominant substrate. The Rosgen classification system described in the seminal published work, *A Classification of Natural Rivers* (Rosgen, 1994), is widely recognized among land use and water resource managers. The Rosgen system synthesizes the results of previous works in stream morphology (Lane, 1957; Leopold & Wolman, 1957; Schumm, 1963; Culbertson, et al., 1967; Khan, 1971) with additional extensive research to create a stream taxonomy that can be used to objectively describe streams observed in all coal regions. Table 3.5-3 presents the nine fundamental Rosgen stream types. For a detailed discussion of the Rosgen Classification system, the reader is directed to *Applied River Morphology* (Rosgen, 1996). A generalized Level 1 discussion of the dominant stream types is presented below. The Level 1 classification within the Rosgen system describes generalized categories of streams using broad descriptions of longitudinal profiles, valley and channel cross-sections, and plan view patterns (Rosgen, 1994).

Streams that are observed in headwater basins of high relief are steep (four to ten percent) to very steep (>ten percent), have high erosion and transport potential, and are recognized as “A” and “Aa+” type streams (Table 3.5-3). These streams are very stable when they exist in resistant bedrock or boulder colluviums, but can incise weak sedimentary rock and finer-grained unconsolidated alluvium. Slopes exceeding ten percent are considered erosional and are susceptible to mass wasting processes such as debris flows. Stream-bed features include alternating steps and pools, cascades and waterfalls. Steps are vertical drops formed by boulders, bedrock, or downed trees and pools are deep flat areas in the stream created by scour (North Carolina State University, 1999). Generally, these single-channel streams are linear in plain view with little sinuosity and are characterized by limited valley floodplain width. Sinuosity is defined as the ratio of the stream channel length to valley length. Streams that have limited floodplains are described as entrenched. The degree of entrenchment is measured as a ratio of the floodplain width to the bankfull channel width.

Moving within the drainage basin from steep headwater areas downstream to areas of moderate relief and gradient, “A” type streams transition to “B” types (Figure 3.5-3). “B” type streams are moderately steep to gently sloped (two percent to four percent). They are also laterally constrained by narrow valley slopes and consequently have narrow floodplains. They are straight, single-channel streams with little sinuosity and exhibit stream bed features such as rapids and alternating riffles and pools. Riffles are sections of streams comprised of gravel-size or larger bed sediment and are shallow and swift at low flows (North Carolina State University, 1999). Similar to “B” type streams; “G” type streams are also moderately steep to gently sloped (two percent to four percent) but are more entrenched and have lower bankfull channel width to bankfull channel depth (W/D) ratios (<12). Measurements of W/D ratios are useful to describe relative differences in channel cross-section and also provide a visual assessment of channel stability. For example, “G” types are recognized as unstable with grade control problems and high bank erosion.

Sinuous streams are stream type “C.” These streams have low channel gradients (less than two percent), and occur within narrow to wide alluvial valleys in landscapes of low relief. These streams are wide and shallow as demonstrated by their high W/D ratios (greater than 12). “C” type streams exhibit enhanced lateral migration or “meandering” due to a lack of lateral constraints, erodible bed and bank materials, and active channel aggradation and degradation processes. A meander is a bend or curve in the stream channel. Typical stream features include riffles, pools, and point bars. Point bars are crescent shaped depositional features with coarse material located on the inside of a bend in the stream (North Carolina State University, 1999).

Table 3.5-3. Rosgen's Nine Fundamental Stream Types

Stream Type	General Description	Entrenchment Ratio[1]	W/D Ratio[2]	Sinuosity[3]	Slope	Landform/Soils/Features
Aa+	Very steep, deeply entrenched, debris transport, torrent streams.	<1.4	<12	1.0 to 1.1	>.10	Very high relief. Erosional, bedrock or depositional features; debris flow potential. Deeply entrenched streams. Vertical steps with deep scour pools; waterfalls.
A	Steep, entrenched, cascading, step/pool streams. High energy/debris transport associated with depositional soils. Very stable if bedrock or boulder dominated channel.	<1.4	<12	1.0 to 1.2	.04 to .10	High relief. Erosional or depositional and bedrock forms. Entrenched and confined streams with cascading reaches. Frequently spaced, deep pools in associated step/pool bed morphology.
B	Moderately entrenched, moderate gradient, riffle dominated channel, with infrequently spaced pools. Very stable plan and profile. Stable banks.	1.4 to 2.2	>12	>1.2	.02 to .039	Moderate relief, colluvial deposition, and/or structural. Moderate entrenchment and W/D ratio. Narrow, gently sloping valleys. Rapids predominate with scour pools.
C	Low gradient, meandering, point-bar, riffle/pool, alluvial channels with broad, well defined floodplains.	>2.2	>12	>1.2	<.02	Broad valleys w/terraces, in association with floodplains, alluvial soils. Slightly entrenched with well-defined meandering channels. Riffle/pool bed morphology.
D	Braided channel with longitudinal and transverse bars. Very wide channel with eroding banks.	n/a	>40	n/a	<.04	Broad valleys with alluvium, steeper fans. Glacial debris and depositional features. Active lateral adjustment, w/abundance of sediment supply. Convergence/divergence bed features, aggradational processes, high bedload and bank erosion.

Stream Type	General Description	Entrenchment Ratio[1]	W/D Ratio[2]	Sinuosity[3]	Slope	Landform/Soils/Features
DA	Anastomosing (multiple channels) narrow and deep with extensive, well vegetated floodplains and associated wetlands. Very gentle relief with highly variable sinuosities and width/depth ratios. Very stable stream banks.	>2.2	Highly variable	Highly variable	<.005	Broad, low-gradient valleys with fine alluvium and/or lacustrine soils. Anastomosed (multiple channel) geologic control creating fine deposition w/well-vegetated bars that are laterally stable with broad wetland floodplains. Very low bedload, high wash load sediment.
E	Low gradient, meandering riffle/ pool stream with low width/depth ratio and little deposition. Very efficient and stable. High meander width ratio.	>2.2	<12	>1.5	<.02	Broad valley/meadows. Alluvial materials with floodplains. Highly sinuous with stable, well-vegetated banks. Riffle/pool morphology with very low width/depth ratios.
F	Entrenched meandering riffle/pool channel on low gradients with high width/depth ratio.	<1.4	>12	>1.2	<.02	Entrenched in highly weathered material. Gentle gradients, with a high width/depth ratio. Meandering, laterally unstable with high bank erosion rates. Riffle/pool morphology.
G	Entrenched “gully” step/pool and low width/depth ratio on moderate gradients.	<1.4	<12	>1.2	.02 to .039	Gullies, step/pool morphology w/moderate slopes and low width/depth ratio. Narrow valleys, or deeply incised in alluvial or colluvial materials, i.e., fans or deltas. Unstable, with grade control problems and high bank erosion rates.

[1] Entrenchment ratio - ratio of the floodplain width to the bankfull channel width

[2] Width to depth (W/D) ratio - ratio of the bankfull channel width to bankfull channel depth

[3] Sinuosity - ratio of the ratio stream channel length to valley length

Source: Rosgen, 1996.

The Rosgen "E" and "F" stream types are similar to "C" stream types in that they exist within landscapes of low relief. These stream types are differentiated from the "C" types by their relative degree of entrenchment and W/D ratios. Relative to "C" types, "E" stream types have lower W/D ratios indicating they are narrower and deeper. "F" types have lower entrenchment ratios (more entrenched), indicating a lack of floodplain.

Streams can also exhibit multiple-channel or "braided" forms. These streams are recognized as "D" types and occur on lands of very low relief with very low gradients. They are shallow in depth, contain abundant sediment supplies, and are highly active with respect to lateral adjustments. The individual channels are separated by depositional bars. The stream-type occurs in landforms comprised of depositional alluvium such as glacial wash and alluvial fans.

Figure 3.5-3. Rosgen stream types relative to topography

http://cfpub.epa.gov/watertrain/moduleFrame.cfm?module_id=27&parent_object_id=1189&object_id=1189

All nine fundamental Rosgen stream types can be further sub-classified using numeric designation (one to six). These numeric designations correspond with the textural class of the dominant channel material. The numeric scale starts with (1) being bedrock and (2) the coarsest of material being boulders. It progresses incrementally to (6) being the finest of material silt/clay. For example, a sinuous single channel of low gradient that exhibits high W/D ratio, high entrenchment ratios (low entrenchment), with cobble channel material would be a "C3" type, while a similar stream with sand channel material would be a "C5" type (Rosgen, 1996).

3.5.4.3 Management Interpretations

The sensitivity of streams to imposed changes such as increases in flow, human disturbance, and the introduction or loss of riparian vegetation varies by stream type. Stream-type sensitivity is shown in Table 3.5-4, as are values for recovery potential, sediment supply, stream bank erosion potential, and vegetative controlling influence. The predictions were derived from rangeland management studies but are applicable to other kinds of disturbances such as silviculture and surface mining (Rosgen, 1994; Rosgen, 1996).

Table 3.5-4 Management Interpretations by Rosgen Stream Type

Stream Type	Sensitivity to Disturbance[1]	Recovery Potential[2]	Sediment Supply[3]	Streambank Erosion Potential	Vegetation Controlling Influence[4]
A1	very low	excellent	very low	very low	negligible

3.5.4.4 Water Quantity and Stream Regime

While streams in the U.S. vary greatly, stream characteristics can be described as a function of the climatic and topographic environment as well as of watershed geology and land cover. Snelder, et al., (2005) proposes that climatic and topographic characteristics of a watershed are the dominant causes of variation in hydrological processes at macro (approximately 400 to 40,000 square miles) and meso (approximately 40 to 400 square miles) spatial scales, and can be used to define distinctive flow regime classes and delineate patterns in flow regimes at these spatial scales.

For example, streams whose watersheds are located in high precipitation areas are expected to have more consistent flows and more frequent flooding. Streams that are located in the rain-shadows or regions of low precipitation are expected to have the extended periods of low flow and flow variation is expected to be higher. Variability in temperature further drives the seasonal response to precipitation. In cool regions, precipitation as snow is stored in winter and released as snowmelt in spring and summer. In warm regions, snow storage is less and runoff regimes will more closely follow the temporal distribution of precipitation (Poff and Ward, 1989; Snelder, et al., 2005).

Snelder, et al., (2005) also discusses how topography influences stream characteristics. Mountainous environments receive higher precipitation than lowland areas and can be expected to have lower flow variability, more sustained base flows, and higher low flows. In regions that receive significant precipitation in the form of snow, snowpack storage dampens the watershed response to precipitation and delays the watershed's release of water until summer. Mountain environments are expected to have low flood frequency and marked summer peak flows (Duncan, 1992; Snelder, et al., 2005). Regions of lower relief and elevation are characterized by limited snow storage that typically melts by mid-to-late spring. Thus, these areas may have two low flow periods, summer and winter. Flow variability and the magnitude and frequency of high flows, relative to median flow, is expected to be higher in areas of low relief as compared to mountain regions because there is less storage of precipitation and attenuation of watershed response to precipitation. Low flows in areas of low relief are expected to be small, relative to median flow, compared to mountain regions for the same reason. Areas of very low relief are least affected by the storage of precipitation as snow, and thus the flow regime is expected to follow seasonal patterns in precipitation and evapotranspiration regimes (Duncan, 1992; Snelder, et al., 2005).

Surface-water quality is described regionally using a three-step approach. First, select designated uses defined by each state within each coal resource area are provided. This information provides the reader with an idea of the types of designated uses that must be protected regardless of the Action Alternative selected. Secondly, the regional discussion summarizes the integrated water quality report assessments for each state. The water quality assessment summary provides a snapshot of the ratio of surface waters attaining their designated use (referred to as "good waters") to those not attaining their designated use (referred to as "impaired waters"). The summary includes the total miles of streams in each of the "good," "impaired," and "threatened" categories as well as information on the number of stream miles assessed versus total stream miles. Readers can compare and contrast these tables between states and coal resource regions to assess surface water quality conditions. Thirdly, readers who seek a more detailed discussion of surface water quality conditions than provided in the summary tables can consult hyperlinks to access the Clean Water Act (CWA) integrated reports for each of the states. Collectively, these three pieces of information provide a general understanding of the existing water quality for each region.

3.5.4.5 Water Usage Overview

Water supply resources include both groundwater and surface water. Groundwater is typically withdrawn via wells from deep aquifers or from shallow aquifers typically found in areas adjacent to rivers and streams. Surface water supply resources include direct withdrawals from reservoirs, rivers, lakes, and streams. Water is typically supplied by public and private utilities. Users may also provide their own water (self-supply) from wells for agricultural and residential use. Water supply resources and suppliers vary in each region.

The pattern of total water usage and distribution varies between each region. Areas differ with respect to the mix of public supply, domestic, commercial/industrial, agricultural, mining, and thermoelectric uses. The use categories are defined below (Templin, et al., 1997).

- A public water supply use is a public or private water system that provides water to at least 25 people or has a minimum of 15 service connections. Public water suppliers provide water to domestic, commercial, and industrial users, to facilities generating thermoelectric power, for public use, and occasionally for mining and irrigation.
- Domestic water use includes water used for household purposes such as drinking, food preparation, bathing, washing clothes and dishes, flushing toilets, car washing, and watering lawns and gardens. For the purposes of this discussion, domestic water use includes private self-supply only.
- Commercial water use includes water used by commercial facilities such as hotels, motels, restaurants, office buildings, government and military facilities, hospitals, educational institutions, and retail sales stores.

- Industrial water use includes water used to manufacture products such as steel, chemical, and paper, as well as water used in petroleum and metals refining. It does not include power generation for sale to other users, mining of minerals, or the extraction of crude petroleum and gases, which are included in other water-use categories.
- Mining water use includes water used for the extraction and on-site processing of naturally occurring minerals including coal, ores, petroleum, and natural gas. The mining category includes product incorporation during dust control, tailings disposal, slurry conveyance, and drying; wastewater treatment; deliveries of reclaimed wastewater; return flow; and dewatering.
- Irrigation includes water applied to crops grown on commercial farms. Irrigation water use is by far the largest use of water diverted from streams or withdrawn from aquifers in the western U.S. (Solley, 1997). Total annual irrigation water use can vary depending on many factors, including climate, foreign trade, commodity prices, production costs, cost efficiency of irrigation, and changes in irrigation technology.
- Livestock water use includes water used to raise cattle, sheep, goats, hogs, and poultry, and horses.
- Aquaculture includes water used for farming of organisms that live in water, such as fish, including fish hatcheries, shrimp, and other shellfish.
- Thermoelectric power generation includes water used in the generation of electric power when the following fuel types are used: fossil, nuclear, biomass, solid waste, or geothermal energy.

For the purpose of this FEIS, commercial and industrial use are treated as a single category. Likewise, irrigation, livestock, and aquaculture uses are combined as agricultural use.

A portion of the total domestic and agricultural water used is self-supplied. Self-supplied water, primarily withdrawn from private groundwater wells, is typically used for household and farming/irrigation applications. Private wells are most common in rural areas not served by municipal water supplies. There are over 15.6 million users of private water supply wells (wells that serve one to five homes) in the U.S. (U.S. Census Bureau, 2008). Unlike municipal water supply, which is monitored for water quality and typically treated prior to distribution, self-supplied water is unregulated by the EPA, and well owners take full responsibility for water quality, availability, and maintenance of their wells. Because private wells may not be routinely monitored or treated under Safe Drinking Water Act regulations, they may be more vulnerable to water quality and supply changes related to mining than a public water supply system. However, under SMCRA, operators are required to mitigate certain water supply impacts related to coal mining operations by replacing the impacted water supply (SMCRA Sections 717 (b) and 720 (a)(2)).

Table 3.5-5 provides a percentage breakdown of the USGS reported 2010 water use by usage category for each of the seven coal resource areas (Maupin et al., 2014). The water usage information is compiled by the USGS every five years. The USGS published the 2010 USGS water-usage data report in November 2014.

Table 3.5-5. Total Water Usage by Category and Region

Category	Appalachian Basin	Colorado Plateau	Gulf Coast	Illinois Basin	Northern Rocky Mountains and Great Plains	Northwest	Western Interior
Thermo-electric	73.0%	1.2%	52.3%	74.7%	1.5%	6.7%	46.5%
Public Supply	13.8%	12.4%	11.0%	10.5%	4.6%	9.1%	13.1%
Domestic	1.4%	0.4%	0.8%	1%	1%	1.7%	0.7%
Agriculture	2.7%	84.6%	27.5%	2.3%	91.5%	78.9%	38.3%
Industrial and Commercial	8.4%	0.8%	6.9%	10.9%	0.9%	0.9%	0.9%
Mining	0.6%	0.6%	1.5%	0.7%	0.4%	2.8%	0.5%

3.5.5 Regional Hydrology

The U.S. coal regions feature diverse hydrological resources. As a foundation for analysis of impacts in Chapter 4, the following regional discussions provide a broad overview of regional water resources.

3.5.5.1 Appalachian Basin Coal-Producing Region

3.5.5.1.1 Groundwater

The eastern extent of the Appalachian Plateaus physiographic province is bound by the Cumberland Front Escarpment in Kentucky and Tennessee. The coal region extends north of the escarpment into the western parts of Virginia, West Virginia and Maryland and into western and northern Pennsylvania. The coal region extends south into northeastern Alabama and northwestern Georgia for a short distance. The western boundary of the Appalachian Basin Coal region follows the extent of Mississippian and Pennsylvanian age rocks, with mineable coal in the Pennsylvanian rocks.

3.5.5.1.1.1 Primary Aquifers

Aquifers in the Appalachian Basin Coal region are either surficial aquifer systems in unconsolidated deposits, or occur in the deeper consolidated rocks. Sand and gravel surficial aquifers overlie the consolidated rock aquifers in much of northeastern Ohio and along the Ohio River and its tributaries. Aquifers in consolidated rocks consist of sedimentary bedrock ranging in age from Mississippian through Permian.

3.5.5.1.1.2 Unconsolidated Aquifers

The unconsolidated surficial aquifer systems consist of sand and gravel deposits of glacial and alluvial origin that filled in bedrock valleys. The alluvial material occurs primarily along existing streams and consists mostly of reworked glacial deposits. Wells completed in the sand and gravel deposits, which have a high hydraulic conductivity, typically have a high associated yield. The reworked glacial material forming unconsolidated aquifer is most common in southward-flowing streams, such as the Allegheny and the Ohio Rivers, which have their headwaters in glaciated areas. Alluvium in the valleys of northward-flowing streams typically consists of material that has been weathered and eroded from exposed consolidated sedimentary rocks. The alluvium along the northward-flowing rivers, such as the Kanawha in West Virginia and the Monongahela in Pennsylvania, generally is finer grained than that along the southward-flowing rivers and often yields less water to wells compared to southward-flowing rivers. Well yields in sand and gravel deposits commonly range from 100 to 500 gallons per minute but can exceed 2,000 gallons per minute. Well yields in the finer grained aquifers commonly range from 25 to 50 gallons per minute (Lloyd and Lyke, 1995).

3.5.5.1.1.3 Primary Bedrock Aquifers

Aquifers in the Pennsylvanian age deposits in the Appalachian Basin Coal region mostly consist of sandstone and limestone, separated by coal and shale deposits. The aquifers in the Pennsylvanian age rocks are grouped into Upper Pennsylvanian aquifers and Middle and Lower Pennsylvanian aquifers. Coal beds and seams also can yield water because they are commonly fractured along joint systems (cleat) that store and transmit water.

The Upper Pennsylvanian aquifers are primarily in the Pennsylvanian Monongahela and Conemaugh Groups, but may be hydraulically connected to sandstones of the Dunkard Group. In southeastern Ohio and northeastern Kentucky, Upper Pennsylvanian rocks are primarily interbedded sandstone, siltstone, and shale with minor coal, grading to shale and siltstone. Together, the Monongehela and the Conemaugh Groups average about 1,000 feet in thickness. Well yields in Upper Pennsylvanian rocks range from 20 to 430 gallons per minute. Individual sandstone beds in Upper Pennsylvanian rocks generally are of limited areal extent, and isolated from other sandstone beds. The discontinuous occurrence and the general fine-grained texture of the unfractured rocks and sparse fracture openings may combine to impede the flow of groundwater. Perched water tables above clay layers underlying coal beds in the upland areas support springs along valley walls (Trapp and Horn, 1997; Lloyd and Lyke, 1995).

Middle and Lower Pennsylvanian aquifers contain the most widespread source of groundwater in the Appalachian Basin. Shale with interbedded sandstone is the dominant lithology of Middle and Lower Pennsylvanian rocks in the northern part of the coal region, whereas sandstone is dominant in the south. In Alabama, the southernmost part of the Appalachian Basin, in Alabama, most of the productive aquifers are associated with solution channels in karst limestone. Wells completed in the Bangor Limestone yield as much as 200 gallons per minute, and springs issuing from the Bangor have reported flows of as much as 4,000 gallons per minute. The Tuscumbia Limestone, combined with the hydraulically connected Fort Payne Chert, yields as much as 2,300 gallons per minute to wells. The Monteagle Limestone generally yields only small volumes of water. Rocks of the Middle and Lower Pennsylvanian aquifers include the Allegheny Formation and the Pottsville Group in Ohio, the Breathitt and the Lee Formations in Kentucky, and several equivalent formations in Tennessee. The Allegheny Formation and the Pottsville Group are primarily interbedded sandstone, siltstone, and shale but contain economically important beds of coal. An average of about 40 percent of the total thickness of the Pottsville Group is sandstone. In Kentucky, the Breathitt Formation is primarily interbedded sandstone, siltstone, and shale, whereas the Lee Formation is predominantly sandstone with some conglomerate. Beds of sandstone in the Breathitt Formation are typically from 30 to 120 feet thick and compose about 50 percent of the total thickness of the formation. About 80 percent of the total thickness of the Lee Formation consists of beds of sandstone and conglomerate. Middle and Lower Pennsylvanian rocks in Tennessee are predominately interbedded conglomerate and sandstone with some siltstone, shale, and coal beds. Some of the Middle and Lower Pennsylvanian sandstone and conglomerate beds are regionally extensive and contain well-developed fracture systems. The primary water-yielding units are sandstone and conglomerate beds in the Crab Orchard Mountains Group; some conglomerate beds in this group locally are 200 feet thick, whereas sandstone beds in the group range from 100 to 300 feet thick and are locally conglomeratic. Well yields from Middle and Lower Pennsylvanian aquifers only range from one to 25 gallons per minute in Ohio but range from five to 50 gallons per minute in Tennessee. Low-permeability layers of underclay beneath coal beds may limit downward movement of the water and create perched water-table conditions above the main water table. The perched water discharges as baseflow to streams, or as at the surface as springs (Lloyd and Lyke, 1995; Miller, 1990).

Figure 3.5-4 illustrates the general extent of the various aquifer types in the Appalachian Basin.

3.5.5.1.1.4 Groundwater Quality

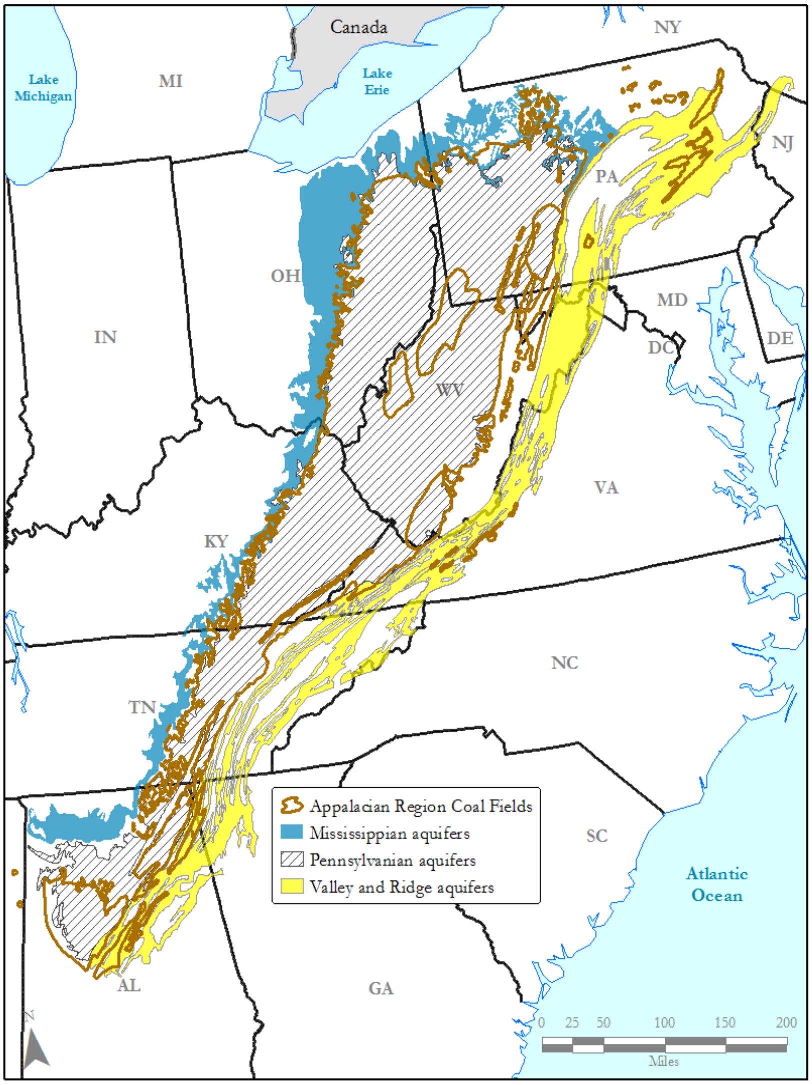
Groundwater from the aquifers in the Appalachian Basin is typically suitable for most intended uses, with chlorination usually being the only treatment required to make the water suitable for drinking. However, locally, elevated concentrations of iron or sulfate may be present and water from the surficial aquifer system and the aquifers in consolidated rocks may be contaminated by saltwater present at shallow depths or by human activity (i.e., disposal of waste water from the development of the coal, oil, and gas resources of the area) (Lloyd and Lyke, 1995).

Water from the surficial aquifer system in the Ohio portion of the region is predominantly a calcium bicarbonate type. According to the USGS Groundwater Atlas for Illinois, Indiana, Kentucky, Ohio and Tennessee, the surficial aquifers in Ohio water generally have larger median concentrations of dissolved solids (413 mg/L), chloride (31 mg/L), and sulfate (76 mg/L) and is harder (337 mg/L $CaCO3$) than water from the aquifers in consolidated rocks in the same area. Iron concentrations also tend to be more elevated in water from the surficial aquifer system than from water in consolidated rock aquifers and generally increase with depth (Lloyd and Lyke, 1995).

Surficial aquifer groundwater quality for the Maryland, Pennsylvania, Virginia and West Virginia area is defined by the USGS Groundwater Atlas of the United States, HA 730-L (Trapp and Horn, 1997) as: "suitable for municipal supplies and most other purposes. Most of the water in the upper parts of the aquifers is not highly mineralized." Trapp and Horn (1997) lists median values for dissolved solids at 250 mg/L; hardness (caused primarily by calcium and magnesium ions) at 140 mg/L; pH at 7.2; chloride at 29 mg/L; sulfate at 29 mg/L; and iron concentration at 100 μg/L.

Lloyd and Lyke (1995) state that "the principal factors governing the chemical quality of groundwater in the aquifers in consolidated rocks are aquifer mineralogy and residence time (the amount of time the water has been in contact with the rocks). Water from sandstone aquifers containing few soluble minerals generally is soft, whereas hard water is obtained from limestone or shale containing more of the soluble minerals calcite and dolomite. Water in the deeper parts of the aquifers tends to be more mineralized than water from shallow depths because the deeply circulating water generally has followed longer flow paths and has been in contact with aquifer minerals for a longer period of time. Generally, water from wells located in recharge areas on ridges is less mineralized than elsewhere because of a shorter residence time in the aquifer. Water from wells located in valleys where discharge occurs is more mineralized than elsewhere."

Figure 3.5-4. Appalachian Basin Region Aquifers



Source: USGS, 2003, Principal Aquifers of the United States.
http://water.usgs.gov/ogw/aquifer/map.html

Water from the Pennsylvanian aquifers in Ohio generally is either a calcium magnesium bicarbonate type or a calcium sodium bicarbonate type. Thin shale beds are present between the sandstone and limestone aquifers in these rocks. The shale contains calcite and siderite (an iron carbonate mineral). These minerals, along with the calcite and minor dolomite in the limestone beds, are the source of the calcium and magnesium. In Kentucky, water from wells completed in the Middle and Lower Pennsylvanian aquifers commonly is a calcium sodium bicarbonate type. Water from the aquifers in Mississippian rocks in Kentucky is a slightly alkaline, calcium bicarbonate type. Excessive hardness and elevated concentrations of iron, chloride, and sulfate are locally present in water from the Pennsylvanian aquifers. Groundwater quality varies with depth in the coal-producing Cumberland Plateau area of Virginia. Generally, the first 100 feet of depth below stream elevation, the groundwater is of poor quality, mainly due to sulfur and iron contamination. Naturally saline waters occur at depths greater than 300 feet in Virginia. Therefore, the best quality waters are usually found between 150 and 300 feet in this area. Data from Pennsylvanian aquifers in Tennessee indicate that water quality ranges from soft to hard and contains small concentrations of dissolved solids. In contrast, water from Mississippian aquifers, which are mostly limestone, generally is a calcium bicarbonate type and is harder and more mineralized than water from Middle and Lower Pennsylvanian aquifers. In Pennsylvania and West Virginia, the aquifer water is typically a calcium sodium bicarbonate type. Dissolved-solids concentrations are small and average only about 230 milligrams per liter. Hardness averages about 95 milligrams per liter. Water from predominately shale aquifers in Pennsylvania is reported to be hard, whereas that from predominately sandstone aquifers is reported to be soft. The median iron concentration is about 0.1 milligram per liter, but concentrations as high as 38 milligrams per liter have been reported. In Alabama, water quality is variable; although suitable for most intended uses, concentrations of sulfate and iron are elevated in places. Large concentrations of hydrogen sulfide, derived from sulfate, can impart a “rotten-egg” odor to the water. The quality of the water in Alabama generally deteriorates with depth as it becomes more mineralized (Miller, 1990; Trapp and Horn, 1997; Lloyd and Lyke, 1995).

Groundwater is an important source of freshwater in the Appalachian Plateaus province. Ohio’s surficial aquifers “are the major source of groundwater because they have the largest well yields of any aquifers in the Appalachian Plateaus province and because many of Ohio’s urban areas are located near major streams whose valleys are filled with sand and gravel deposits of the surficial aquifer system” (Lloyd and Lyke, 1995).

Surficial aquifers are more prevalent in Ohio and northwestern and northeastern Pennsylvania than elsewhere in the Appalachian Plateaus province. Lloyd and Lyke (1995) observe that “Despite their generally lower yields, the aquifers in consolidated rocks are also important sources of water. Upper Pennsylvanian aquifers provide domestic supplies, and Mississippian aquifers provide domestic and small public supplies. Middle and Lower Pennsylvanian aquifers are used primarily for domestic, stock, and small public and industrial supplies throughout the Appalachian Plateaus Province.”

3.5.5.1.2 Surface Water

The coal fields of the Appalachian Basin region exist principally within the Ohio River, Tennessee River, and Alabama River drainage basins. Larger tributary basins of the Ohio River basin include the Allegheny, Monongahela, and Susquehanna of Pennsylvania (46,110 square miles of total contributing area); the Upper Ohio, Muskingum, Kanawha, Middle Ohio, and Big Sandy River basins of Ohio, Virginia and West Virginia (48,130 square miles of total contributing area); and the Kentucky and Cumberland River basins of Virginia and Tennessee (28,200 square miles of total contributing area).

Larger tributary basins of the Tennessee River basin include the Upper and Middle Kentucky River basins of Tennessee and Alabama (32,660 square miles of total contributing area); and the Alabama and Mobile River basins (44,600 square miles of total contributing area) of the larger Alabama River of Alabama (Seaber, et al., 1994).

3.5.5.1.2.1 Stream Morphology

Appalachian Mountain Stream of "A" Type

Source: OSMRE, 2015a

Streams within the Appalachian Basin coal resource area exist within the Appalachian Plateaus physiographic province, which includes the Allegheny Mountains, Cumberland Mountain, and Cumberland Plateau and Kanawha (or unglaciated Allegheny Plateau) physiographic sections as described in Section 3.4 (Topography). As their names convey, the Allegheny and Cumberland Mountains physiographic provinces are areas of high relief. The Cumberland Plateau and Kanawha physiographic sections also have high relief and are highly dissected, although to a lesser degree. Characteristic stream types in this coal region include ephemeral, intermittent and perennial headwater Rosgen "A," "Aa+," and "B" types. These streams are steep to very steep, straight, single channel streams that are laterally confined. Stream substrates include combinations of exposed bedrock and coarse sediment (including boulders, cobbles, and gravel). In-stream features include cascading step pools, waterfalls, and alternating rapids, riffles, and pools.

At lower elevation and gentler gradients, relatively wide and shallow perennial type "C" streams exist in mountain valleys. These streams are characterized by moderate sinuosity in broad valleys and well developed floodplains. Typical in-stream features include alternating riffles and pools. The degree of lateral migration or meandering of the channels varies according to the erodibility of bank materials and abundance of riparian vegetation. When channel and bank substrate is primarily comprised of course material such as boulders, cobble, and gravel, sediment supply for these stream types is generally very low.

3.5.5.1.2.2 Surface Water Quantity / Stream Regime

Studies have shown that forested watersheds typically have little surface runoff and subsurface processes (such as interflow) dominate (Sloan and Moore, 1984). Water that infiltrates into the forest soils is slowly released, thereby sustaining streamflow (Chang, 2003). Ten to 20 percent of annual precipitation is intercepted by the forest canopy (Chang, 2003) and approximately one percent to five percent of the annual precipitation is absorbed by forest detritus (Helvey and Patric, 1965). The portion of the infiltrated flow that does not proceed as interflow primarily moves through stress-relief fractures in the weathered and unweathered underlying geological strata and is discharged through seeps. A portion of the flow migrates through deeper strata.

Streamflow in the Appalachian coal region generally follows a pattern that varies seasonally with precipitation and evapotranspiration. Beginning in late October, streamflow generally increases and maintains a high runoff rate through May. This is due to enhanced precipitation (rain and snowmelt) and a corresponding decrease in evapotranspiration. Increases in regional evapotranspiration begin in May, reducing the amount of available runoff; low flow season begins in August and continues through October (Kiesler, et al., 1983; Quinones, et al., 1983). During the summer months of July and August monthly streamflow may be augmented by thunderstorm activity (Harkins et al., 1980).

In addition to climatic influences described above, principal basin characteristics such as the size of the contributing area, physiography, and geologic character of the region significantly influence how runoff is expressed as streamflow. Other important drainage basin characteristics include land use, vegetation, and existing soil types. Hufschmidt and others (1981) has noted that as the recurrence interval of a precipitation event becomes greater (less frequent), other basin characteristics such as land use, vegetation, and soil type become less influential. In some areas of the Appalachian coal region predictive equations may have been developed to estimate mean annual and monthly flows (Herb, et al., 1981); flood magnitude and frequency (McCabe, 1962; Hannum, 1976; Quinones, et al., 1983; Randolph and Gamble, 1976; Gamble, 1983); and average minimum discharge (Flippo, 1982; Herb, et al., 1981) using principal drainage basin characteristics. Drainage basin characteristic of significance in predicting low flow are contributing area, annual precipitation, geology, and channel slope. The magnitude of peak flow predictions are correlated to contributing area, mean annual precipitation, and potential evapotranspiration.

The Appalachian coal region topography is generally one of high relief that is conducive to producing severe floods. The region is characterized by steep slopes with narrow valleys. When this topography is coupled with intense storms, floods of short duration and large magnitude are common. In areas of unglaciated physiography, valley configuration demonstrating narrow flood plains and steep slopes leads to rapid accumulation of storm runoff during periods of rainfall. In previously glaciated areas, broad flood plains and flat slopes produce a less rapid accumulation of runoff and a longer duration of flood flow (Engelke, et al., 1981; Quinones, et al., 1983; Harkins et al., 1980).

Studies suggest the flow in streams draining coal-bearing rock is poorly sustained. Low flow diminishes rapidly and base flows are poorly sustained during dry periods due to poor recharge and storage conditions. Studies in Kentucky have determined that in contributing areas less than 100 square miles, streamflow approaches zero during low flow in the season from June to October (Quinones, et al., 1983). In areas of the Cumberland Plateau, low-flow data suggest that Pennsylvania sandstones, shales, and coals demonstrate significantly lower flow than Pre-Pennsylvanian limestones and dolomites. It is unclear whether this finding is attributable to their storage potential or enhanced mining activity associated with the Pennsylvania geology (Hufschmidt et al., 1981). Findings by Harkins and Others (1980) suggest that low-flow discharge in drainage basins existing in Pre-Pennsylvanian geology is higher than in drainage basins existing in Pennsylvanian geology. Kiesler, et al. (1983) observed higher low-flow discharges in drainage basins existing primarily in the Lee Formation than drainage basins existing primarily in the Breathitt Formation. Both are Pennsylvanian in origin but the Lee Formation consist of sandstone, conglomerate, shale, siltstone, coal, and underclay; in contrast, the Breathitt Formation consist of siltstone, sandstone, shale, coal, underclay, ironstone, and limestone. Low flows are higher in glaciated regions due to their groundwater storage potential than in unglaciated relatively impermeable sandstones, shales, coals and limestone (Engelke et al., 1981).

3.5.5.1.2.3 Surface Water Quality

Table 3.5-6 shows that states within the Appalachian Basin have more than 80 state-defined designated use categories that are used to classify and protect their surface waters. Pennsylvania and Maryland have the most individual designated use classifications, while Alabama and Kentucky have the least.

The water quality assessments used as the basis for the integrated reports provide insight into the aquatic health of the region's surface waters. Table 3.5-7 shows that 96 percent of the waters assessed in Ohio are categorized as impaired waters. In contrast, Pennsylvania had the lowest percentage of stream impairment at 19 percent. In terms of number of stream miles impaired, Ohio had the most at 50,771.2 miles, and Alabama had the least at 3,060.8 miles. In addition, the table shows that 81 percent of the assessed streams in Pennsylvania are characterized as good waters compared to only four percent of assessed streams in Ohio. In terms of the number of stream miles attaining a good water designation Pennsylvania contains the highest number (69,686.2 miles), and Maryland has the least (2,534.2 miles). Tennessee was the only state to report streams in the "threatened waters" category. They reported 38.9 miles of threatened waters in 2010.

Overall, the Appalachian Basin region contains over 420,393.9 miles of streams, of which, 233,719.2 miles of steams have been assessed. Approximately 116,198.5 of the 233,719.2 stream miles are attaining their designated use, while 117,471.8 are deemed impaired. This means approximately 50 percent of the streams assessed in the Appalachian coal region are attaining their designated use, while approximately 50 percent are impaired.

It is important to note that this portion of the FEIS examines general water-quality conditions for each of the coal regions. The discussion includes all causes of stream impairment and is not limited to mining-related impairments.

Table 3.5-6. Selected State-Defined Designated Use – Appalachian Basin Coal-Producing Region

Selected State-Defined Designated Uses for Surface Water							
Alabama	**Kentucky**	**Maryland**	**Ohio**	**Pennsylvania**	**Tennesse**	**Virginia**	**West Virginia**
Outstanding Alabama Water	Warm water aquatic habitat	**Use I (basic water use)**	**Aquatic Life**	**Aquatic Life**	Domestic Water Supply	**General Uses**	**Aquatic Life**
Public Water Supply	Cold water aquatic habitat	Swimming	Warmwater	Cold Water	Industrial Water Supply	Recreational uses	Trout waters
Swimming and Other Whole Body Water-Contact Sports	Primary contact recreation	Boating	Limited warmwater	Warm Water Fishes	Fish and Aquatic Life	The propagation of growth of a balanced, indigenous population of aquatic life	Wetlands
Shellfish Harvesting	Secondary contact recreation	Fishing	Exceptional warmwater	Migratory Fishes	Trout Stream	Wildlife	**Water Supply**
Fish and Wildlife	Domestic water supply	Water Contact	Modified warmwater	Trout Stocking	Naturally Reproducing Trout Stream	Production feedible and marketable natural resources	Public water
Limited Warmwater Fishery	Outstanding state resource water	Protection of aquatic life and wildlife	Seasonal Salmonid		Recreation		Water contact recreation
Agricultural and Industrial Water Supply		Agricultural supply	Coldwater	**Water Supply**	Livestock Watering and Wildlife	**Subcategories**	Irrigation
		Industrial water supply	Limited resource water	Potable Water Supply	Irrigation	Migratory Fish Spawning and Nursery	Livestock watering
				Industrial Water Supply	Navigation	Shallow-water Submerged Aquatic Vegetation	Wildlife
		Use I-P	**Water Supply**	Livestock Water Supply		Open Water Aquatic Life	Water transport
		All Use I plus Public Water Supply	Public	Wildlife Water Supply		Deep Water Quatic Life	
			Agricultural	Irrigation		Deep Channel Seasonal Refuge	**Other**
		Use II	Industrial				Cooling water

3.5.5.1.4 Water Usage

Based on 2010 USGS data, water resources in this region are used as follows: 73.0 percent thermoelectric, 13.8 percent public supply, 8.4 percent industrial/commercial, 2.7 percent agricultural, and 1.4 for domestic and mining. The total water usage for the year 2010 was 49,006 million gallons per day (MGD) (Maupin et al., 2014).

Approximately 45 percent of groundwater is withdrawn by public supply utilities and 20 percent is used for domestic purposes. Industrial/commercial uses account for approximately 16 percent, agriculture 13 percent, and mining five percent. Thermoelectric facilities use the lowest percentage of groundwater withdrawals at about 1 percent.

Approximately 78 percent of surface water withdrawals are associated with thermoelectric facilities. Approximately 11 percent each are used for public supply and for industrial/commercial demand. Agricultural uses 1.9 percent. Less than one percent of surface water withdrawals are used for mining and domestic purposes.

Regional drinking water withdrawals are represented by the public supply and domestic withdrawal data. According to 2010 USGS data, approximately 71 percent of total drinking water withdrawals are from surface water sources. Of the public water supply withdrawals, 77.5 percent are from surface water. Additionally, since 1985, domestic (private) water withdrawals have remained largely unchanged; whereas, public water supply withdrawals had increased 17 percent as of 2005, indicating that overall regional drinking water demand is increasing.

A review of USGS water use data for the years 1985 to 2010 indicates that the total share of the population supplied by a public water supplier is increasing while the proportion of the population that is self-supplied is decreasing (Table 3.5-8) (USGS, 2013a). However, 2010 data (the most recent available information) show a domestic self-supply population of 10 million, 18 percent of the total regional population (Maupin et. al, 2014). This self-supply population relies primarily on private wells for their water supply. Because these wells are not routinely monitored or treated, this population is particularly susceptible to changes in groundwater quality and supply.

Table 3.5-8. Summary of Domestic Water Supply by Population (thousands/percent of total) – Appalachian Basin

Year	Self-Supply Population	Public Supply Population
2010	10,034 (18%)	45,310 (82%)
2005	3,445 (19%)	14,753 (81%)
2000	NA	NA
1995	4,129 (23%)	13,723 (67%)
1990	4,130 (24%)	13,261 (66%)
1985	5,061 (28%)	12,751 (62%)

3.5.5.2 Colorado Plateau Coal-Producing Region

3.5.5.2.1 Groundwater

The Colorado Plateau aquifers underlie an area of approximately 110,000 square miles in western Colorado, northwestern New Mexico, northeastern Arizona, and eastern Utah. The Colorado Plateau coal region is approximately coincident with the Colorado Plateaus Physiographic Province. The distribution of aquifers in the Colorado Plateau is controlled in part by the structural deformation and erosion that has occurred since deposition of the sediments composing the aquifers. Information for groundwater characterization of the Colorado Plateau Coal region was largely derived from USGS summary reports developed to support Environmental Assessments and Impact Study Reports (Wynn et al., 2001; Kuhn et al., 1983; Lines, 1985; Eakin et al., 1976; Hren et al., 1987; Roybal et al., 1983; Roybal et al., 1984).

In general, the aquifers in the Colorado Plateau Coal region are composed of permeable, moderately to well-consolidated sedimentary rocks. The rocks within and adjacent to coal development are Cretaceous and Tertiary in age, and vary greatly in thickness, lithology, and hydraulic characteristics. The stratigraphic relations of the rocks are complicated in places, and the stratigraphic nomenclature consequently is diverse. Many water-yielding units have been identified in these rocks, and most publications pertaining to the hydrogeology of the area describe only a few of the units or pertain to only part of the region. The many water-yielding units in the area are generally grouped into three principal aquifers relative to coal mining activities: the Uinta-Animas aquifer, the Mesaverde aquifer, and the Dakota-Glen Canyon aquifer system (Robson and Banta, 1995).

3.5.5.2.1.1 Unconsolidated Aquifers

In the more mountainous areas of the Colorado Plateau Coal region, much of the alluvium in the stream valleys is too thin, narrow, and discontinuous to be considered a major aquifer, even though some of the larger mountain alluvial deposits (such as those near the Sevier River in central Utah and in the Uinta Basin of northeastern Utah) contain locally important surficial aquifers (Robson and Banta, 1995). Groundwater springs are an important source of water in Arizona and Utah coal resource areas. Springs are used for public water supplies and irrigation; provide water for livestock and wildlife; and provide the major source of baseflow to perennial streams (Lines, 1985). Although not part of the major aquifer systems described later in this section, springs in mountain areas of Utah and drainages of arid northern Arizona are a vulnerable and carefully protected resource.

3.5.5.2.1.2 Primary Bedrock Aquifers

The Uinta-Animas aquifer primarily is composed of Lower Tertiary rocks in the Uinta Basin of northeastern Utah, the Piceance Basin of northwestern Colorado, and the San Juan Basin of northwestern New Mexico. Aquifers in each basin are present in different parts of the stratigraphic section. Some formations are considered to be an aquifer in more than one basin; however, some formations vary so much in their hydraulic characteristics that they are considered to be an aquifer in one basin and a confining unit in another. Water-yielding units in the Uinta-Animas aquifer in the Uinta Basin commonly are separated from each other and from the underlying Mesaverde aquifer by units of low permeability composed of claystone, shale, marlstone, or limestone. The Uinta-Animas aquifer in the Piceance Basin consists of silty sandstone, siltstone, and marlstone. The Uinta-Animas aquifer in the San Juan Basin generally consists of permeable, coarse, arkosic sandstone inter-layered with mudstone. The thickness of the Uinta-Animas aquifer generally increases toward the central part of each basin. The Uinta Basin aquifer ranges in thickness from zero feet at the southern margin of the aquifer to as much as 9,000 feet in the north-central part of the aquifer. In the Piceance Basin, the Uinta-Animas aquifer is as much as 2,000 feet thick in the central part of the basin. In the northeastern part of the San Juan Basin, the maximum thickness of the Uinta-Animas aquifer is about 3,500 feet (Robson and Banta, 1995).

The Mesaverde aquifer comprises water-yielding units in the Upper Cretaceous Mesaverde Group, and some adjacent Tertiary and Upper Cretaceous formations. The Mesaverde aquifer is at or near land surface in extensive areas of the Colorado Plateaus and underlies the Uinta-Animas aquifer. The aquifer is of regional importance in the Piceance, Uinta, Black Mesa, and San Juan Basins. Some of the rocks forming the Mesaverde aquifer contain coal beds, particularly in Black Mesa Basin. The rocks composing the Mesaverde aquifer are conglomerate, sandstone, siltstone, mudstone, claystone, carbonaceous shale, limestone, and coal. Because these rocks primarily were deposited in environments that changed as sea level changed during the Late Cretaceous, lithology varies vertically and laterally, and inter-tonguing is common among the various formations and strata making up the aquifer (Robson and Banta, 1995).

The Dakota-Glen Canyon aquifer system is generally divided into four primary aquifers: Dakota Aquifer, Morrison Aquifer, Entrada Aquifer, and Glen Canyon Aquifer. Sandstone, conglomerate, and conglomeratic sandstone are the major water-yielding materials in these aquifers. Mudstone, claystone, siltstone, shale, and limestone generally form the confining units separating these aquifers (Robson and Banta, 1995). In the northern Arizona Black Mesa Basin, the Glen Canyon aquifer is regionally significant for municipal and industrial supply. From 1971 to 2005, approximately 4,000 acre-feet per year was pumped for industrial use from the Glen Canyon aquifer, which is locally referred to as the Navajo aquifer system. In 2005, the Black Mesa coal slurry transportation system was discontinued, reducing industrial supply withdrawal to approximately 1,500 acre-feet per year. Municipal groundwater withdrawals have steadily increased in the Black Mesa Basin and currently account for approximately 3,000 acre-feet per year (Macy, 2010). Other significant groundwater withdrawals in Navajo County are to the south of Black Mesa Basin, and beyond the coal resource areas.

Figure 3.5-5 illustrates the general extent of the various aquifer types in the Colorado Plateau Coal-Producing region.

3.5.5.2.1.3 Groundwater Quality

Groundwater chemistry in the Colorado Plateau Quaternary aquifers (unconsolidated) is naturally variable and generally high in mineral content. Calcium, sodium, bicarbonate, and sulfate are the predominant major ions in water from the Quaternary aquifers. Concentrations of total dissolved solids are typically less than 3,500 mg/L, and average approximately 600 mg/L (Wynn et al., 2001; Kuhn et al., 1983; Lines, 1985; Eakin et al., 1976; Hren et al., 1987; Roybal et al., 1983; Roybal et al., 1984).

Groundwater chemistry in the Tertiary aquifers varies throughout the Colorado Plateau, but the principal chemical constituents are generally sodium, calcium, sulfate, and bicarbonate. Concentrations of total dissolved solids in the Tertiary Wasatch, Green River, and Fort Union Formations are typically low, and range from 160 to 1,200 mg/L, with a median concentration of approximately 400 mg/L (Wynn et al., 2001; Kuhn et al., 1983; Lines, 1985; Eakin et al., 1976; Hren et al., 1987; Roybal et al., 1983; Roybal et al., 1984).

Cretaceous aquifers of the Colorado Plateau coal resource area are extensive. Elevated chloride concentrations typically indicate marine depositional conditions. Water in coal and shale deposits tends to be saline, with minor concentrations of sulfate, indicating a chemical reducing environment. Principal constituents of the Cretaceous Mesa Verde Group and Kaiparowits Formation are typically sodium, magnesium, sulfate, and bicarbonate. Completed wells commonly exceed the fluoride drinking water standard. Concentrations of total dissolved solids range from 300 to 8,300 mg/L, with an average concentration of approximately 1,400 mg/L (Wynn et al., 2001; Kuhn et al., 1983; Lines, 1985; Eakin et al., 1976; Hren et al., 1987; Roybal et al., 1983; Roybal et al., 1984).

3.5.5.2.2 Surface Water

The coal fields of the Colorado Plateau exist principally in the Upper and Lower Colorado River Basins and the Rio Grande River Basin. Larger Upper Colorado River tributaries of northwest Colorado and the Utah coal fields include the White-Yampa, Dolores, Gunnison, Dirty-Devil, Colorado Headwaters, and Lower Green River drainage basins. When combined, these drainage basins total 66,910 square miles of contributing area. Lower Colorado River tributaries include the San Juan River of southwestern Colorado, northwestern New Mexico, and southwestern Utah, draining 24,600 square miles. The Little Colorado River of Arizona drains approximately 26,900 square miles. The Rio Grande River drains approximately 28,900 square miles from Upper Rio Grande headwaters in Colorado to the Elephant Butte Dam near Truth or Consequences, New Mexico (Seaber, et al., 1994).

3.5.5.2.2.1 Stream Morphology

Streams within the Colorado Plateau coal region exist within the Colorado Plateau physiographic province, including the Navajo (Arizona and New Mexico) and High Plateaus and Uinta Basin (Utah and Colorado) physiographic sections. These physiographic provinces are areas of moderate to high relief, including highly dissected mountains and plateaus with deep canyons that transition to alluvial valleys at lower elevation.

Characteristic stream forms in areas of very high to moderate relief include ephemeral and intermittent Rosgen “A,” “B,” and “G” types. In mountainous areas that receive significant amounts of snow precipitation, streams of these types exist as perennial headwater streams. These streams are steep to very steep straight single channel streams that are laterally confined by geologic control. Stream substrates include combinations of exposed bedrock, colluviums such as boulders, cobble and gravel, and cohesive silt/clay. In-stream features may include cascading step pools, waterfalls; and at lower elevation, alternating rapids, riffles, and pools. When formed in residual soils derived from highly weathered sedimentary rock or grussic granite, "A" types may be expressed as a highly incised gully. In valley slopes less than four percent but greater than two percent, these gully streams are recognized as "G" types. "G" types develop in terminal alluvial fans generating high bank erosion rates that contribute significant bedloads and suspended sediment.

Braided stream in Colorado Plateau of "D" Type

Source: OSMRE, 2015a

At lower elevation and relief, Rosgen "C," "F," and "D" types are characteristic. In the arid southwest, these streams frequently occur as intermittent and ephemeral streams. Relatively wide and shallow single-channel "C" types exist in valleys of gentle gradients. These streams are characterized by moderate sinuosity in broad valleys with developed floodplains. In-stream features include alternating depositional point bar features with sections of riffles and pools. The degree of lateral migration or meandering of the channel varies according to the erodibility of bank materials and relative abundance of riparian vegetation. Sediment supply in these streams is high. In the late 19th century, ephemeral stream channels throughout the American Southwest began to incise into alluvial valleys, creating deep continuous channels that are collectively referred to as "arroyos." Arroyos are defined by Elliot, et al. (1999) as large-scale, continuous, and persistent erosional features created when stream channels incise into their alluvial valleys (Levick et al., 2008). Arroyos correspond with "F" type streams. These streams are highly incised, deeply entrenched channels in alluvium. Unique to "F" types is the complete lack of floodplain.

Rosgen "D" type streams are wide, shallow, multi-channel, braided steams formed in broad depositional valleys of very low gradient. These streams have low sinuosity and have very high width-to-depth ratios. They are sediment transport–limited, with abundant sediment supply. Through excessive deposition longitudinal and transverse bars develop forming the characteristic braided form. Formed in non-cohesive sandy alluvium, these streams experience high bank erosion and widening. In the arid southwest, ephemeral streams of these types are regionally recognized as "washes."

3.5.5.2.2.2 Surface Water Quantity / Stream Regime

Streams within the Colorado Plateau coal region demonstrate large variations in annual and seasonal flow. Excluding anthropogenic causes (e.g., diversions, reservoir impounding and significant in-stream withdrawals) these variations in streamflow are attributable to the natural geologic, physiographic, and climatic variability characteristic of the region. Regions of high elevation (mean basin elevation > 8,000 feet) that receive 15 inches or more of annual precipitation are distinguished from areas of low elevation (mean basin elevation < 8,000 feet) that receive less than 15 inches of annual precipitation. In regions of high elevation, snowmelt is the dominant source of streamflow, while in the lower elevations thunderstorms are the dominant source. Streams originating in mountainous regions demonstrate greater average annual flow per square mile than streams originating in lower-elevation semiarid regions. Consequently, streams originating in the mountains will tend to sustain perennial flows while streams originating in areas of lower elevation tend to be ephemeral flowing only a few days each year. Runoff resulting from snowmelt occurs from April through July and thunderstorms in the lower elevations occur in the summer months. Craig and Rankl (1978) found that on small drainages (less than 11 square miles) at lower elevation, high intensity thunderstorms cause larger runoff events and snowmelt contributions are not significant. The average flow of streams that originate in the mountains usually increases downstream. The exception occurs when the streams flow through a low-altitude area, where infiltration and evapotranspiration may be greater than inflow, exhibiting high transmission losses. During periods of little or no precipitation, streamflow is sustained primarily by groundwater discharge. Larger streams are affected by diversions and reservoirs during periods of low flow (Wynn et al., 2001; Lines, 1985; Eakin et al., 1976; Hren et al., 1987; Roybal et al., 1983; Roybal et al., 1984).

3.5.5.2.2.3 Surface Water Quality

Table 3.5-9 shows that states within the Colorado Plateau region have approximately 50 state or tribe-defined designated use categories to classify and protect surface waters. The water quality assessments used for the integrated reports provide insight into the aquatic health of the region's surface waters. Excluding Colorado, states and tribal lands within this region have a low percentage of their surface waters assessed. Table 3.5-10 shows that three of the four states have less than 13 percent of their waters assessed, while Colorado has 55.5 percent of its waters assessed. Based on available data, 56 percent of the waters assessed in New Mexico are not achieving their designated use ("impaired waters"), while Colorado had the lowest percentage of stream impairment at 18 percent. Colorado had the most stream miles impaired at 11,135.5 miles, and Arizona had the least at 1,016 miles. In terms of number of stream miles achieving their designated use, Colorado contains the highest number (48,503.4 miles) and Arizona has the least (1,747.7 miles).

Overall, the Colorado Plateau region is comparable to Appalachian Basin in the number of stream miles. The Appalachian Coal region contains 420,393 miles of stream and the Colorado Plateau region contains 394,435 miles of streams. Unlike the Appalachian Basin region, however, only 20.1 percent of streams in the Colorado Plateau region have been assessed. Approximately 59,708.5 of the 79,284.0 stream miles that have been assessed (75 percent) are achieving their designated use, while 19,576.5,920 (25 percent) are considered impaired. Impairment is associated with all pollution sources, and is not limited to mining-related impairments.

3.5.5.2.4 Water Usage

Based on 2010 USGS data, water resources in this region are predominantly used for agriculture (85 percent), with 12 percent for public supply, just over one percent for thermoelectric use, and less than one percent each for domestic, industrial/commercial, and mining. The total water usage for the year 2010 was 24,357 MGD (Maupin et al. 2014).

Approximately 75 percent of groundwater withdrawals are associated with agricultural operations. Another 19 percent of groundwater is withdrawn by public water suppliers. Only approximately two percent of groundwater is withdrawn by domestic self-suppliers. The primary aquifer system and source of groundwater in this region are the Colorado Plateaus aquifers. The most productive water yielding aquifers within this system are the Uinta-Animas aquifer, the Mesaverde aquifer, the Dakota-Glen Canyon aquifer system, and the Coconino-De Chelly aquifer (Robson and Banta, 1995). Water recharge to aquifers in this region generally occurs in upland areas, which receive more precipitation than the lower elevation areas (Maupin et al. 2014).

Within the Colorado Plateau Basin, a widespread water table decline has not been identified, but isolated areas of 40-foot water table declines have been identified (Reilly, et al., 2008). This would indicate that, for the most part, stress on the aquifer is confined to isolated areas and is not widespread.

Public water suppliers obtain 57 percent of their withdrawals from surface water (Maupin et al. 2014). Surface water is generally not used for private domestic purposes in the region (USGS, 2010b).

A review of USGS water use data for the years 1985 to 2010 indicates that the total share of the population supplied by a public water supplier is increasing. In contrast, the self-supply population is relatively unchanged, but has decreased as a share of total population (see Table 3.5-11). In 2010, there was an estimated regional domestic self-supply population of about 0.9 million, 5 percent of the total regional population (Maupin et al. 2014). This self-supply population relies primarily on private wells for their water supply. Because these wells are not routinely monitored or treated, this population is particularly susceptible to changes in groundwater quality and supply.

Table 3.5-11. Summary of Domestic Water Supply by Population (thousands/percent of total) – Colorado Plateau

Year	Self-Supply Population	Public Supply Population
2010	884 (5%)	15,360 (95%)
2005	408 (13%)	2,710 (87%)
2000	NA	NA
1995	396 (16%)	2,056 (84%)
1990	373 (17%)	1,792 (83%)
1985	406 (20%)	1,629 (80%)

3.5.5.3 Gulf Coast Coal-Producing Region

3.5.5.3.1 Groundwater

The Gulf Coast coal region consists of lignite fields that spread eastward from southern Texas through the coal-producing areas of Louisiana and Mississippi. Extending into southern Alabama, the field significantly diminishes in central Georgia and the Florida panhandle. The lignite field also extends northward up the Mississippi River embayment area to include much of eastern Arkansas, southeastern Missouri, and parts of westernmost Kentucky and Tennessee. Although lignite is present in all of the states included in this region, it is only mined in Texas, Louisiana, and Mississippi. For this reason, the following discussion focuses on the lignite-mining portions of these three states.

The Gulf coastal area extending from Texas eastward into Florida and north along the Atlantic coast comprises the Coastal Plain physiographic province. In Texas, the lignite fields of economic importance are located in the West Gulf Coastal Plain (Interior Coastal Plains) section of this province, which is characterized by relatively parallel ridges and valleys with geologic strata, consisting predominantly of unconsolidated sands and muds, dipping towards the Gulf of Mexico (Bureau of Economic Geology, 1996). The West Gulf Coastal Plain continues into northwestern Louisiana where unconsolidated deposits consist mainly of sand, gravel, silt, and mud deposits with discreet lenses of lignite that are relatively flat-lying with localized variably-dipping beds (Paleontological Research Institution, 2013; Hayes and Kennedy, 1903). In Mississippi, lignite is mined in the North Central Hills section, which is characterized by ridges and valleys (Stewart, 2003). Deposits in this region consist mainly of sand, clay, and silt with discontinuous lignite layers (USGS, 2010c; Warwick, et al., 1997).

3.5.5.3.1.1 Primary Aquifers

Significant aquifers within the mined areas of Texas, Louisiana, and Mississippi are comprised of unconsolidated deposits of deltaic, fluvial, or marine origin. In Texas, the major aquifer within the lignite region belongs to the upper Paleocene Wilcox Group and the lower Eocene Carrizo Formation of the Claiborne Group (Tertiary Period). This aquifer is contained within the Texas coastal uplands aquifer system along with several minor aquifers and confining layers (Ryder, 1996). The most widespread groundwater structure underlying Louisiana and Mississippi is the Mississippi embayment aquifer system (Renken, 1998).

3.5.5.3.1.2 Unconsolidated Aquifers

3.5.5.3.1.3 Texas Coastal Uplands Aquifer System

The Texas coastal uplands aquifer system underlies all or parts of 60 counties (about 48,000 square miles) in south and southeastern Texas. This system contains both aquifers and confining layers and is located stratigraphically in proximity to the major lignite-producing intervals of the Jackson, Claiborne, and Wilcox Groups (Ryder, 1996).

There are four major aquifers and two confining layers constituting the Texas coastal uplands aquifer system. In descending order, the aquifers include the Upper Claiborne, Middle Claiborne, Lower Claiborne-Upper Wilcox, and Middle Wilcox. The two confining layers, the Middle Claiborne and the Lower Claiborne, are located above and below the Middle Claiborne aquifer, respectively (Ryder, 1996).

Of the four aquifers listed above, the Lower Claiborne-Upper Wilcox (Carrizo-Wilcox aquifer) is the most widely used aquifer in Texas (Ryder, 1996). Its distribution is widespread, extending from southern Texas northeastward into Arkansas and Louisiana. The Carrizo-Wilcox provides water in all or parts of 60 counties in Texas and is a major source of water in northwestern Louisiana and southern Arkansas (Ashworth and Hopkins, 1995). The thickness of the freshwater sands in the Carrizo-Wilcox is variable, with a maximum thickness of nearly 3,000 feet (Ryder, 1996). In addition to its hydrologic significance, the Carrizo-Wilcox is located stratigraphically in proximity to economically important lignite seams.

Well yields from the Carrizo-Wilcox typically range from 500 to 3,000 gallons per minute with irrigation and municipal withdrawals accounting for the majority of usage, especially in Texas (Ashworth and Hopkins, 1995). Recharge occurs predominantly via infiltration of precipitation through overlying material or direct infiltration at outcrop areas. Conditions in the aquifer range from unconfined in outcrop regions, to confined in down-dip areas when the unit is overlain by low-permeability material (Ryder, 1996).

As a result of heavy usage for irrigation and municipal purposes, many areas of Texas are experiencing significant declines in water levels in the Carrizo-Wilcox aquifer. Over the past 70 years, levels have dropped as much as 500 feet in some areas.

3.5.5.3.1.4 Mississippi Embayment Aquifer System

The Mississippi embayment aquifer system is an important source of fresh water in parts of Arkansas, Mississippi, and Louisiana. Within this system, there are six distinct aquifers comprised mostly of weakly consolidated to unconsolidated sand, silts, and clays. The upper four aquifers (Upper Claiborne, Middle Claiborne, Lower Claiborne-Upper Wilcox, and Middle Wilcox) are comparable to the four major aquifers discussed above in the Texas coastal uplands aquifer system. Likewise, the upper two confining layers, the Middle Claiborne and the Lower Claiborne (located stratigraphically above and below the Middle Claiborne aquifer, respectively), are comparable to those located in Texas. Below the Middle Wilcox aquifer, the Mississippi embayment system contains two additional aquifers and one confining layer as compared to the Texas coastal uplands. In descending order, these units include the Lower Wilcox aquifer, the Midway confining layer, and the McNairy-Nacatoch aquifer (Renken, 1998).

Sediments comprising the embayment system are thinnest along the margins of the basin and progressively thicken to more than 6,000 feet towards the axis. The greatest thickness occurs in south-central Louisiana and southwestern Mississippi. Several of the upper aquifers (Upper and Middle Claiborne and Lower Claiborne-Upper Wilcox) become less permeable and progressively thin southwards until the units disappear, while some of the confining layers become more permeable and thin northwards. In some areas, the aquifer system is hydraulically connected to the Mississippi River Valley alluvial aquifer (Renken, 1998).

The Middle Claiborne is the most heavily used aquifer within the Mississippi embayment system. Well yields in Louisiana and Mississippi typically range from 100 to 300 gallons per minute with higher yields reported in Arkansas (300 to 1,000 gallons per minute). In parts of extreme northern Mississippi and eastern Arkansas, the Lower Claiborne confining layer is absent, allowing the Middle Claiborne and Lower Claiborne-Upper Wilcox aquifers to merge, producing well yields up to 2,000 gallons per minute (Renken, 1998). The combined unit is locally referred to as the Memphis aquifer.

Recharge to the Mississippi embayment system occurs predominantly via infiltration of precipitation through overlying material or direct infiltration at outcrop areas. Groundwater flow is generally from recharge areas at higher elevations to lower, more flat-lying regions of the Mississippi Alluvial Plain. Water levels in the Middle Claiborne have declined as much as 100 feet due to large withdrawals in southern Arkansas and northern Louisiana (Renken, 1998).

Figure 3.5-6 illustrates the general extent of the various aquifer types in the Gulf Coast Coal-Producing region.

3.5.5.3.1.5 Groundwater Quality

Water quality in the widely used Carrizo-Wilcox aquifer typically ranges from fresh to slightly saline with many areas exhibiting dissolved solid concentrations less than 500 milligrams per liter (Ryder, 1996). Although the water is typically harder at recharge zones, the dissolved solid concentrations are lower relative to those in downdip regions. The aquifer may contain hydrogen sulfide and methane in limited areas, and elevated levels of iron are common in the northeastern region. In southwestern Texas, the aquifer may be contaminated with oil field brines as a result of local activities associated with petroleum-related exploration and processing (Ashworth and Hopkins, 1995).

Water within the Middle Claiborne aquifer is also relatively fresh in over half of its areal extent, with dissolved solids measuring less than 500 milligrams per liter. The dissolved solid concentration increases in east-central Louisiana where the aquifer is present in the vicinity of the Mississippi River. The water quality also degrades with depth, with dissolved solids increasing to 10,000 milligrams per liter or more (Renken, 1998).

http://water.usgs.gov/ogw/aquifer/map.html

3.5.5.3.2 Surface Water

The lower Mississippi River, Red River, and Brazos River comprise the major drainage basins within the lignite fields of the Gulf Coast coal region. The largest of these three, the lower Mississippi River basin, drains 101,324 square miles from the confluence of the Mississippi and Ohio Rivers in Illinois to the Gulf of Mexico (Turnipseed and Storm, 2003). The Red River drains 93,200 square miles mostly in Texas and Oklahoma, with lesser acreage in Arkansas and Louisiana (Kammerer, 1990). The Red River is a major tributary to the Mississippi River and joins the Mississippi along the east-central border of Louisiana. The Brazos River drains 45,600 square miles predominantly in Texas, with minor contributions from New Mexico (Kammerer, 1990). The Brazos River discharges into the Gulf of Mexico at Freeport, Texas.

3.5.5.3.2.1 Stream Morphology

Streams within the Gulf Coast coal region exist within the Coastal Plain physiographic province. In Texas, the lignite fields of economic importance are located mostly in the West Gulf Coastal Plain (Interior Coastal Plains) section of this province and are characterized by relatively parallel ridges and valleys, with geologic strata consisting predominantly of unconsolidated sands and muds, dipping towards the Gulf of Mexico. The West Gulf Coastal Plain continues into northwestern Louisiana where unconsolidated deposits consist mainly of sand, gravel, silt, and mud deposits. Discreet lenses of lignite are relatively flat-lying with localized variably-dipping beds. Elevations in the coal mining areas range from 80 to 1,350 feet, with local relief approximately zero to 500 feet (Orme, 2002).

Topography of the East Coastal Plains is widely varied, with areas of rounded, eroded hills, cuestas, and nearly featureless plains (Neilson, 2007). In Mississippi, lignite is mined in the North Central Hills section, characterized by moderately dissected uplands and wide flat areas in major stream drainages. Deposits in this region consist mainly of sand, clay, and silt with discontinuous lignite layers.

Other than in the steeper headwater areas, the characteristic stream form in the Gulf Coast region consist of intermittent and perennial streams of Rosgen "C" type. These streams exist in areas of low relief within well-developed floodplains. They are generally described as wide and shallow, exhibiting high width/depth ratios (>12). Typical in-stream features include alternating riffles and pools, runs, glides and characteristic point bars within the active channel. They are representative of the classic sinuous meandering stream where the degree of lateral migration achieved through aggradation and degradation processes varies according to the erodibility of bank materials, abundance of riparian vegetation, upstream watershed conditions, and flow and sediment regime.

Streams of Rosgen type "E" and "F" also persist and are distinguished from Rosgen "C" types by their relative degree of entrenchment, width-to-depth ratio and sinuosity. Streams of Rosgen "E" type demonstrate higher sinuosity and lower width to depth ratios (narrow and deep) than the "C" type. Rosgen "F" types are distinguished by their moderately to highly entrenched (incised) steam profile, with little to no developed floodplain. Ephemeral streams are also widespread across the Gulf Coast coal region.

3.5.5.3.2.2 Surface Water Quantity / Stream Regime

In this part of the country, the majority of precipitation occurs in the form of rain as moisture moves in from the Gulf of Mexico. The southern coastal parts of Texas, Louisiana, and Mississippi generally experience greater rainfall amounts than the more inland areas. On average, precipitation amounts are greater in Louisiana and Mississippi as compared to Texas, with Louisiana ranking as the second wettest state in the country and Mississippi ranking third (Baker, 2012). Rainfall occurs year-round and can be extreme as hurricanes move inland from the Gulf of Mexico. Historically, more Atlantic hurricanes occur in the fall (NOAA, 2009).

Streams located in areas with sufficient topographic relief generally have headwaters in upland areas with relatively steep slopes and gradients that become more gentle as the streams flow downward into wider, flat drainage areas of major streams. As a result, flash floods occurring in the headwaters will generally have peak flows that occur rapidly and then slow as the stream gradient decreases.

In the upland areas of Mississippi, including the active lignite mining area, many of the streams have been modified (dredging, dam construction, etc.) to help alleviate the effects of flooding (Wilson and Turnipseed, 1989). These modifications have resulted in channel and bank instability in many of the streams (Wilson and Turnipseed, 1989). In addition, streams have also been channelized for agricultural purposes. To better understand and enable flood estimations, the USGS conducted a flood study and estimated flood magnitudes for recurrence intervals from two to 500 years for 330 gaged sites in Mississippi (Landers and Wilson, 1991). Most of the streams located in the upland area eventually drain into the Mississippi River.

Flooding is also relatively common along the Red River and many of its tributaries in the lignite mining areas of northwestern Louisiana and eastern Texas. Both historical and more recent flood events have been documented as a result of heavy rainfall from thunderstorms and tropical systems that have moved inland from the Gulf of Mexico (LakeBistineau.com, 2011).

Much of the lignite mining region in southeastern Texas is drained by the Brazos River. This river is the longest in the state, encompassing about 16 percent of the land area (Wurbs, et al., 1993). Although precipitation generally occurs throughout the year, droughts do occur. Texas ranks 35th in precipitation for the continental U. S. (Baker, 2012). Peak discharges for waterways within the Brazos river drainage basin generally occur in late spring or early fall (Raines, 1998).

The Brazos is a meandering river with many associated oxbow lakes (Wurbs, et al., 1993). The river has many monitoring gages as well as reservoirs for water storage (Wurbs, et al., 1993). Reservoirs are also common along many of its tributaries (Raines, 1998). Within the Brazos River basin, severe flooding has occurred, resulting in the loss of life and personal property (Phillips, 2006; Raines, 1998). Minor flooding along the river and its tributaries is common and generally occurs annually. As a result, the USGS conducted an extensive study and developed regionally specific regression equations for estimating peak flow frequency for varied recurrence intervals (Raines, 1998). These equations were developed for natural streams, defined as "…a stream for which the annual peak discharges are not affected by reservoirs, regulation, diversions, urbanization, or any other human-related activity" (Raines, 1998). USGS also developed extreme peak discharge curves to estimate extreme flood potential. These tools supply valuable insight for water-resource planning and management (Raines, 1998).

3.5.5.3.2.3 Surface Water Quality

Table 3.5-12 lists the designated use to classify and protect the surface waters in the Gulf Coast region. State water quality assessments provide insight into the health of the region's surface waters. The states within the Gulf Coast region have a low percentage of their surface waters assessed. Table 3.5-13 shows that Louisiana has the highest percentage of streams assessed at 14.3 percent while Mississippi has the least at 4.6 percent. About 76 percent of the waters assessed in Louisiana are not achieving their designated use ("impaired waters"). Texas had the lowest percentage of stream impairment at 43 percent. Texas had the most stream miles impaired (10,320.7) and Mississippi had the least (2,182.8). In terms of number of stream miles achieving their designated use, Texas contains the most (13,225.7 miles) and Louisiana has the least (2,305.2 miles).

Overall, the Gulf Coast region contains 341,525 miles of streams of which only 36,883.3 have been assessed. Approximately 17,201.5 of the 36,883.3 stream miles that have been assessed (47 percent) are achieving their designated use, while 19,681.8 (53 percent) are considered impaired. This reflects the impact of all pollution sources and is not limited to mining-related impairments.

Table 3.5-12. Selected State-Defined Designated Use – Gulf Coast Coal-Producing Region

Selected State-Defined Designated Uses for Surface Water		
Louisiana	**Mississippi**	**Texas**
Argriculture	Public Water Supply	Recreation - Contact

3.5.5.3.4 Water Usage

Based on 2010 USGS data, water resources in this region are used for agriculture and thermoelectric (93.9 and 45.2 percent respectively). Other water uses include 9.6 percent public supply, five percent industrial/commercial, less than one percent domestic, and 0.3 percent for mining. The total water usage for the year 2010 was 35,143 MGD (Maupin, et al. 2014).

Agricultural operations use about 74 percent of groundwater withdrawn in this region. Only three percent of the groundwater is withdrawn for domestic purposes (i.e., private residential wells).

Thermoelectric facilities account for about 65 percent of surface water withdrawals. Approximately 14 percent of surface water withdrawn is used by agriculture. Fourteen percent is used by public supply and no surface water in the region is utilized for private domestic purposes (Maupin et al., 2014).

According to 2010 USGS data, 60 percent of total drinking water withdrawals are from surface water sources. Public water utilities obtain 64 percent of their withdrawals from surface water sources (Maupin et al., 2014). As of 2005, domestic (private, self-supplied) withdrawals had increased 85 percent since 1985, and public water supply withdrawals had increased 26 percent, indicating that regional drinking water demand is increasing (USGS, 2010b).

A review of USGS water use data for the years 1985 to 2010 indicates that the split between public and private supplies has remained relatively unchanged (see Table 3.5-14). In 2010, there was an estimated regional domestic self-supply population of nearly 3.4 million, 11 percent of the total regional population. This self-supply population relies primarily on private wells for water. Because these wells are not routinely monitored or treated, this population is particularly susceptible to changes in groundwater quality and supply.

Table 3.5-14. Summary of Domestic Water Supply Population (thousands/percent of total) – Gulf Coast Coal-Producing Region

Year	Self-Supply Population	Public Supply Population
2010	3,474 (11%)	29,170 (89%)
2005	2,553 (13%)	17,580 (87%)
2000	NA	NA
1995	2,039 (12%)	15,576 (88%)
1990	1,935 (12%)	14,585 (88%)
1985	2,027 (12%)	14,318 (88%)

3.5.5.4 Illinois Basin Coal-Producing Region

3.5.5.4.1 Groundwater

The Illinois Basin is a spoon-shaped structural depression underlying most of Illinois, parts of southwestern Indiana, and parts of western Kentucky. The basin measures nearly 53,000 square miles and trends north/northwest to south/southeast. At its greatest depth, the basin contains nearly 15,000 feet of sedimentary rocks (Lloyd and Lyke, 1995).

The majority of the Illinois Basin is located in the Central Lowland physiographic province. This province consists of areas that have experienced extensive glaciation during the Pleistocene Epoch resulting in the surficial landscape seen today. The Central Lowland is "…characterized by a low-relief surface formed by glacial till, outwash plains, and glacial-lake plains. Long, low, arcuate ridges, which were formed by recessional moraines and generally are concave to the north, are common features on these plains. The glacial deposits composing the ridges and plains have completely buried the pre-glacial topographic features" (Lloyd and Lyke, 1995).

The remaining portion of the Illinois Basin includes extreme southern Illinois and parts of southern Indiana and northwestern Kentucky and is part of the Shawnee Hills Section of the Interior Low Plateau province. "This Section is part of the Interior Low Plateaus geomorphic province. Extensive sandstone bluffs, cuestas, rise up to 100 feet (30 meters) above the terrain in front of them and dip gently down the back slope. Other landforms include steep-sided ridges and hills, gentler hills and broader valleys, karst terrain, gently rolling lowland plains, and bottom lands along major rivers, with associated terraces and meander scars. A notable but very minor landform is anthropogenic lands that have been strip-mined exhibit hummocky or ridge-swale topography" (USFS, 1994).

The surficial, unconsolidated deposits in the Illinois Basin consist of clays, silts, sands and gravels reflecting the glacial history of this region. Consolidated bedrock above the Precambrian basement rock consists mostly of Paleozoic sedimentary units of shale, siltstone, limestone, sandstone, dolomite, and coal deposited during the Cambrian to Pennsylvanian Period. The primary bituminous coal reserves are found within the Pennsylvanian rock which underlies the unconsolidated sediments (Zuehls, et al., 1981; Zuehls, et al., 1984).

Where not cited specifically, the majority of the information contained below was obtained from USGS Water-Resources Investigations Open-File Reports 81-403 (Zuehls, et al., 1981), 81-498 (Wangsness, et al., 1981), 82-638 (Quinones, et al., 1983), and 83-544 (Zuehls, et al., 1984).

3.5.5.4.1.1 Primary Aquifers

The most productive aquifers within the Illinois Basin consist of sand and gravel deposits of alluvial and glacial origin. Those found along major waterways or within buried valleys can provide significant volumes of water. The upper Paleozoic strata can also be a source of potable water; however, the yields are much lower and highly variable. Deeper aquifers generally contain groundwater that is not suitable for consumption.

3.5.5.4.1.2 Unconsolidated Aquifers

Unconsolidated sands and gravels are the most productive aquifers in the Illinois Basin. Within the glaciated section of the Basin, these deposits are generally located in glacial drift deposits, in buried valleys, as lenses in till or lacustrine deposits, and along streams and rivers. In the coal fields of western Kentucky, these deposits are present in valleys along the Ohio River and its tributaries. Recharge is generally from direct infiltration of precipitation or seepage from streams.

Wells completed in the Basin's unconsolidated aquifers can produce water at highly variable rates ranging from a few to hundreds of gallons per minute. This wide range is due to the variability in the thickness, areal extent, composition, and occurrence of the sand and gravel layers. In parts of southern Illinois, the glacial deposits are often thin and limited in extent, resulting in domestic users relying more on bedrock sources for portable water. In contrast, the thickness of sand and gravel in the buried Mahomet Bedrock Valley in north-central Illinois can exceed 100 feet, with potential rates of 500+ gallons per minute. The inconsistencies within the unconsolidated layers also result in discreet and variable groundwater flow in the various layers.

3.5.5.4.1.3 Primary Bedrock Aquifers

The most widely used bedrock source for potable groundwater in the Illinois Basin is the Pennsylvania-age strata immediately underlying the unconsolidated layers discussed above. Sandstone and limestone make up the more prolific Pennsylvanian aquifers, although some areas rely on local coal seams for small quantities of water. The sandstone and limestone units are often found in alternating layers with shale and siltstone. "Sheet-like and channel-fill sandstones at the bases of the sedimentary sequences are some of the most productive aquifers in Pennsylvanian rocks. However, a zone of fractures, joints, and bedding plains commonly occurs in the upper parts of exposed Pennsylvanian rocks, and these openings yield water to wells regardless of rock type" (Lloyd and Lyke, 1995).

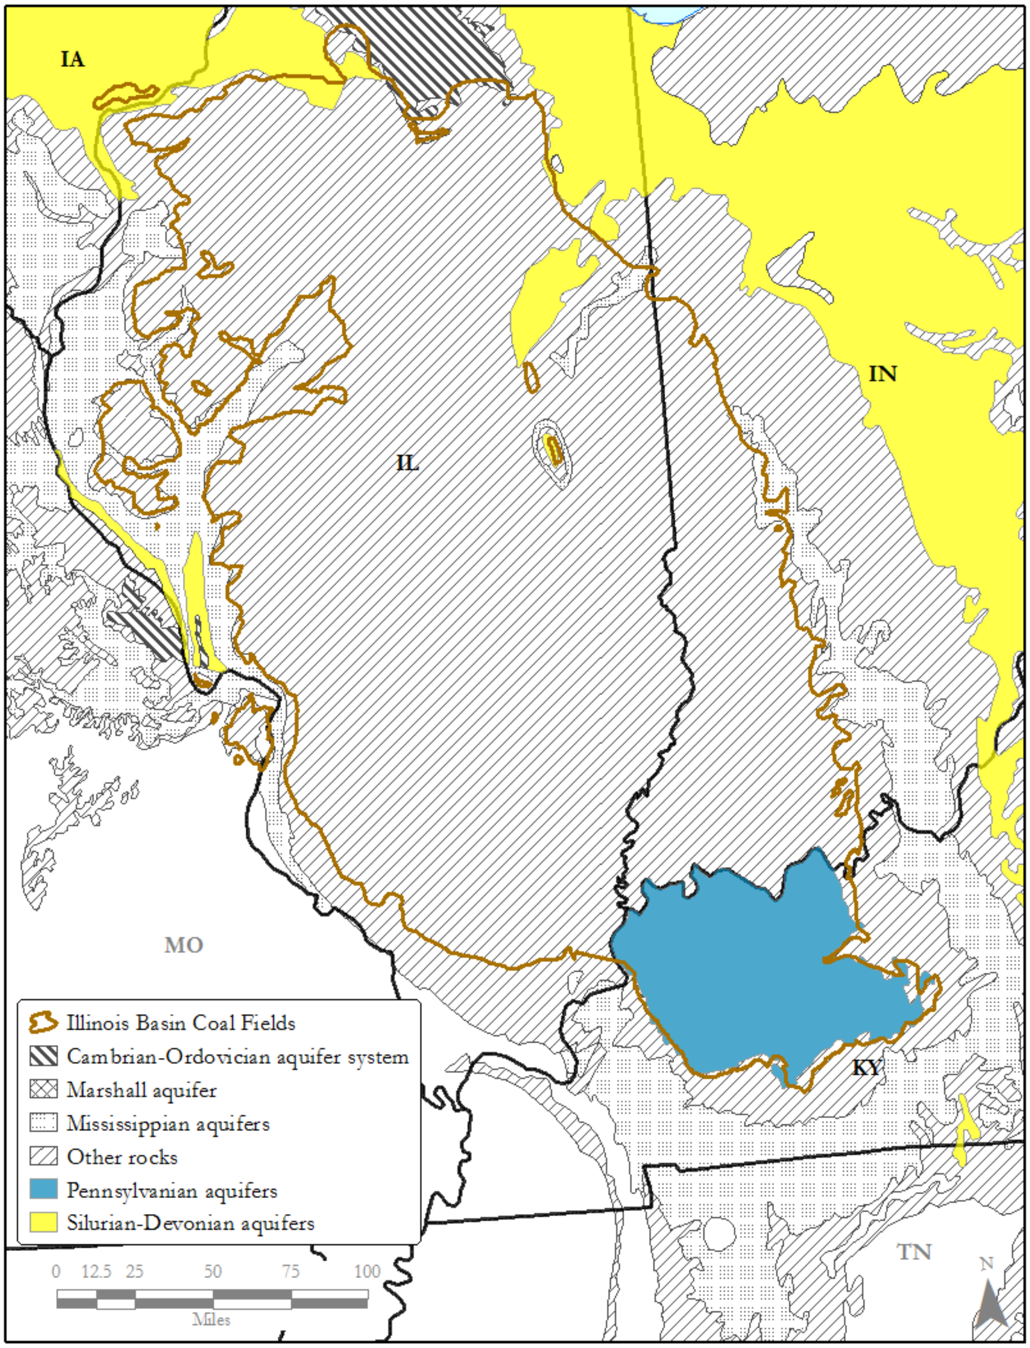
The Pennsylvanian aquifers are present throughout the Illinois Basin, except in limited areas along the western border and in east-central Illinois and southern Indiana where these units have been eroded, exposing Mississippian strata at the ground surface. Although wells have been reported to yield from one to 100 gallons per minute, the average is generally ten gallons per minute (Lloyd and Lyke, 1995).

Due to the presence of low-permeability layers interbedded with the Pennsylvanian water-bearing units, most of the aquifers in this region are under confined conditions. In some areas, artesian conditions may be present resulting in free-flowing wells and the presence of seeps and springs. Groundwater moves along bedding planes and fractures and through solution-enhanced openings within the matrix. The aquifers are recharged from precipitation infiltrating through the overlying material.

In addition to the Pennsylvanian-age bedrock, small quantities of groundwater may be obtained from Mississippian-age limestone and sandstone. These rocks underlie the Pennsylvanian strata in most of the basin, except where erosion has removed the Pennsylvania rock and exposed the underlying Mississippian units. Like the Pennsylvanian strata, Mississippian aquifers consist mainly of limestones (predominantly in the lower portion of the Mississippi strata) and sandstones (predominantly in the upper portion of the Mississippi strata). Because of gradational changes from limestone to shale that occur in an eastwardly direction across Illinois, eastern Illinois and western Indiana have fewer aquifers within the lower Mississippi strata than in the western part of Illinois (Lloyd and Lyke, 1995).

Recharge to the Mississippian-age aquifers is from precipitation infiltrating through the overlying unconsolidated material and Pennsylvanian rocks or direct infiltration at outcrops. Similar to the overlying Pennsylvanian aquifers, aquifers of Mississippian age are reported as having yields from one to 100 gallons per minute with an average of ten gallons per minute. Greater yields are possible when wells are completed in fractured aquifers and those with solution-enhanced cavities. As a result of the great depth to these aquifers in most of the Illinois Basin and the decreasing water quality with depth, Mississippian aquifers accounted for only three percent in Illinois and one percent in Indiana of the total groundwater withdrawn in 1985 (Lloyd and Lyke, 1995). Figure 3.5-7 illustrates the general extent of the aquifers making up the Illinois Basin aquifer system.

Figure 3.5-7. Illinois Basin Region Aquifers



Source: USGS, 2003, Principal Aquifers of the United States.
http://water.usgs.gov/ogw/aquifer/map.html

3.5.5.4.1.4 Groundwater Quality

Water quality in the sand and gravel aquifers is generally suitable for most purposes although some treatment may be required. On average, the water is hard with a neutral pH owing to the presence of bicarbonates. The groundwater may contain elevated levels of iron (greater than 0.3 milligrams per liter) and generally has a median dissolved solid concentration near 500 milligrams per liter. Chloride and sulfate values are generally present at acceptable levels (below 250 milligrams per liter) (Lloyd and Lyke, 1995).

Lloyd and Lyke (1995) state that "The quality of water obtained from the upper parts of the Pennsylvanian aquifers generally is similar throughout the area. However, pronounced water-quality changes occur with depth. Because the water-yielding sandstones and limestones are thin and are interlayered with thin, low-permeability deposits, such as shale and coal, the water withdrawn from these aquifers tends to be a composite water type, which reflects interaction of the groundwater with several rock types that contain different minerals." Groundwater in the upper sections is moderately hard with an average concentration of 500 milligrams per liter dissolved solids. Dissolved solids increase with depth, owing to higher concentrations of sodium, chloride, fluoride, and bicarbonate (Lloyd and Lyke, 1995; Wangsness, et al., 1983). In some areas, wells constructed to depths of 300 feet or more provide only highly mineralized or saline water (Wangsness, et al., 1983). The depth to poor quality water decreases towards the central portion of the basin. "Near the southern limit of the area, only the upper ten percent of the Pennsylvanian rocks contain freshwater" (Lloyd and Lyke, 1995).

Water quality is also an issue in the deeper Mississippian aquifers. In areas where these aquifers are shallow and beneath unconsolidated sands and gravels or thin layers of Pennsylvanian strata, the water quality is generally acceptable for most purposes. However, as the rock layers become more substantial and deeply buried under thick units of Pennsylvanian rocks, the water quality declines due to a lack of freshwater circulation. This is the case in the central portion of the Illinois Basin, which contains the thickest Pennsylvanian and Mississippian strata (Lloyd and Lyke, 1995).

3.5.5.4.2 Surface Water

The Illinois Basin coal region consists of bituminous reserves underlying most of Illinois, parts of southwestern Indiana, and parts of western Kentucky. These coal fields are located predominantly in the Central Lowland physiographic province and in the Upper Mississippi and Ohio River Basins. The Upper Mississippi River basin drains 189,000 square miles from its source in Itasca, Minnesota to the confluence of the Mississippi and Ohio Rivers in southern Illinois (Upper Mississippi River Basin Association, 2011). The Ohio River basin drains 203,000 square miles along its route from Pennsylvania to southern Illinois (Kammerer, 1990).

3.5.5.4.2.1 Stream Morphology

Streams within the Illinois Basin coal resource area exist within the Central Lowlands and Interior Low Plateaus provinces, which includes the Till Plains and Highland Rim physiographic sections. The surficial geology and dominant landforms significantly influence the types of streams present.

The dominant stream forms in this coal region include intermittent and perennial streams of Rosgen "C" type. These streams exist in areas of low relief within well-developed floodplains. They are generally described as wide and shallow, exhibiting high width/depth ratios (>12). Typical in-stream features include alternating riffles and pools, runs, glides, and characteristic point-bars within the active channel. They are representative of the classic sinuous meandering stream. Streams of Rosgen type "E" and "F" also persist and are distinguished from Rosgen "C" types by their relative degree of entrenchment, width-to-depth ratio, and sinuosity. Streams of Rosgen "E" type demonstrate higher sinuosity and lower width-to-depth ratios (narrow and deep) than the "C" type. Rosgen "F" types are distinguished by their moderately to highly entrenched (incised) steam profile, with little to no developed floodplain. Ephemeral streams are also widespread across the Illinois Basin.

3.5.5.4.2.2 Surface Water Quantity / Stream Regime

The Illinois Basin region experiences severe weather, including drought conditions (< 13 inches) approximately once every five years. The area also experiences a high frequency of intense, short-duration, warm-season rainstorms. About 50 percent to 70 percent of the annual precipitation is produced by thunderstorms and generally occurs from April through September. Likewise, streamflow in the area generally follows a seasonal pattern. The yearly cycle begins in October, the month of lowest precipitation and lowest streamflow. November has a period of increased streamflow which is maintained through the spring months and into May. Precipitation increases and evapotranspiration decreases, helping maintain streamflow through the winter months before the spring rains cause an increased level of runoff. The low-flow season follows in early June and usually extends into early October. Approximately 75 percent of flooding occurs between January and April (McCabe, 1962).

Mean annual streamflow is dependent upon drainage basin characteristics, including drainage area; soil index and mean annual precipitation; percentage of forest covered area; percentage of area covered by lakes and ponds; mean elevation of drainage area; mean channel slope; and distance of channel from the topographic divide (Sieber, 1970). Regionally specific regression equations used to predict average discharge, peak flow, and channel slope have been developed and demonstrate adequate predictive power. In areas with significant topographic relief, flash floods often occur in headwater streams during spring months. Floods peak slowly at sites with gentle stream gradient and relief, and peak quickly on small streams with steeper stream gradients. Low flows occur after many days of no precipitation or snowmelt and are principally sustained by subsurface contributions in the form of springs and seeps. Many lakes have been constructed in the region to attenuate high streamflows and provide flood control (Zuehls, et al., 1981).

3.5.5.4.2.3 Surface Water Quality

Table 3.5-15 lists the state-defined designated use categories used to classify and protect the surface waters in the Illinois Basin region. The water quality assessments used for the integrated reports help characterize the aquatic health of the region's surface waters. Table 3.5-16 shows that Indiana has the highest percentage of streams assessed at 67.5 percent, while Illinois has the least at 21.8 percent. About 64 percent of the waters assessed in Kentucky are impaired, while approximately 69 percent of streams in Indiana and 60 percent of streams assessed in Illinois are impaired. Indiana had the most impaired stream miles at 16,654.3 miles, and Kentucky had the least at 6,877.5 miles. Overall, Indiana contains the highest number of stream miles achieving use designations (7,415.7 miles) while Kentucky has the least (3,896.4 miles).

Overall, the Illinois Basin contains 156,172 miles of streams of which only 50,412.9 have been assessed. Approximately 17,539.4 of the 50,412.9 stream miles that have been assessed are achieving their designated use while 32,873.4 are considered impaired. Stated differently, 35 percent of the streams assessed in the region are achieving their designated use while 65 percent are impaired. This assessment includes all causes of stream impairment and is not limited to mining-related impairments

Table 3.5-15. Selected State-Defined Designated Use – Illinois Basin Coal-Producing Region

Selected State-Defined Designated Uses for Surface Water		
Indiana	**Illinois**	**Kentucky**

3.5.5.4.3 Hyperlinks to Integrated CWA Reports – Illinois Basin Coal Region

The following links provide additional detail on water quality in the Illinois Basin region.

State	Hyperlink
Illinois	**http://www.epa.state.il.us/water/water-quality/**
Indiana	**http://www.in.gov/idem/nps/2639.htm**
Kentucky	**http://water.ky.gov/waterquality/Pages/IntegratedReport.aspx**

3.5.5.4.4 Water Usage

Approximately 75 percent of the water resources in this region are used for thermoelectric applications, 11 percent for public supply as well as 11 percent for industrial/commercial, two percent for agriculture, and one percent or less for domestic wells and mining. The total water usage for the year 2010 was 26,023 MGD (Maupin et al., 2014).

Agricultural operations use about 23 percent of groundwater withdrawn in the region. Approximately 46 percent of groundwater withdrawals go to public supply utilities. Only 0.1 percent of groundwater withdrawals are associated with private, self-supply wells (Maupin et al., 2014).

Approximately 80 percent of surface water withdrawn is used by thermoelectric facilities. Public suppliers withdraw about eight percent of surface water. No surface water is used by private self-suppliers of domestic water (Maupin et al., 2014).

According to 2010 USGS data, 66 percent of total drinking water withdrawals are from surface water sources. Public water supply operations obtain 71 percent of their water from surface sources (Maupin et al., 2014). As of 2005, domestic water withdrawals had decreased 12 percent from 1985, and public water supply withdrawals had increased 79 percent, indicating that regional drinking water demand is increasing on net (USGS, 2010b).

In 2010, the domestic self-supply population was nearly 3.5 million, 15 percent of the total regional population. This self-supply population relies primarily on private wells (nearly all domestic water is supplied from groundwater) (Maupin et al., 2014). Because these wells are not routinely monitored or treated, this population is particularly susceptible to changes in groundwater quality and supply (Table 3.5-17).

Table 3.5-17. Summary of Domestic Water Supply by Population (thousands/percent of total) – Illinois Basin Coal-Producing Region

Year	Self-Supply Population	Public Supply Population
2010	3,484 (15%)	20,210 (85%)
2005	1,058 (14%)	6,424 (86%)
2000	1,268 (17%)	5,399 (74%)
1995	1,364 (19%)	5,720 (81%)
1990	1,275 (18%)	5,686 (82%)
1985	1,302 (18%)	5,799 (82%)

3.5.5.5 Northern Rocky Mountains and Great Plains Coal-Producing Region

3.5.5.5.1 Groundwater

The majority of the mineable coal in the Northern Rocky Mountains and Great Plains Coal region is within the Tertiary and Cretaceous age deposits of the Powder River Basin, Williston Basin, Bull Mountain Basin, and the Green River Basin. Information for groundwater characterization of the Northern Rocky Mountains and Great Plains Coal region was largely derived from USGS summary reports developed to support Environmental Assessments and Impact Study Reports (Crosby and Klausing, 1983; Slagle et al., 1986; Lowry et al., 1986; Lowham et al., 1985).

3.5.5.5.1.1 Primary Aquifers

The Powder River Basin is largely located in northeast Wyoming and extends into southeastern Montana. According to Lewis and Hotchkiss (1981), the shallow aquifer system of the Powder River Basin is comprised of five hydrogeologic units above the regionally persistent Upper Cretaceous shale aquitard. The Williston Basin is a geologic structural basin extending north-south approximately 475 miles, and 300 miles east-west. The Williston Basin is present over the western two-thirds of North Dakota, northeastern Montana, and into Saskatchewan, Canada. The Bull Mountain Basin is located north of Billings, Montana, in south-central Montana in an asymmetrical syncline with beds that dip generally less than five degrees. The Bull Mountain Basin covers an area of approximately 750 square miles. The Green River coal area covers approximately 15,400 square miles mostly in southwestern Wyoming with some area extending into northwestern Colorado. The mineable coal beds of these four primary basins are predominantly in the Tertiary Fort Union Formation.

3.5.5.5.1.2 Unconsolidated Aquifers

Unconsolidated-deposit aquifers are composed of sand and gravel deposited as alluvium along streams as thin, narrow bands. The material is from alpine mountain glacial outwash transported and deposited by streams as alluvium during the Quaternary Period. In some valleys, the basin-fill alluvial deposits contain glacial outwash and other types of deposits that resulted from alpine glaciations. Clayey lake-bed deposits form confining units in some basins. The thickness of the unconsolidated-deposit aquifers is unknown in most basins because no wells totally penetrate the aquifers, but may be as much as 900 feet in some basins. Basin-fill deposits typically are coarse grained near basin margins and finer-grained toward basin centers. Sand and gravel making up alluvial deposits and glacial outwash generally are extremely permeable, whereas fine-grained lake deposits and poorly sorted till have minimal permeability and commonly form local confining units (Whitehead, 1996).

3.5.5.5.1.3 Primary Bedrock Aquifers

The Upper Tertiary aquifers are mostly comprised of unconsolidated to semi-consolidated Pliocene age and Eocene age sand and gravel, commonly interbedded with deposits of clay and silt. The upper Tertiary aquifers consist of broad, extensive alluvium deposited as overlapping and coalescing alluvial fans by streams entering the basins from the surrounding mountains. The source of the alluvium was mostly derived from the Middle Rocky Mountains. The upper Tertiary aquifers are part of the High Plains aquifer system, which is as much as 1,000 feet thick in southeastern Wyoming. The hydraulic conductivity of the upper Tertiary aquifers is variable due to the sorting and grain size distribution of the deposits composing the aquifers. Highest hydraulically conductive aquifers consist primarily of sand and gravel, and hydraulic conductivity decreases as clay content increases (Whitehead, 1996).

Lower Tertiary aquifers consist primarily of semi-consolidated to consolidated sandstone beds. Water-yielding sandstones are interbedded with shale, mudstone, siltstone, lignite, and coal. Some coal beds yield water, particularly if the coal is fractured or contains clinker zones of partially burned coal. Most of the lower Tertiary rocks were deposited in continental environments, but some of the shale and limestone beds were deposited in a marine environment and form confining units. Lower Tertiary aquifers in eastern Montana, western North Dakota, and northeastern Wyoming consist mostly of sandstone beds in the Fort Union Formation. The lower Tertiary aquifers in this area are down-warped into the Williston and the Powder River Basins and consist of parts of the uppermost consolidated-rock formations in these basins. Lower Tertiary rocks generally are less than 1,000 feet thick in the Williston Basin, but not all these rocks yield water. The rocks composing the lower Tertiary aquifers contain more shale in their eastern parts than elsewhere, and the transmissivity of the aquifers, therefore, decreases to the east. The hydraulic conductivity of the lower Tertiary aquifers is variable and dependent on the amount of interconnected pore space in the sandstone beds composing the aquifers. Thick coal seams, which are interbedded with sandstone or with fine-grained sediments, also can have joints and bedding planes that store and transmit water (Whitehead, 1996).

The upper Cretaceous aquifers are mostly comprised of consolidated sandstone beds. The sandstone is interbedded with shale, siltstone, and occasional thin, lenticular beds of coal. Upper Cretaceous aquifers crop out mostly around the edges of the Williston and the Powder River Basins, but are exposed in smaller areas along the margins of the Green River, the Great Divide, the Hanna, the Wind River, and the Bighorn Basins. The aquifers are down-warped and faulted to depths of several thousand feet in these basins but contain mostly saline water in their deeper parts. The principal water-yielding formations are the Hell Creek Formation and the Fox Hills Sandstone. In western Wyoming, some water is obtained from the Lance Formation, and some from the deeper Mesaverde Formation. The upper Cretaceous Pierre Shale is a major confining unit and separates deeper aquifers (Whitehead, 1996).

Formations of consolidated sandstone compose the lower Cretaceous aquifers. Lower Cretaceous aquifers are exposed at the land surface mostly as exposed bands in uplifted areas. Recharge predominantly occurs at surface outcrop areas. In Montana, North Dakota, and Wyoming, the Muddy Sandstone and equivalent water-yielding rocks overlie the Skull Creek Shale and are equivalent to the

Newcastle Sandstone. Sandstones equivalent to the Inyan Kara Group in North Dakota are part of the Kootenai Formation in central and western Montana. The Cloverly Formation in Wyoming, which is equivalent to the Dakota Sandstone, is an important aquifer. The sandstones of the Dakota aquifer receive some recharge at high altitudes and some by upward leakage from deeper aquifers. The water in the aquifer is under high artesian pressure. During development of the Dakota aquifer in the late 19th century, many wells completed in the aquifer flowed at the land surface. The rate of flow of some wells was as much as 4,000 gallons per minute. Much of the water was not put to productive use because these wells were allowed to flow continuously causing water levels to decline 700 feet in some places (Whitehead, 1996).

Figure 3.5-8 illustrates the general extent of the aquifers making up the Northern Rocky Mountains and Great Plains aquifer systems associated with coal resource areas.

3.5.5.5.1.4 Groundwater Quality

Groundwater chemistry in the Quaternary aquifers is naturally variable and generally high in mineral content. Calcium, sodium, bicarbonate, and sulfate are the predominant major ions in water from the Quaternary aquifers. Concentrations of total dissolved solids commonly increase with depth, and ranges from 106 to 16,500 mg/L, with a median value of approximately 1,500 mg/L (Crosby and Klausing, 1983; Slagle et al., 1986; Lowry et al., 1986; Lowham et al., 1985).

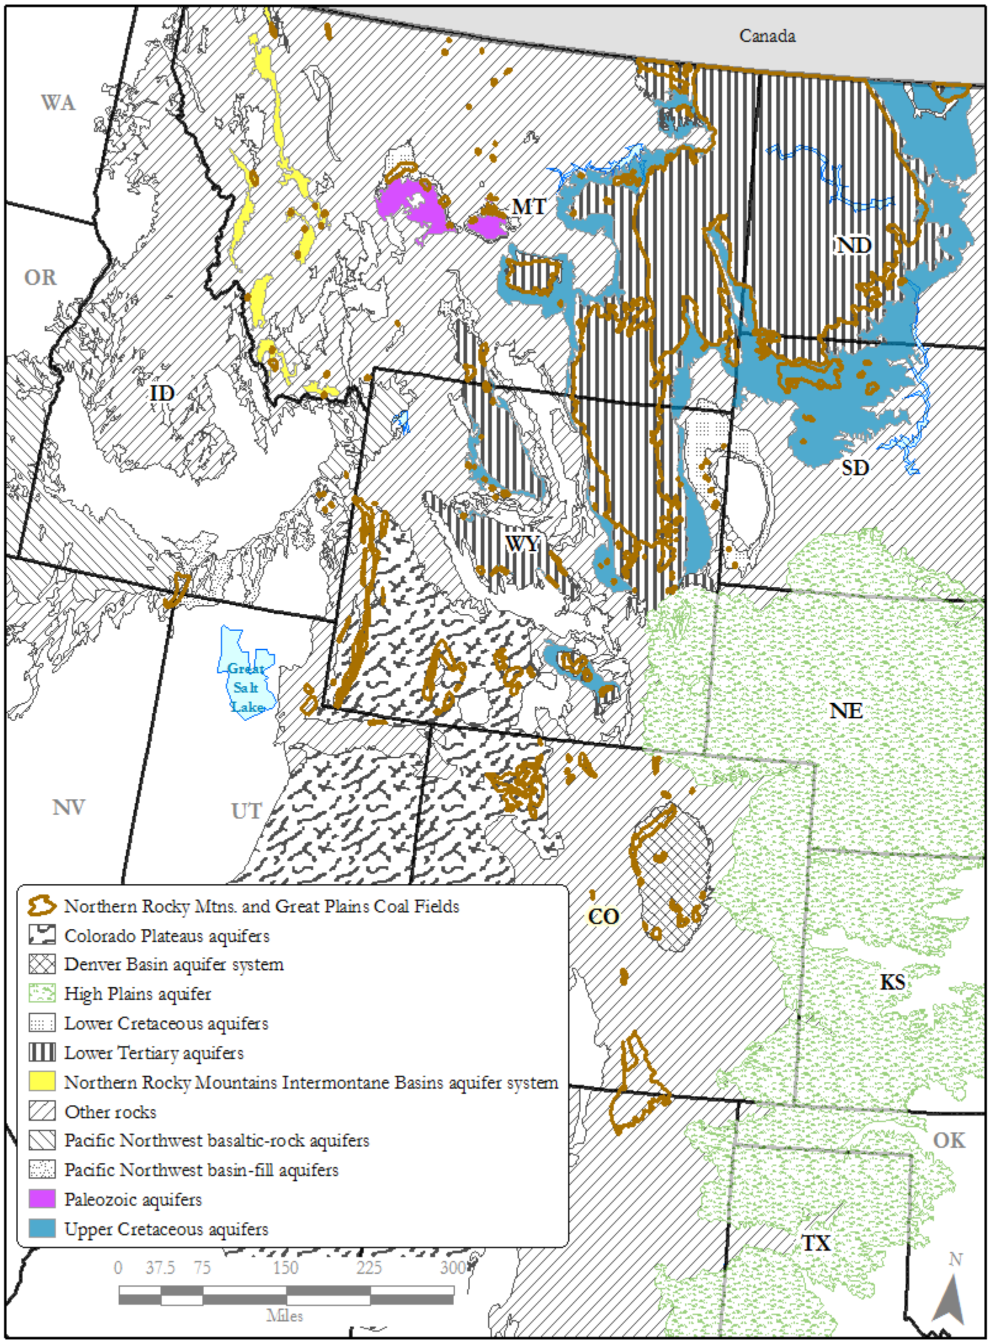
Groundwater chemistry in the Tertiary aquifers is naturally variable and generally high in mineral content, with magnesium, sodium, bicarbonate, and sulfates the most common major ions. Waters from the lower Tertiary aquifers generally were more mineralized. Concentrations of total dissolved solids range from 123 to 11,700 mg/L, with a median concentration of 1,300 mg/L (Crosby and Klausing, 1983; Slagle et al., 1986; Lowry et al., 1986; Lowham et al., 1985).

Cretaceous aquifers of the coal resource areas are extensive, but contain freshwater only where they crop out and are covered by younger rocks (Whitehead, 1996). Groundwater chemistry in the Cretaceous aquifers is naturally variable and generally high in mineral content, with sodium, chloride, bicarbonate, and sulfates the most common major ions. Concentrations of total dissolved solids range from 126 to 13,000 mg/L, with a median concentration of approximately 2,200 mg/L (Crosby and Klausing, 1983; Slagle et al., 1986; Lowry et al., 1986; Lowham et al., 1985).

3.5.5.5.2 Surface Water

The coal fields of the Northern Rocky Mountains and Great Plains exist principally in the Upper Colorado and Missouri River Basins. In the southwest corner of Wyoming, the Green River Basin, Rock Springs Uplift, and Washakie Basin contribute to the Upper Green River drainage basin and the Great Divide closed drainage basin. The Yampa coal fields of northwest Colorado contribute to the White-Yampa River drainage basin. The combined drainage area of the Upper Green, Great Divide and White-Yampa River drainage basins is 33,700 square miles. Both the Upper Green and the White-Yampa River drainage basins contribute to the Upper Colorado. The Great Divide closed basin of Wyoming has a contributing area of 3,870 square miles (Seaber, et al., 1994).

Figure 3.5-8 Northern Rocky Mountains and Great Plains Region Aquifers



Source: USGS, 2003, Principal Aquifers of the United States. http://water.usgs.gov/ogw/aquifer/map.html

To the north, coal resource areas including the Powder River Basin of Wyoming and Montana, North Dakota coal fields, and the Wyoming Hanna Basin coal field contribute to the Missouri River Basin. Larger Missouri River Basin tributaries include the North Platte, Powder-Tongue, Big Horn, Little

Missouri, Lower Yellowstone, Cheyenne, Oahe, and Poplar River drainage basins. The combined drainage area of these tributary basins is 176,300 square miles (Seaber, et al., 1994).

3.5.5.5.2.1 Stream Morphology

Streams within the Northern Rocky Mountains and Great Plains coal region exist principally within the Wyoming Basin and Great Plains, and to a lesser extent the Middle Rocky Mountain physiographic provinces, including the Missouri Plateau physiographic section of the Great Plains (as described in Section 3.4). The topography is diverse and includes rolling plains with wide alluvial valleys, dissected plateaus and mountains of high relief.

Characteristic stream forms in areas of very high to moderate relief include ephemeral and intermittent Rosgen “A,” “B,” and “G” types. In mountainous areas that receive significant amounts of snow, streams of these types may exist as perennial headwater streams. These streams are steep to very steep straight single channel streams that are laterally confined by geologic control. Stream substrates include combinations of exposed bedrock, colluviums (such as boulders, cobble and gravel) and cohesive silt/clay. In-stream features may include cascading step pools, waterfalls, and at lower elevation alternating rapids, riffles, and pools. When formed in residual soils derived from highly weathered sedimentary rock or grussic granite, “A” types may be expressed as a highly incised gully. In valley slopes less than four percent but greater than two percent these gully streams are recognized as “G” types. “G” types develop in terminal alluvial fans generating high bank erosion rates that contribute significant bedloads and suspended sediment.

A “C” type meandering stream in the Powder River Basin

Source: OSMRE, 2015a

At lower elevation and relief, the characteristic stream forms include ephemeral and intermittent streams of Rosgen “C” type. Perennial streams of this type exist in the region, but to a much lesser extent. These streams exist in areas of low relief within well-developed floodplains. They are generally described as wide and shallow exhibiting high width/depth ratios (>12). Typical in-stream features include alternating riffles and pools, and characteristic point bars within the active channel. They are representative of the classic sinuous meandering stream. Streams of Rosgen type “E” and “F” also persist and are distinguished from Rosgen “C” types by their relative degree of entrenchment, width-to-depth ratio and sinuosity. Streams of Rosgen “E” type demonstrate higher sinuosity and lower width-to-depth ratios (narrow and deep) than the “C” type. Rosgen “F” types are distinguished by their moderately to highly entrenched (incised) steam profile, with little to no developed floodplain.

3.5.5.5.2.2 Surface Water Quantity / Stream Regime

Similar to Colorado Plateau, streamflow in the Rocky Mountains and Great Plains coal region can be highly variable and is dependent upon elevation, prevailing source of runoff, and relative contribution of baseflow from groundwater sources.

Runoff from mountains is a function of climatic factors (precipitation, temperature, wind, evaporation, and solar radiation) and the physical characteristic of the basin (elevation and drainage area). Flows from mountains are highly variable depending on snowpack, rate of increase in temperature, and distribution and quantity of spring rains. Extreme long term variability is observed when annual rates are compared to long term averages and can vary from 13 percent to 250 percent of the long term average. Extremely large flows or flooding can occur when deep snow pack, warm air, and rain occur simultaneously. Streams near mountains exhibit perennial flow, with most of the flow generated from snow melt.

Moving into the plains of lower elevation, streams are primarily ephemeral and intermittent with reaches of groundwater contribution depending on local aquifer systems. The average annual runoff from streams in the plains is a function of the quantity and intensity of precipitation events, drainage area, evaporation, and evapotranspiration, and permeability of surface material. For comparison, the average annual runoff per square mile from mountainous areas exceeds 200 acre-feet versus ten acre-feet per square mile in the plains. Flow is generally proportional to drainage area and increases downstream. Flow duration curves for smaller tributaries in the plains demonstrate similar form, where the slope of the plotted data is fairly steep, including the lower end of the curve indicating ephemeral regime and a lack of baseflow. The average annual runoff for small drainage basins in the plains is less variable than in near-mountain streams. However, the opposite is true for plains within Wyoming where high variability in precipitation can produce variable streamflow in annual and seasonal runoff. In addition, in mountainous areas of Wyoming where stream flow occurs mainly from snowmelt there is relatively low in annual and seasonal runoff (Lowham, 1988).

Mountain streams will typically peak in June as a function of spring snowmelt, while plains streams may experience their peak in the spring months of March through April (snowmelt derived) or in the summer months of May through September (rainfall derived). Most of the annual peak flows in the plains are derived from snowmelt, but the larger peak flows experienced on the plains are from rainfall events. Flood hydrographs of streams near mountain headwater drainages demonstrate a gradual rise and gradual receding of flow with daily fluctuations due to the diurnal temperature fluctuation. Conversely, plains streams demonstrate steeply rising and receding flow response and overall shorter flood duration than their mountain counterparts. In general, the relative magnitude of floods varies inversely with the drainage area; the larger the area, the smaller the proportion of the area affected by extreme runoff events. The potential for damage from flooding is greater near the mountains than on the plains. Precipitation is highly spatially variable, so while there may be flooding every year, it is rare to have flooding on all major streams within any given year.

Man-made alteration of runoff (e.g., irrigation, stock ponds) can significantly impact streamflows through evaporation and consumptive use. Flows can be augmented through discharge from Coal Bed Methane development and aquifer pumping associated with coal mining (Lowham et al., 1985; Crosby and Klausing, 1983; Slagle et al., 1986; Lowry et al., 1986; Kuhn et al., 1983).

3.5.5.5.2.3 Surface Water Quality

Table 3.5-18 shows that states within the Northern Rocky Mountains and Great Plains Coal region have approximately 30 state-defined designated use categories that are used to classify and protect their surface waters. The water quality assessments used as the basis for the integrated reports provide insight into the aquatic health of the region’s surface waters. Table 3.5-19 shows that 85 percent of the waters assessed in

Montana are not achieving their designated use ("impaired waters") while North Dakota had the lowest percentage of stream impairment at about seven percent. In terms of number of stream miles impaired, Montana had the most at 17,263.3 miles while Wyoming had the least at 1,432.3 miles. About 87 percent of the assessed streams in North Dakota are achieving their designated use ("good waters") compared to only 15 percent of assessed streams in Montana. Colorado contains the highest number of stream miles achieving designated use (48,503.4 miles) while Montana has the least (3,022.5 miles). North Dakota was the only state to report waters in the "threatened waters" category (4,341.6 miles).

Overall, the Northern Rock Mountains and Great Plains Coal region contains over 447,527 miles of streams, of which 152,043.8 miles have been assessed. Approximately 114,313.6 of the 152,043.8 stream miles are achieving their designated use (75 percent) while 33,535.7 are considered impaired (25 percent). This assessment considers all causes of stream impairment and is not limited to mining-related impairments. Hence, it is possible that a state could have very few stream impairments related to mining. For example in 2014, the state of Wyoming only has about two percent of their stream impairments related to mining (Wyoming Department of Environmental Quality, 2016).

Table 3.5-18. Selected State-Defined Designated Use – Northern Rocky Mountains and Great Plains Coal-Producing Region

Selected State-Defined Designated Uses for Surface Water			
Colorado	**Montana**	**North Dakota**	**Wyoming**
Agriculture	Agricultural	Municipal and Domestic Water	Agriculture
Aquatic Life Cold Water - Class 1	Aquatic Life	Fish and Aquatic Biota	Fisheries
Aquatic Life Cold Water - Class 2	Cold Water Fishery	Recreation	Industry
Aquatic Life Warm Water - Class 1	Warm Water Fishery	Agricultural uses	Drinking water
Aquatic Life Warm Water - Class 1	Industrial	Industrial Water	Recreation
Domestic Water Source	Drinking Water		Scenic value
Recreation Primary Contact	Primary Contact Recreation		Aquatic life other than fish
Recreation Secondary Contact			Wildlife
			Fish conumption

Wyoming	http://deq.state.wy.us/wqd/watershed/#Assess

3.5.5.5.4 Water Usage

Based on 2005 USGS data, water resources in this region are used for primarily for agriculture (92 percent), with five percent for public supply, and two percent or less for domestic and industrial/commercial. There is no reported water usage for mining or thermoelectric. The total freshwater usage for the year 2010 was 23,692 MGD (Maupin et al., 2014).

Approximately 81 percent of groundwater withdrawn is used by agriculture. Approximately 11 percent of groundwater withdrawals are associated with public supply utilities, and only three percent of the groundwater is withdrawn from private wells for domestic use. Within the Northern Rocky Mountains and Great Plains region, a widespread water table decline has not been identified, but isolated areas of 40-foot water table declines have been identified in Wyoming (Reilly, et al., 2008). This would indicate that, for the most part, stress on the aquifer is confined to isolated areas and is not widespread.

Approximately 90 percent of the surface water withdrawn is used agriculture. Thermoelectric facilities use approximately five percent of the surface water withdrawals and approximately four percent is withdrawn by public water supply utilities. Only a small fraction of surface water is used for private water supplies (Maupin et al., 2014).

According to 2010 USGS data, 71 percent of total drinking water withdrawals are from surface water sources. Seventy-six percent of public water supply withdrawals are from surface water. Additionally, since 1985, domestic water withdrawals have increased 92 percent, and public water supply withdrawals have increased seven percent, indicating that overall regional drinking water demand is increasing (Maupin et al., 2014).

In 2010, there was an estimated domestic self-supply population of nearly 0.8 million, about ten percent of the total regional population (See Table 3.5-20). This self-supply population relies primarily on private wells for their water supply (Maupin et al., 2014; USGS, 2010b). Because these wells are not routinely monitored or treated, this population is particularly susceptible to changes in groundwater quality and supply.

Table 3.5-20 Summary of Domestic Water Supply of Population (thousands/percent of total) – Northern Rocky Mountains and Great Plains Coal-Producing Region

Year	Self-Supply Population	Public Supply Population
2010	760 (10%)	6,497 (90%)
2005	544 (10%)	4,798 (90%)
2000	683 (14%)	4,223 (85%)
1995	604 (13%)	3,887 (87%)
1990	492 (12%)	3,538 (88%)
1985	553 (14%)	3,540 (86%)

3.5.5.6 Northwestern Coal-Producing Region

3.5.5.6.1 Groundwater

The Northwest Coal region includes potentially mineable resources in Oregon, Washington, and Alaska. The description of the affected environment is limited to Alaska, because there is neither active mining nor evidence of continued production in Oregon and Washington. The Northern Alaska coal fields are also not discussed due to the questionable potential for their development and production at this time. The Usibelli Coal Mine, near Healy Alaska, is the only coal operation with active production; therefore, the potentially affected groundwater environment specific to this coal operation is described.

3.5.5.6.1.1 Primary Aquifers

The Usibelli Coal Mine produces coal from three seams in the Miocene age Suntrana Formation in interior Alaska. The coal reserves roughly correspond to the Hoseanna Creek drainage basin. Throughout the Hoseanna Creek Basin, the coal seams tend to function as aquifers, confined below by impermeable clay and above by tight, fine-grained sandstone (Miller and Whitehead, 1999). Specifically, the Moose coal seam is the only significant aquifer with appreciable extent, and is the lowest aquifer affected by mining (Ray and Vohden, 1992). Groundwater flow in the Moose coal seam aquifer is controlled by fractures within the coal, and bound by faulting in the Suntrana Formation (Ray and Vohden, 1992). Groundwater also is present in shallow alluvium in surrounding drainages with surficial gravel deposits. However, the alluvial gravel deposits in the area do not contain significant quantity of water for sustainable development due to the discontinuous nature of the deposits and variable thickness (Miller and Whitehead, 1999).

The water, classified by the dominant dissolved ions it contains, is a calcium bicarbonate type. Dissolved solids concentrations in the water are typically less than 400 milligrams per liter. In general, most dissolved trace metals from samples within the permit area were either not detectable or detected at concentrations near the method detection limits. Detected dissolved metals concentrations include barium (0.092 to 0.574 mg/L), iron (0.13 to 3.26 mg/L), manganese (0.181 to 0.606 mg/L), and zinc (<0.008 to 0.144 mg/L) (Ray and Vohden, 1992). Groundwater from the adjacent alluvium has concentrations of several dissolved metal analytes, which are elevated compared to concentrations of the Moose coal seam aquifer. The metals include barium, cadmium, iron, manganese, nickel, and zinc (Ray and Vohden, 1992).

3.5.5.6.2 Surface Water

The Yukon River Basin contains many streams and rivers. Using the Alaska Hydrologic Unit Classification system (Seaber, et al., 1994; USGS, 2013b) and a similar classification system for Canada, the Yukon River Basin can be divided into 13 major basins. These basins represent the eight major tributaries to the Yukon River and the major lowland areas that drain directly into the Yukon River (Brabets, et al., 2000). The Tanana River Basin encompasses the Alaskan coal mining area within the overall Yukon River Basin. The Tanana River Basin is approximately 44,300 square miles in area, and primarily drains the north side of the Alaska Mountain Range, including glaciers (Seaber et al., 1994).

3.5.5.6.2.1 Stream Morphology

The coal resources of Alaska for this FEIS exist within the northern foothills of the Alaska Range. The terrain includes steep bluffs and gently rolling plateau topography with deep stream valleys and steep slopes. At lower elevation, the topography transitions to irregular hummocky terrain.

Characteristic stream forms in this coal region include ephemeral, intermittent, and perennial headwater Rosgen "A" and "B" types. These streams are steep to very steep, straight, single-channel streams that are laterally confined. Stream substrates include combinations of exposed bedrock and coarse sediment (including boulders, cobbles, and gravel). In-stream features include cascading step pools, waterfalls, and alternating rapids, riffles, and pools.

At lower elevation and relief, Rosgen "C," "E," and "D" types exist. Relatively wide and shallow single channel "C" types exist in valleys of gentle gradients. These streams are characterized by moderate sinuosity in broad valleys with developed floodplains. In-stream features include alternating depositional point bar features with sections of riffles and pools. The degree of lateral migration or "meandering" of the channels varies according to the erodibility of bank materials and relative abundance of riparian vegetation. Sediment supply in these streams is high. Streams of Rosgen "E" type demonstrate higher sinuosity and lower width-to-depth ratios (narrow and deep) than the "C" type.

Rosgen "D" type streams are wide shallow multi- channel braided steams formed in broad depositional valleys of very low gradient. These streams have low sinuosity and have very high width-to-depth ratios. They are sediment transport limited, with abundant sediment supply. Through excessive deposition, longitudinal and transverse bars develop forming the characteristic braided form. Formed in non-cohesive sandy alluvium, these stream experience high bank erosion and stream widening. Stream of type "D" are common to valleys receiving glacial outwash.

3.5.5.6.2.2 Surface Water Quantity / Stream Regime

Three basic patterns of runoff are exhibited throughout the Yukon River Basin: lake runoff, snowmelt runoff, and glacier runoff. Generally, beginning in October and ending in late April to mid-May, runoff is minimal, and streamflow gradually decreases. Most runoff occurs from May to September; however, the timing of runoff in the rivers is different, depending on the particular basin characteristics (Brabets, et al., 2000). During the snowmelt period (generally late April), snow is released as stream-flow over a relatively short period, making snowmelt the major hydrological event of the year (Bonanza Creek LTER, 2011).

The overall average discharge of the Yukon River Basin is 227,000 cubic feet per second, with the Tanana River Basin providing approximately 44,600 cubic feet per second of that amount (Brabets, et al., 2000). Due to glacial activity and associated discharge contribution, the Tanana River Basin's calculated percentage of flow contribution is disproportionately large relative to its contributory drainage area.

In the Yukon River Basin, annual high flows for most of the major rivers occur during the summer rainy season. However, on the main stem of the Yukon, flooding commonly occurs from ice jams in the spring. Although levees have been built at Dawson to prevent flooding from ice jams, villages located along the lower part of the Yukon River are still subject to flooding each spring. Since 1949, three major floods have occurred in the Yukon River Basin: in 1964, 1967, and 1994. These floods covered large areas of the basin and caused considerable property damage. The 1967 flood involved a ten-inch rainfall in the middle and lower Tanana River Basin near Fairbanks, which nearly equaled the average annual precipitation for the area. Flood discharge on the Salcha River at Fairbanks was almost twice that of a 100-year recurrence interval.

3.5.5.6.2.3 Surface Water Quality

Table 3.5-21 provides designated use categories that are used to classify and protect Alaskan surface waters. The water quality assessments used as the basis for the integrated reports provide insight into the aquatic health of the region's surface waters. Table 3.5-22 shows that only 0.2 percent of Alaska's surface waters have been assessed, so any characterization using the assessment data should be used with caution. The table shows about 74 percent of the waters assessed in Alaska are not achieving their designated use ("impaired waters"). This translates into 443.4 stream miles. In Alaska, over 26 percent of the assessed streams are achieving their designated use (158.4 miles). The assessment includes all causes of stream impairment and is not limited to mining-related impairments.

Table 3.5-21. Selected State-Defined Designated Use – Northwestern Coal-Producing Region

Selected State-Defined Designated Uses for Surface Water

3.5.5.6.4 Water Usage

The use of groundwater by the coal operators and wildlife within the producing Usibelli permit and adjacent area is negligible. The Usibelli Coal Mine withdraws alluvial groundwater at the mouth of Hoseanna Creek for vehicle washing and industrial uses (Usibelli Coal Mine Inc., 1996. Potable water for the Usibelli Coal Mine is obtained from the Nenana River alluvium.

3.5.5.7 Western Interior Coal-Producing Region

3.5.5.7.1 Groundwater

The Western Interior Coal region includes the bituminous coal reserves of central and southern Iowa, northwestern and central Missouri, southeastern Nebraska, eastern Kansas, eastern Oklahoma, and west-central Arkansas. These coal deposits are Pennsylvanian in age and mostly located within three distinct structural basins: the Forest City Basin which includes about 47,000 square miles in Iowa, Nebraska, Kansas, and Missouri; the Cherokee Basin consisting of about 26,500 square miles in Kansas, Missouri, and Oklahoma; and the Arkoma Basin which includes about 13,500 square miles in Oklahoma and Arkansas (U.S. EPA, 2004a). Additional coal resources in Oklahoma are located in the northeast Oklahoma platform. The limited bituminous coal reserves in Texas are not included in this discussion as these reserves are not currently mined.

The majority of the Western Interior region is located within the Central Lowland physiographic province with lesser areas within the Quachita province, Ozark Plateaus, and Coastal Plain province. In the northern portion of the region, unconsolidated deposits consist of alluvium along streams and rivers, and glacial drift and loess deposits; these deposits are evidence of the extensive glacial history of this area. Further south, terrace deposits and alluvium of sandy and clayey silts are common along with occasional thin lenses of sand and gravel. Bedrock underlying the unconsolidated material consists predominantly of upper Paleozoic-age, marine and non-marine deposits of shale and siltstone interbedded with varying amounts of sandstone, limestone, and coal (Detroy, et al., 1983; Marcher, et al., 1984; Marcher, et al., 1987).

3.5.5.7.1.1 Primary Aquifers

The most productive aquifers within the Western Interior are sand and gravel deposits of alluvial and glacial origin. Those found along major waterways or within buried valleys can provide significant volumes of water. The upper Paleozoic strata may also be a source of potable water; however, the yields are generally much less than the unconsolidated aquifers and are more highly variable. With few exceptions, the Lower Paleozoic rocks usually contain groundwater that is not suitable for consumption (Detroy, et al., 1983; Marcher, et al., 1984; Marcher, et al., 1987).

3.5.5.7.1.2 Unconsolidated Aquifers

The most significant unconsolidated aquifers in the Western Interior Coal region consist of sand and gravel deposits. Within the glaciated section of the region, these surficial deposits may be found in buried valleys and within alluvium along major waterways. Farther south into the non-glaciated areas, the sands and gravels are again within alluvial deposits associated with significant rivers and streams and also within terrace deposits, although the terrace units generally supply much less water due to the composition of the layers (Detroy, et al., 1983; Marcher, et al., 1983; Marcher, et al., 1987).

The unconsolidated aquifers can produce water at highly variable rates, depending on the thickness and aerial extent of the sand and gravel deposits. Wells completed in thick, buried channel deposits have been found to yield up to 1,000 gallons per minute with quality generally suitable for most purposes. Alluvial sands and gravels up to 150 feet thick have been noted to produce upwards of 2,000 gallons per minute in wells along the Missouri River (Detroy, et al., 1983; Marcher, et al., 1983; Marcher, et al., 1987).

Recharge to the unconsolidated aquifers in the Western Interior is from direct precipitation, infiltration from overlying unconsolidated material, or seepage from adjacent streams. Groundwater movement, although highly variable, is generally towards nearby streams and rivers and down valleys (Detroy, et al., 1983; Marcher, et al., 1983; Marcher, et al., 1987).

3.5.5.7.1.3 Primary Bedrock Aquifers

Within the Western Interior, Pennsylvanian-age strata are the most widespread Paleozoic units immediately underlying the surficial unconsolidated material. These strata generally consist of shale and siltstone interbedded with thin sandstone and limestone. Although the sandstones and limestones are potential sources of groundwater, yields are generally limited. Some wells completed in the Pennsylvania rocks have reported yields of 20 gallons per minute or more, but the average yield is generally less than five gallons per minute. Regardless of the low rate, these limited aquifers are often the only source of water for those living in some rural areas. The quality of the groundwater is also variable but often suitable for domestic purposes (Detroy, et al., 1983; Marcher, et al., 1983; Marcher, et al., 1987).

Underlying the Pennsylvanian strata are Mississippian-age rocks that may provide a potable source of groundwater. These units actually underlie unconsolidated materials in those areas where the Pennsylvanian units have been eroded (Detroy, et al., 1983; Marcher, et al., 1983; Marcher, et al., 1987).

In the northern part of the Western Interior region, the Mississippian aquifer underlies most of northern Missouri. Miller and Appel (1997) state that "The Mississippian aquifer is so named because it consists of limestone of Mississippian age. The Keokuk, the Burlington, the Fern Glen, the Sedalia, and the Chouteau Limestones compose the aquifer; of these formations, the Keokuk and the Burlington are the principal water-yielding rocks. Both formations consist of crystalline limestone and yield water primarily from solution cavities. In most places, the aquifer is overlain by a confining unit of Pennsylvanian shale and sandstone and is everywhere underlain by a confining unit of Mississippian shale. The thickness of the Mississippian aquifer averages about 200 feet but locally exceeds 400 feet in northwestern Missouri. The aquifer is thickest in part of the Forest City Basin, which is a structural downwarp that extends northward into Iowa, and is thinnest near the Mississippi and the Missouri Rivers where it has been dissected or partially removed by erosion."

Mississippian-age rocks in the southern part of the Western Interior may also serve as local aquifers. In the Oklahoma and southwest Missouri area, cherty limestone with thin sandy or shaley zones can provide groundwater of suitable quality at rates up 300 gallons per minute, although most yields are less than ten gallons per minute. The units often have a combined thickness of 300 to 400 feet (Miller and Appel, 1997).

On a local scale, groundwater in the Mississippian aquifer of northern Missouri moves towards nearby streams. Regional groundwater movement has not been determined (Miller and Appel, 1997).

As reported in Marcher, et al., 1983, Cambrian and Ordovician rocks comprise a significant aquifer in discreet areas of the Western Interior, including northeast Oklahoma, southeast Kansas, and central Missouri. The aquifer consists mostly of dolomite with lesser amounts of sandstone, siltstone, and shale for a combined thickness locally of 1,400 feet. Although these rocks are present throughout this region, they are generally very deep and contain poor-quality water. In the Oklahoma-Kansas-Missouri area, the Cambrian-Ordovician rocks are shallower and outcrop in some areas with suitable quality for most domestic uses. Reported well yields in the tristate area vary from small quantities to 1,000 gallons per minute. The direction of water movement is towards the west/northwest.

The Cambrian-Ordovician aquifer extends northwards into Iowa at greater depths (upwards of 3,000 feet) as compared to the Oklahoma-Kansas-Missouri area. Well yields up to 1,000 gallons per minute are also reported in Iowa; however, the quality of the water is often considered marginal (Detroy, et al., 1983). Regardless of the depth and quality of the water, the Cambrian-Ordovician aquifer is the only source of groundwater in some areas (Detroy, et al., 1983).

The bedrock aquifers are recharged mostly by infiltration from overlying units, from direct precipitation at outcrops, or seepage from adjacent streams. Recharge may also occur through solution-enhanced zones, particularly in the Cambrian-Ordovician and Mississippian-age aquifers (Detroy, et al., 1983).

Figure 3.5-9 illustrates the general extent of the aquifers making up the Western Interior region aquifer system.

3.5.5.7.1.4 Groundwater Quality

As noted in Detroy, et al., 1983, water within the glacial sand and gravel aquifers generally exhibited a neutral pH, alkalinity averaging 266 milligrams per liter, and dissolved solids of 840 milligrams per liter. Nitrate concentrations averaged 24.6 milligrams per liter with wide ranges in iron (0.01 to 16 milligrams per liter) and manganese (0.01 to 2.1 milligrams per liter). Water from the alluvial aquifers within the glaciated region was found to be similar to that within the glacial sand and gravel deposits in pH, alkalinity, dissolved solids, and iron concentrations. Nitrates were less (average of 3.2 milligrams per liter), but the range in manganese was greater (0.05 to 17 milligrams per liter).

Alluvial and terrace deposits in non-glaciated areas of the Western Interior have been found to contain water that is alkaline, with dissolved solids ranging from 148 to 889 milligrams per liter. The following ranges (presented in milligrams per liter) were also noted: sodium, 5.3 to 250; sulfate, 0 to 3,970; manganese, ten to 1,750; iron, ten to 34,000; and chloride, 0.8 to 454 (Marcher, et al., 1983; Marcher, et al., 1987). Marcher, et al. (1983) observe that "Large concentrations of sodium, chloride, and particularly sulfate may be present in unconsolidated deposits in the smaller valleys. Sulfate is a major component of groundwater in stream valleys draining shale of Pennsylvanian age. Water with a pH of less than 6.5, sulfate concentrations greater than 250 to 300 milligrams per liter, and dissolved iron and manganese concentrations of more than 100 to 200 milligrams per liter may indicate mineralization from pyritic materials associated with coal or metal mines."

Water within the Mississippian aquifer varies from relatively fresh in the eastern portion of the Western Interior, to very saline in the west. Similar to the Mississippian aquifers in the Illinois Basin, the volume of overlying material (and therefore the depth to the aquifer) is an important factor with regards to dissolved solid concentrations. The greater thickness in overburden generally correlates to higher dissolved solids.

Mississippian strata in the southern part of the region may also serve as local aquifers, with water quality that is generally suitable for most purposes (Miller and Appel, 1997). Groundwater in this area is generally alkaline with low concentrations of dissolved solids. Average concentrations of chloride, fluoride, manganese, nitrates, sodium, iron, and sulfate are also low (Marcher, et al., 1983).

3.5.5.7.2 Surface Water

The major drainage basins for this region are the Upper Mississippi, Missouri, and Arkansas River basins. The Upper Mississippi River basin drains 189,000 square miles from its source in Itasca, Minnesota to the confluence of the Mississippi and Ohio Rivers in southern Illinois (Upper Mississippi River Basin Association, 2011)). The Missouri River drainage area consists of 529,000 square miles across much of the north-central U. S. from Montana to near St. Louis, Missouri (Kammerer, 1990). The Arkansas River basin drains 161,000 square miles in seven states from Colorado eastwards to Arkansas (Kammerer, 1990).

3.5.5.7.2.1 Stream Morphology

In the northern portion of the region, unconsolidated deposits consist of alluvium along streams and rivers and glacial drift and loess deposits. Further south, terrace deposits and alluvium of sandy and clayey silts are common, along with occasional thin lenses of sand and gravel (Detroy, et al., 1983; Marcher, et al., 1983; Marcher, et al., 1987). The general topography of the region is very flat plain, with elevations ranging from 500 to 1,200 feet above mean sea level, with very little local relief. An exception to this is in the Ozark Plateau province, which resembles the Appalachian Province but with lower average altitudes and relief. “A maximum altitude of 2,000 feet is reached in the southern part of this province” (Vogel, 1981).

The dominant stream forms in this coal region include intermittent and perennial streams of Rosgen “C” type. These streams exist in areas of low relief within well-developed floodplains. They are generally described as wide and shallow, exhibiting high width/depth ratios (>12). Typical in-stream features include alternating riffles and pools, runs, glides and characteristic point bars within the active channel. They are representative of the classic sinuous meandering stream. Streams of Rosgen type “E” and “F” also persist and are distinguished from Rosgen “C” types by their relative degree of entrenchment, width-to-depth ratio, and sinuosity. Streams of Rosgen “E” type demonstrate higher sinuosity and lower width-to-depth ratios (narrow and deep) than the “C” type. Rosgen “F” types are distinguished by their moderately to highly entrenched (incised) steam profile, with little to no developed floodplain. Ephemeral streams are also widespread across the Western Interior region.

3.5.5.7.2.2 Surface Water Quantity / Stream Regime

Daily and seasonal variations in precipitation cause considerable differences in monthly and yearly streamflow patterns and volumes. Most of the precipitation in the Western Interior occurs in the form of rain, typically in the spring and summer months as a result of storms moving eastward across the region. Corresponding with this increased rainfall, streamflows are generally higher in spring and early summer, followed by lower flows in late summer and fall. The lower flow volumes in the latter part of the year are exacerbated by evapotranspiration, which peaks during this time. As a result, it is common for many streams in this region to experience periods of no flow, particularly those with limited drainage areas (Detroy, et al., 1983; Marcher, et al., 1983; Marcher, et al., 1987).

During periods of low precipitation and high evapotranspiration, low groundwater levels result in little baseflow to streams. In addition, many waterways are surrounded by low-permeability materials that impede groundwater infiltration, or are underlain by competent bedrock with limited storage and transmittal properties (Detroy, et al., 1983; Marcher, et al., 1983; Marcher, et al., 1987). Due to the high variability in streamflows, especially in those areas with limited groundwater resources (e.g., central Oklahoma), surface water is often stored in lakes and reservoirs in order to meet demand (Marcher, et al., 1987).

Flooding along many waterways is not uncommon in the Western Interior, particularly during early spring and summer when precipitation amounts are greatest, although precipitation alone does not ensure flooding will occur. Land slopes, drainage patterns, and other basin characteristics, along with land use and development patterns, influence flooding patterns and frequencies. Many states in the Western Interior have statistically evaluated flood-frequency data on gaged streams to better predict future discharge rates and the time intervals that may be expected for any particular rate to occur. For streams that are not monitored on a regular basis, flood-frequency curves have been developed using region-specific equations. The ability to plan for future flood conditions based on typical patterns is crucial for development and municipal planning (Detroy, et al., 1983; Marcher, et al., 1983; Marcher, et al., 1987). Man-made structures, such as reservoirs and ponds that have been constructed along the Arkansas River, can help moderate both the frequency and magnitude of floods (Marcher, et al., 1987).

3.5.5.7.2.3 Surface Water Quality

Table 3.5-23 lists designated use categories used to classify and protect the surface waters in the Western Interior region. Oklahoma has the least number of state-defined designated uses while Missouri has the most. The water quality assessments used as the basis for the integrated reports provide insight into the health of the region's surface waters. The percentage of water assessed within each of the three states ranges from 15.8 percent (Oklahoma) to 21.8 percent (Kansas). Table 3.5-24 shows about 88 percent of the waters assessed in Kansas are not achieving their designated use ("impaired waters") while Missouri classifies 53.1 percent of its streams as impaired. Kansas has the greatest number of impaired stream miles (25,755.8 miles) while Missouri has the least (5,412.6 miles). Missouri contains the highest number of stream miles achieving designated use (4,776.9 miles) while Oklahoma has the least (2,297.8 miles).

Overall, the Western Interior region contains 265,094 miles of streams, of which only 51,997.5 have been assessed. Approximately 10,653.5 of the 51,997.5 stream miles that have been assessed (20 percent) are achieving their designated, use while 41,344 (80 percent) are considered impaired. The assessment includes all causes of stream impairment and is not limited to mining-related impairments.

Table 3.5-23. Selected State-Defined Designated Uses – Western Interior Coal-Producing Region

Selected State-Defined Designated Uses for Surface Water		
Kansas	**Missouri**	**Oklahoma**
Agricultural water supply - Irrigation	Warm-water aquatic community	**Public and private water supply**
Agricultural water supply - Livestock watering	Cool-water aquatic community	Fish and wildlife propagation
Aquatic life support - Special aquatic life	Cold-water aquatic community	Agriculture
Aquatic life support - Expected aquatic life	Modified aquatic community	Primary body contact recreation (such as swimming)
Aquatic life support - Restricted aquatic life	Exceptional aquatic community	Seconary body contact recreation (such as boating/fishing)
Domestic Water Supply	While body contact recreation	Navigation
Food procurement	Secondary contact recreation	Aesthetics
Groundwater recharge	Human health protection	
Industrial water supply	Livestock and wildlife pretection	
Recreational - Primary contact :swimming beach	Drinking water supply	
Recreational - Primary contact: Public access	Irrigation	
Recreational - Primary contact: restricted access	Industrial water supply	
Recreational - Secondary contact: restricted	Aesthetics	
	Runoff storage and attenuation	
	Wildlife habitat protection	
	Recreational, cultural, educational, scientifiec, and natural aesthetic use protection	
	Hydrologic cycle mainteance	
	Outstanding resource waters

Oklahoma	http://www.deq.state.ok.us/WQDnew/305b_303d/index.html

3.5.5.7.4 Water Usage

Based on 2010 USGS data, water resources in this region are used primarily for thermoelectric power generation (47 percent) and agriculture (39 percent). Public water suppliers use 13 percent, and industrial/commercial establishments use one percent. Mining and domestic wells use less than one percent each. The total water usage for the year 2005 was 5,265 MGD (Maupin et al., 2014).

Precipitation is the primary source of recharge to the stream valley aquifers (Miller and Appel 1997; Ryder, 1996). Equal portions (42 percent each) of groundwater withdrawals are for both agriculture and public supply. Approximately five percent of groundwater withdrawals are associated with private domestic wells (USGS, 2010b).

Within the Western Interior region basin, a widespread water table decline has not been identified, but isolated areas of 40-foot water table declines have been identified (Reilly, et al., 2008). This would indicate that, for the most part, water demand and associated stress on the aquifer is confined to isolated areas and is not widespread.

About 76 percent of surface water withdrawn is utilized by thermoelectric facilities. Public water suppliers account for approximately 15 percent of surface water withdrawals. No surface water is diverted for private domestic use.

According to 2010 USGS data, 65 percent of total drinking water withdrawals are from surface water sources. Seventy percent of these public water supply withdrawals are from surface water. As of 2005, domestic water withdrawals had decreased 27 percent from 1985, and public water supply withdrawals had increased 39 percent, indicating that regional drinking water demand is increasing on net.

A review of USGS water use data for the years 1985 to 2010 indicates that the total proportion of the population supplied by a public water supplier is increasing while the total population and proportion of the population that is self-supplied is decreasing, as summarized in Table 3.5-25. In 2010, the domestic self-supply population was about 1.4 million, eleven percent of the total regional population. This self-supply population relies primarily on private wells for their water supply (all domestic water is supplied from groundwater) (Maupin et al., 2014). Because these wells are not routinely monitored or treated, this population is particularly susceptible to changes in groundwater quality and supply.

Table 3.5-25. Summary of Domestic Water Supply of Population (thousands/percent of total) – Western Interior Coal-Producing Region

Year	Self-Supply Population	Public Supply Population
2010	1,350 (11%)	11,250 (89%)
2005	291 (5%)	5,377 (95%)
2000	322 (6%)	5,160 (94%)
1995	527 (10%)	4,653 (90%)
1990	676 (14%)	4,294 (87%)
1985	731 (15%)	4,221 (85%)

3.6 Air Quality, Greenhouse Gas Emissions, and Climate Change

3.6.1 Introduction and Background

Air emissions from coal mining operations are primarily governed by federal regulations promulgated under the authority of the Clean Air Act (CAA) (42 U.S.C. § 7401 et seq.). Implementation of performance standards for blasting, however, also falls under the purview of SMCRA. The purpose and need for the proposed action considered in this EIS has no direct connection to air resources; OSMRE is not proposing to change any of our regulations that pertain to the control of emissions from mining activities, and OSMRE does not regulate emissions related to the combustion of the coal for electricity generation or any other end use. The regulatory alternatives may, however, have an indirect effect on emissions from mining and combustion. The discussion below provides a brief review of existing conditions in the coal regions in respect to air quality parameters, and a brief review of air quality regulations to put this information into context. Air quality effects that result from mining and combustion are discussed in the corresponding section of Chapter 4, specifically in section 4.2.4.

The Western region office of OSMRE has recently completed an EIS for the Four Corners Power Plant and Navajo Mine Energy Project (OSMRE, 2015b). Detailed discussions of the sources of emissions involved in mining and combustion and the requirements of the Clean Air Act related to those emissions are contained in the “Regulatory Compliance Framework” discussion contained on pages 4.1-1 through 4.1-17 of the Four Corners Power Plant and Navajo Mine Energy Project (FCPP) EIS. These discussions are summarized and incorporated into the text below where appropriate.

As discussed in the FCPP Final EIS coal mining and the use of coal involves both stationary and mobile sources of air pollutants. Coal mining causes air emissions from combustion of motor fuels (diesel and gasoline) used to operate mining equipment, portable equipment, and support vehicles. Some mining activities also cause air emissions, specifically nitrogen dioxide (NO_2), sulfur dioxide (SO_2), and carbon monoxide (CO) from explosives detonation and fugitive dust released during earthmoving activities. In addition as discussed in section 3.6.1.2. below, some emissions occur from the disturbance of the coal and surrounding rock; for example, coal seams and surrounding rock strata may contain methane (CH_4), which can be released during mining.

After the coal is mined, transportation of the coal from the mine site to the end user may generate emissions. Similarly, because virtually all of the coal is burned at some point, the combustion of the coal will generate emissions. Most coal mined in the U.S. is used to generate electricity; however, some is used to produce coke and for other industrial, commercial, and institutional purposes (U.S. EIA, 2014e). In the context of electricity generation, power plants are generally large stationary sources that emit substantial amounts of CO_2, NO_X and SO_2, along with coarse particulate matter ($PM_{10,}$ particulate matter up to ten micrometers in size) and fine particulate matter ($PM_{2.5,}$ particulate matter up to 2.5 micrometers in size). Power plant operation and maintenance would cause air emissions from the combustion of coal in boilers as well as motor fuels (diesel and gasoline) used in off-road equipment, portable equipment, and support vehicles.

3.6.1.1 Clean Air Act Regulatory Framework

3.6.1.1.1 Air Quality Standards

Air quality in a given location is determined by the concentration of various pollutants in the atmosphere. The EPA has established National Ambient Air Quality Standards (NAAQS) under the CAA of 1970 (amended 1977 and 1990, 42 U.S.C. § 7401 et seq.). Current standards are found on the EPA’s website at https://www.epa.gov/criteria-air-pollutants/naaqs-table for each pollutant for which there is a standard.

The NAAQS represent maximum levels of background pollution that are considered safe, with an adequate margin of safety, to protect public health (primary standards) and welfare (secondary standards such as diminished production and quality of agricultural crops, reduced visibility, degraded soils, materials and infrastructure damage, and damaged vegetation). Individual states have the option to adopt more stringent standards than the NAAQS and to include other pollution sources.

Federal law defines criteria pollutants to include ozone (O_3), NO_x, CO, SO_2, PM_{10}, $PM_{2.5}$, and lead (Pb). Elimination of tetraethyl lead in motor gasoline has eliminated emissions of Pb from vehicles and portable equipment. O_3 is not directly emitted, rather, its precursors NO_X and volatile organic compounds (VOCs) are the pollutants which react with sunlight to form ground-level photochemical O_3 and contribute to regional haze, along with SO_2 and particulate matter. Criteria emissions – also referred to as regulated pollutants – caused by coal mining activities and combustion would include reactive organic compounds (ROCs) or VOCs, NO_X as NO and NO_2, CO, SO_2, PM_{10}, and $PM_{2.5}$. Discussions of each of these pollutants can be found on pages 4.1-1 to 4.1-7 of the FCPP Final EIS.

In the 1977 CAA amendments, Congress classified those areas that meet or exceed the NAAQS as Class I, Class II, or Class III (42 U.S.C. § 7472). Based on an area's classification, regulatory authorities can permit certain amounts of increased pollution. The difference between a preexisting level of pollution and a new level is called an "increment." Congress decided that most national parks and wilderness areas already in existence at the time of the 1977 amendments would be designated as Class I areas, where only a small increase in pollution levels could be permitted. The legislation designated the rest of the clean air areas as Class II, where some additional pollution could occur. In addition, Congress allowed states to designate some areas as Class III, where the most pollution would be allowed but still not enough to cause a violation of the NAAQS. In the coal-producing regions, areas which have attained the NAAQS for criteria pollutants are designated as Class I, II, or "unclassifiable" and are regulated under the Prevention of Significant Deterioration (PSD) program.

As discussed below in 3.6.2, within the coal-producing regions, there are NAAQS nonattainment areas for the following criteria air pollutants: $PM_{2.5}$, PM_{10}, Ozone, lead and SO_2. Mining activities and associated coal combusting activities in proximity to these nonattainment areas may contribute to further degradation of the air quality and may be subject to more stringent requirements to minimize emissions.

3.6.1.1.2 Hazardous Air Pollutants

Hazardous Air Pollutants (HAPs), also known as toxic air pollutants or air toxics, are those pollutants that cause or may cause cancer or other serious health effects, such as reproductive effects or birth defects, or adverse environmental and ecological effects. Title III of the CAA Amendments of 1990 currently identifies 187 pollutants as HAPs, the federal term for air toxics. In 2001, the EPA identified 21 HAPs as mobile source air toxics, six of which are designated priority pollutants (66 FR 17230): acetaldehyde, acrolein, benzene-1, 3-butadiene, diesel exhaust (PM and organic gases), and formaldehyde. Diesel particulate matter (DPM) is considered a carcinogenic air toxic. An EPA assessment "examined information regarding the possible health hazards associated with exposure to diesel engine exhaust (DE), which is a mixture of gases and particles. The assessment concludes that long-term (i.e., chronic) inhalation exposure to DPM is likely to pose a lung cancer hazard to humans, as well as damage the lung in other ways depending on exposure. Short-term (i.e., acute) exposures to DPM can cause irritation and inflammatory symptoms of a transient nature, these being highly variable across the population" (EPA 2002).

In addition to DPM from mining equipment and heavy trucks, coal combustion may emit a wide range of inorganic and organic HAPs from stacks, according to the EPA (EPA 2011a, 40 CFR 63 Subpart UUUUU). Inorganic metals include compounds of the following: antimony (Sb), arsenic (As), beryllium (Be), cadmium (Cd), chromium (Cr), cobalt (Co), copper (Cu), lead (Pb), manganese (Mn), mercury (Hg), nickel (Ni), and selenium (Se). Organics and nonmetallic inorganics include: acetaldehyde, acetophenone, acrolein, benzene, benzyl chloride, bis(2-ethylhexyl)phthalate (DEHP), carbon disulfide, chlorobenzene, chloroform, cyanide, 2,4-dinitrotoluene, ethyl benzene, ethyl chloride, formaldehyde, hexane, hydrogen chloride, hydrogen fluoride, isophorone, methyl bromide, methyl chloride, methyl ethyl ketone, methylene chloride, polycyclic aromatic hydrocarbons (PAHs), phenol, propionaldehyde, tetrachloroethylene, toluene, styrene, and xylenes (ortho-, meta-, para- isomers).

Historically, coal-fired power plants have been the largest source of mercury and acid gas emissions in the U.S. and prior to implementation of the Mercury and Air Toxics Standards (MATS) rule discussed below were responsible for about 50 percent of mercury emissions and about 77 percent of acid gas emissions. For more discussion of the topic of mercury and air toxic standards, specifically refer to page 4.1-9 of the FCPP Final EIS.

On December, 21, 2011, the EPA finalized the MATS to limit emissions of mercury, hazardous acid gases, and other toxic pollutants from new and existing coal-and oil-fired power plants (77 FR 9304). On March 28, 2013, the EPA finalized updates to certain emission limits for new power plants under the MATS rule. All affect coal-and oil-fired power plants were required to be in compliance with the final MATS requirements by April 16, 2016.

3.6.1.1.3 Federal Visibility Protection Control Programs

Visibility and haze are regulated under the Regional Haze Rule of the CAA (40 CFR part 51 subpart P). Under the CAA, Class I areas are those in which visibility is protected more stringently than under NAAQS. Class I areas include national parks and monuments, wilderness areas, and other areas of special national and cultural significance. Section 169A (42 U.S.C. § 7491) of the CAA sets forth a national goal for visibility which is the ‘‘prevention of any future, and the remedying of any existing, impairment of visibility in mandatory Class I Federal areas which impairment results from manmade air pollution.’’

There are 156 Class I areas in the U.S., 49 of which are national parks and monuments. The Regional Haze Rule, enacted in 1999, requires states to establish goals and emission reduction strategies for improving visibility in all Class I areas as part of State Implementation Plans (SIPs) as geographically applicable (64 FR 35714). In addition, the EPA encourages states to work together in regional partnerships to develop and implement multistate strategies to reduce emissions of visibility-impairing fine particle ($PM_{2.5}$) pollution (64 FR 35714). Due to long range transport of visibility-impairing fine particles, all 50 states are required to participate in planning, analysis, and in many cases, emission control programs.

For more information related to the relationship of visibility standards to NAAQS, and Best Available Retrofit Technology in relation to coal combustion at power plants refer to page 4.1-10 to 4.1-11 of the FCPP Final EIS.

3.6.1.1.4 Atmospheric Deposition

Since the 1970s, implementation of CAA regulations has reduced emissions of NO_X, SO_2, and mercury and reduced the impact of atmospheric deposition on water quality and aquatic ecosystems. Three key regulations or programs have contributed to reductions in acid rain precursors: (1) Title II emission standards for mobile sources (motor vehicles), (2) actions designed to meet primary NAAQS, and (3) the Acid Rain Program.

The Acid Rain Program implements requirements for significant decreases in the emissions of NO_X and SO_2 from power plants to improve air quality and protect ecosystems that have been damaged by acid rain, including aquatic ecosystems. According to the 2011 National Acid Rain Precipitation Assessment Program report, the Acid Rain Program has been successful in reducing NO_X and SO_2 emissions from electric power generation to below levels set by Congress in 1990. By 2009, SO_2 emissions from power plants were 3.25 million tons lower than the final 2010 cap level of 8.95 million tons, and NO_X emissions were 6.1 million tons less than the levels projected for 2000.

Similar to NO_X and SO_2 emission reductions, mercury emissions from power plants also declined from about 59 tons of mercury in 1990 to about 30 tons of mercury in 2008 (EPA 2011b; GAO, 2013). When fully implemented, EPA projects that the Mercury and Air Toxics Standards rule will reduce future mercury emissions from domestic power plants to about 9 tons by 2016, a 70 percent reduction from 2008 (GAO, 2013).

3.6.1.1.5 Federal Prevention of Significant Deterioration Program

PSD (40 CFR 51.166 and 52.21) provides the overall regulatory framework for permitting new or existing stationary sources, such as oil refineries, factories, or power plants. PSD permitting applies to new major sources or major modifications at existing sources located in NAAQS attainment or unclassified areas for applicable pollutants.

3.6.1.1.6 Federal Stationary Source Regulations

Title V Operating Permits Parts 70 and 71 implement Title V of the CAA, 42 U.S.C. § 7661, et seq. Title V operating permits are legally enforceable documents that permitting authorities issue to major stationary sources of air pollution regulating their emissions. Title V major source thresholds are defined by the NAAQS attainment status of the jurisdiction, with progressively lower (more stringent) thresholds in moderate, serious, severe, and extreme nonattainment areas. Part 70 permits are issued by state and local (county or district) permitting authorities. Part 71 permits are issued either directly by the EPA or through tribal EPAs on sovereign tribal lands. There are many other Parts within the Section that provide additional requirements for monitoring and limits on emissions at stationary sources such as coal burning power plants. Pages 4.1-15 through 4.1-16 of the FCPP Final EIS provide a thorough description of requirements related to the Four Corners Power Plant, including enforceable limitations on SO_2, NO_x, PM, and opacity emissions that would be applicable to all power plants (40 CFR 49.23), and we are incorporating that discussion here by reference.

3.6.1.1.7 Mobile Source Regulations

Federal Tier 1 standards for off-road diesel engines were adopted in 1995. Federal Tier 2 and Tier 3 standards were adopted in 2000 and selectively apply to the full range of diesel off-road engine power categories. Both Tier 2 and Tier 3 standards include durability requirements to ensure compliance with the standards throughout the useful life of the engine (40 CFR 89.112). In 2004, the EPA finalized the rule implementing Tier 4 emission standards which phased-in from 2008 to 2015 (69 FR 38957-39273, June 29, 2004). The Tier 4 standards require that emissions of PM and NO_X be further reduced by about 90 percent. Such emission reductions can be achieved through the use of advanced control technologies – including advanced exhaust gas after treatment similar to those required by the 2007-2010 standards for highway diesel engines. It should be noted that emissions from diesel engines used in underground mining equipment are exempt from these requirements, as such engines are regulated by the Mine Safety and Health Administration (MSHA) through regulations contained in 30 CFR part 7, subpart E and 30 CFR part 72, subpart D.

3.6.1.2 Greenhouse Gas Emissions

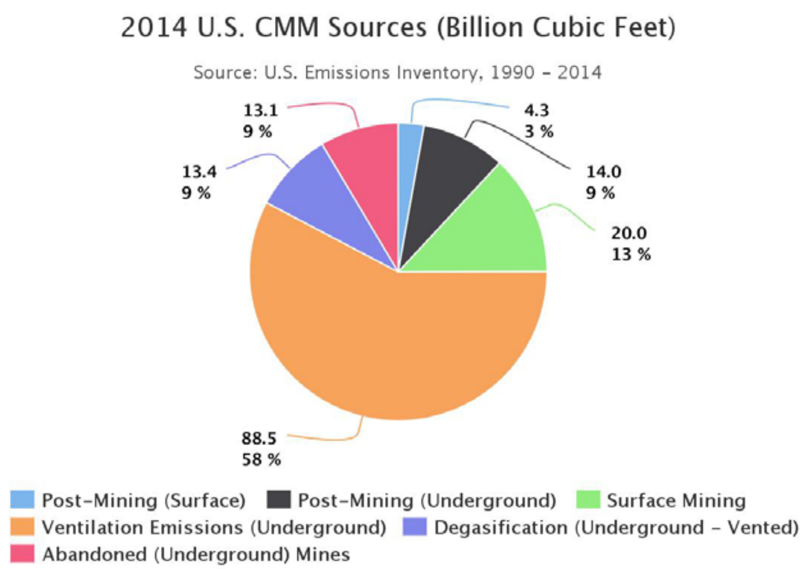
Greenhouse gases (GHG) trap solar energy in the atmosphere and cause it to warm. This phenomenon is called the greenhouse effect and is necessary to support life on Earth; however, excessive buildup of GHGs can change Earth's climate and result in undesirable effects on ecosystems, which affects human health and welfare (EPA 2012i). GHG constitutes an air pollutant, and EPA regulates GHG emissions. GHG emissions from the combustion of fossil fuels for energy include carbon dioxide (CO2), methane (CH4) and Nitrous Oxides (N2O), and represent the largest share of U.S. total GHG emissions (U.S. EPA, 2013a; U.S. EPA, 2013b).

The EPA tracks GHG emissions in the U.S. and publishes an annual update to its Inventory of U.S. Greenhouse Gas Emissions and Sinks (EPA 2012b, 2014). From the current report, the main source of GHG emissions in the U.S. is electric power generation, which accounts for 32 percent of GHG emissions nationwide. Over 70 percent of electric power is generated by burning fossil fuels, mainly coal and natural gas. GHG emissions from electric power generation in the U.S. have increased by about 24 percent since 1990 as demand for electric power has grown, and fossil fuels have remained the dominant energy source for generation due to their low private cost and high reliability. Coal combustion is much more carbon-intensive than burning natural gas or petroleum to generate electricity. In 2012, consumption of energy generated by coal decreased by 12.3 percent. Coal generated about 33 percent of electric power in the U.S. and in 2012 accounted for about 40 percent of CO_2 emissions from the power sector (EPA 2014b).

The amount of CH_4 released during coal mining depends on a number of factors, the most important of which are coal rank, coal seam depth, and method of mining. Coal rank represents the differences in the stages of coal formation and depends on the temperature history of the coal seam. As coal rank increases, the amount of CH_4 produced also increases. Because pressure increases with the depth of the coal seam and the adsorption capacity of coal increases with pressure, deeper coal seams generally contain more methane than shallow seams of the same rank. In addition, over time methane can be released to the atmosphere from near surface coal seams through natural fractures in overburden strata. Coal extraction tends to lead to the release of more methane than was originally trapped within the mined coal seam itself because the drop in pressure draws in additional gas from surrounding strata. Also, the mining process tends to fracture the surrounding strata including neighboring seams, particularly where longwall extraction is used. Underground coal mining typically releases more methane than surface mining because of the higher gas content of deeper seams (Irving and Tailakov, 1999).

The U.S. EPA Greenhouse Gas Inventory Reports provide a detailed description of methane emissions from coal mining and how they are estimated. According to these reports, three types of coal mining and related activities release methane to the atmosphere: underground mining, surface mining, and postmining (i.e., coal-handling) activities. Underground coal mines contribute the largest share of CH_4 emissions (Figure 3.6-1). Underground coal mines employ ventilation systems to maintain safe CH_4 levels for workers. These systems can exhaust significant amounts of CH_4 to the atmosphere in low concentrations. Additionally, some U.S. coal mines supplement ventilation systems with degasification systems. Degasification systems are wells drilled from the surface or boreholes drilled inside the mine that remove large volumes of CH_4 before, during, or after mining. In 2011, 14 coal mines collected CH_4 from degasification systems and used this gas, thus reducing emissions to the atmosphere; all of these mines sold CH_4 to the natural gas pipeline, including one that also used CH_4 to fuel a thermal coal dryer (U.S. EPA, 2013a). As of the 2015 report, this number had risen to 24 coal mines (U.S. EPA, 2015b). Surface coal mines also release CH_4 as the overburden is removed and the coal is exposed, but the level of emissions is much lower than from underground mines. Finally, some of the CH_4 retained in the coal after mining is released during processing, storage, and transport of the coal. In comparison to 1990 the total CH_4 emissions from coal mining in 2011 were 25 percent lower (U.S. EPA, 2013a) and 33 percent lower by 2013 (U.S. EPA, 2015b) .

Figure 3.6-1. Sources of Coalbed Methane - 2014 U.S. CMM Emissions (Billion Cubic Feet)



Source: U.S. EPA Coal Mine Methane Sources, U.S. Emissions Inventory, 1990- 2014 Report. https://www.epa.gov/epa-coalbed-methane-outreach-program/coal-mine-methane-sources

The EPA has established a voluntary program to reduce methane emissions in the coal mining industry. This program, known as the Coalbed Methane Outreach Program (CMOP), helps the coal industry identify the technologies, markets, and finance sources to profitably use or sell the methane that coal mines would otherwise vent to the atmosphere (U.S. EPA, 2013c).

3.6.1.3 Greenhouse Gas Regulation for Stationary Sources

On May 13, 2010, EPA issued the Prevention of Significant Deterioration and Title V Greenhouse Gas Tailoring Rule (75 FR 31514, June 3, 2010). The Greenhouse Gas Tailoring Rule set thresholds for GHG emissions, defining when CAA major source permits are required for new and existing industrial facilities that emit GHGs.

On June 23, 2014, the Supreme Court determined that EPA may not treat GHGs as an air pollutant for purposes of determining whether a source is a major source required to obtain a PSD or Title V permit. *Utility Air Regulatory Group v. EPA*, 134 S. Ct. 2427 (2014). On June 25, 2014, EPA issued a clarifying memorandum stating they will no longer require permits for sources that triggered permitting requirements based solely on their GHG emissions. On April 10, 2015, the D.C. Circuit issued an amended judgment in *Coalition for Responsible Regulation, Inc. v. Environmental Protection Agency*, Nos. 09-1322, 10-073, 10-1092 and 10-1167 (D.C. Cir. April 10, 2015), which vacated the PSD and Title V regulations to the extent that they require a stationary source to obtain a PSD or title V permit solely because the source emits or has the potential to emit GHGs above the applicable major source thresholds.

Currently under the Greenhouse Gas Tailoring Rule, EPA regulates GHG emissions and requires application of Best Available Control Technology (BACT) for new major sources and major modifications at existing sources that require PSD and Title V permitting for their applicable emissions (referred to as “anyway pollutants”). EPA will still be able to regulate 83 percent of stationary source GHG emissions under the PSD and Title V permitting process because almost all these sources also emit significant quantities of criteria (anyway) air pollutants. It is estimated that only three (3) percent of new or modified GHG-only stationary sources previously subject to the Tailoring Rule will now no longer be subject to regulation (Jennings; 2014).

3.6.1.4 Clean Power Plan

On August 3, 2015, President Obama and EPA announced the Clean Power Plan (CPP) to reduce carbon pollution from existing fossil fuel-fired power plants. EPA also issued final Carbon Pollution Standards for new, modified, and reconstructed fossil fuel-fired power plants. The CPP requires that States develop and implement plans to ensure the power plants in their state – either individually, together, or in combination with other measures – achieve the emission requirements starting in 2022, with full implementation by 2030. EPA and industry analysts anticipate that many of the reductions will be met through shifting generation to less carbon-intensive sources of energy. On February 9, 2016, the Supreme Court stayed implementation of the Clean Power Plan pending judicial review.

3.6.1.5 Greenhouse Gas Reporting Program (GHGRP)

EPA requires underground coal mines that liberate 36,500,000 actual cubic feet or more of CH_4 annually to report their annual emissions to the Greenhouse Gas Reporting Program (GHGRP) established by the Mandatory Reporting of Greenhouse Gases rule (74 FR 56260, 40 CFR part 98, effective December 29, 2009). Part 98 requires reporting of GHG data and other relevant information from large sources and suppliers in the U.S. pursuant to Fiscal Year 2008 Consolidated Appropriations Act (Pub. L. No. 110-161).

The rule facilitates collection of accurate and comprehensive emissions data to provide a basis for future EPA policy decisions and regulatory initiatives. It requires specified industrial source categories and facilities with an aggregated heat input capacity of 30 MMBtu or more per hour or that emit 25,000 metric tonnes or more per year (MT/yr) of CO_2 equivalent (CO_2e) GHGs to submit annual reports to the EPA. The gases covered by the rule are CO_2, CH_4, N_2O, and hydrofluorocarbons, perfluorocarbons, sulfur hexafluoride (SF6), and other fluorinated gases including nitrogen trifluoride and hydrofluorinated ethers.

In 2015, over 9,000 facilities and suppliers subject to Part 98 reported their emissions to the GHGRP (EPA 2016c). This included 123 underground coal mines that reported to EPA under subpart FF of the program. Subpart FF facilities are required to report:

- CH_4 liberated from mine ventilation and degasification systems
- CH_4 destruction from systems where gas is sold, used onsite, or otherwise destroyed (including by flaring and ventilation air methane (VAM) oxidation)
- Net CH_4 emissions from ventilation and degasification systems (CH_4 liberated less CH_4 destroyed)
- CO_2 emissions from coal mine CH_4 destruction occurring at the facility, where the gas is not a fuel input for energy generation or use. (This applies primarily to CH4 that is flared or destroyed by VAM oxidation.)

In addition, each facility must report GHG emissions of other source categories for which calculation methods are provided in the rule. For example, facilities must report CO_2, N_2O, and CH_4 emissions from each stationary combustion unit on site by following the requirements of 40 CFR part 98, subpart C (General Stationary Fuel Combustion Sources).

Reporting year 2011 was the first year emissions data was collected for underground coal mines under subpart FF of the GHGRP (Table 3.6-1). The 2012 reported emissions data (U.S. EPA) revealed that the primary sources of GHG emissions from underground mines are located in West Virginia and Pennsylvania. These two states comprised 57.7 percent of the total reported emissions nationwide in 2012. Figure 3.6-2 provides an updated representation of the contributors, by state, to underground coal mine emissions across the nation.

Table 3.6-1. Greenhouse Gas Emissions from Underground Mines, million metric tons CO2e

	2015	2014	2013	2012	2011
Number of facilities:	123	128	129	118	117
Total emissions (CO_2e):	42.9	43.2	40.5	38.4	40.4
Emissions by greenhouse gas (CO_2e)					
Carbon dioxide (CO_2):	0.3	0.5	0.3	0.2	0.2
Methane (CH_4):	42.6	42.7	40.3	38.2	40.2
Nitrous oxide (N_2O):	**	**	**	**	**

Source: U.S. EPA, 2016c. Greenhouse Gas Reporting Program, Subpart FF (Underground Coal Mines). https://www.epa.gov/ghgreporting/ghgrp-underground-coal-mines

Notes:

Totals may not equal sum of individual GHGs due to independent rounding.
NR means that this value was not reported.
** Total reported emissions are less than 0.05 million metric tons CO_2e.

3.6.1.6 Climate Change

Evidence collected by scientists and engineers from around the world have determined the climate is changing; the planet is warming and over the last half century primarily driven by human activity—predominantly due to the GHG emissions from burning fossil fuels. The U.S. average temperature has increased by 1.3°F to 1.9°F since 1895, and most of this increase has occurred since 1970. The most recent decade was the Nation’s and the worlds hottest ever recorded, and 2012 was the hottest year on record in the continental United States. Temperatures are projected to rise another 2°F to 4°F in most areas of the U.S. over the next few decades (USGCRP, 2015).

Changes in extreme weather and climate events, such as heat waves and droughts, are the primary way that most people experience climate change. There has been an increase in the U.S. in prolonged periods of excessively high temperatures, heavy downpours, and in some regions, severe floods and droughts over the last 50 years. The location, timing, and amounts of precipitation will also change as temperatures rise. In general, the northern part of the U.S. is projected to see more winter and spring precipitation, while the southwestern U.S. is projected to experience less precipitation in the spring. Wet regions are generally projected to become wetter while dry regions become drier. Summer drying is projected for parts of the U.S., including the Northwest and southern Great Plains. Increased temperatures and changing precipitation patterns will alter soil moisture, which is important for agriculture and ecosystems and has many societal implications (USGCRP, 2015).

3.6.2 Air Quality by Coal-Producing Region

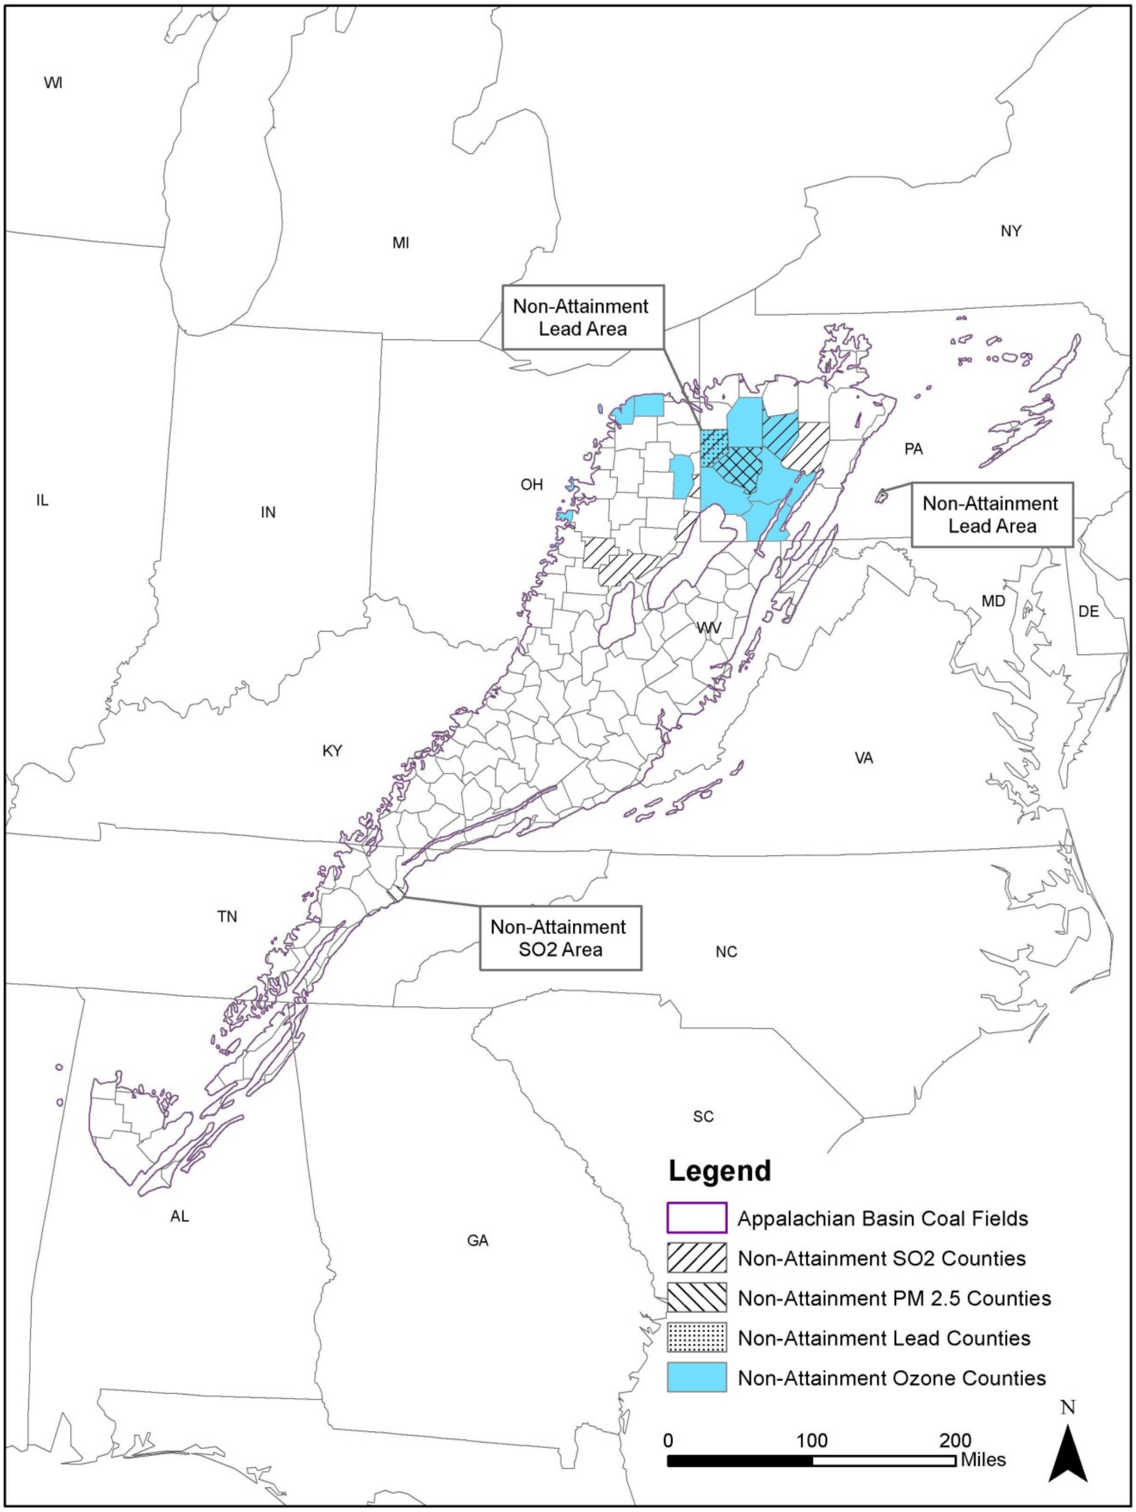
As discussed below, within the coal-producing regions, there are NAAQS nonattainment areas for the following criteria air pollutants: $PM_{2.5}$, PM_{10}, ozone, and SO_2. Mining activities in proximity to these nonattainment areas may contribute to further degradation of the air quality and may be subject to more stringent requirements to minimize emissions.

3.6.2.1 Appalachian Basin Region

3.6.2.1.1 Nonattainment Areas

Five ambient air pollutants in the Appalachian Basin exist in concentrations that exceed ambient air quality standards: $PM_{2.5}$, PM_{10}, ozone, lead and sulfur dioxide (U.S. EPA, 2016). Figure 3.6-3 depicts the locations of these nonattainment areas.

Figure 3.6-3. Nonattainment Areas in the Appalachian Basin Region



Source: Data- U.S. EPA, 2016, The Green Book Nonattainment Areas for Criteria Pollutants, http://www.epa.gov/oar/oaqps/greenbk/index.html

Air quality readings exceed the 24-hour standard $PM_{2.5}$ in some cities in Pennsylvania, and Tennessee. Within the Appalachian coal basin, Ohio and Pennsylvania are the only states containing nonattainment counties for the current 8-hour ozone standard (U.S. EPA, 2016). The northeast region of the U.S. experiences high levels of ozone due to high-altitude transport of pollutants from Midwest and eastern power plants and other large industrial sources. As a result, state rules in these affected states (which include Pennsylvania) regulate new emission sources of VOC and NOx under nonattainment rules.

As of June 17, 2016 the following Appalachian coal basin counties were listed as nonattainment counties for the specified criteria pollutants:

- Ohio:
    - Ozone: Fairfield, Knox, Licking, Medina, Portage, and Summit Counties;
    - SO_2: Jefferson, Morgan, and Washington Counties
- Pennsylvania:
    - Lead: Beaver County
    - Ozone: Allegheny, Armstrong, Beaver, Butler, Fayette, Washington, and Westmoreland Counties;
    - $PM_{2.5}$: Allegheny, and Lebanon Counties;
    - SO_2: Allegheny, Armstrong, Beaver, and Indiana Counties;
- **Tennessee**: $PM_{2.5}$: Anderson and Roane Counties; and
- **West Virginia**: SO_2: Brooke, and Marshal Counties (U.S. EPA, 2016).

3.6.2.1.1.1 Pollutants of Concern

Throughout the Appalachian Basin, ample forestland and trees are a source of biogenic VOC, such that in this region NOx is the only limiting factor for ozone formation. NOx is formed as a result of combustion; consequently any fuel combustion at mine, power plant, or other facility can potentially contribute to ozone formation.

Appalachian coal generally contains a significant amount of sulfur, although Virginia coal has less than one percent sulfur. Some mines require washing of the coal to remove this sulfur or ash material. Before this coal can be shipped, it must be dried using conveyor dryers or kilns. Hot air is supplied to these dryers by burning fuel. When coal is burned at the mine to supply heat to the dryer, the sulfur in the coal is oxidized to sulfur dioxide that contributes to SO_2 and fine particulate formation ($PM_{2.5}$) in the atmosphere. It also would be a primary contributor in an area that is in nonattainment with the air quality standards for these pollutants. Therefore, operations that burn coal at the mines for use in coal processing activities may be required to install air pollution controls on these sources, especially in Armstrong County, which is classified as a nonattainment area for sulfur dioxide in Pennsylvania.

3.6.2.1.1.2 State and Local Air Quality Authorities

Each state in the Appalachian Basin has an EPA-approved State Implementation Plan (SIP) that grants states permitting authority over their air management districts. In addition to state permitting authorities, Alabama, Kentucky, Tennessee, Ohio, and Pennsylvania have local permitting authorities that issue air permits within their jurisdictions. Permitting in other states is done by state agencies (U.S. EPA, 2011c).

3.6.2.1.1.3 Federal Class I Air Quality Areas

Federal Class I areas include designated federal parks and wilderness areas and other lands where air quality is subject to a higher level of protection. In the Appalachian Basin, there are numerous Class I areas around the Smoky Mountains and other portions of the Appalachian Mountain chain. A mine subject to PSD regulation must review its impact on all Class I areas within 300 kilometers (km).

Figure 3.6-4 shows the locations of the Class I areas within 300 kilometers of the Appalachian Basin. The numbered areas are presented in Table 3.6-2 (U.S. EPA, 2011e; National Atlas of the United States, 2005).

3.6.2.2 Colorado Plateau Region

3.6.2.2.1 Nonattainment Areas

Utah County, Utah is the only county in the Colorado Plateau region that is in a nonattainment status for any criteria pollutant. This county is currently in nonattainment for both $PM_{2.5}$ and PM_{10} (EPA, 2016). Figure 3.6-5 depicts the locations of these nonattainment areas.

3.6.2.2.2 Pollutants of Concern

Sulfur dioxide is a pollutant of concern in Arizona, which has neighboring counties classified as nonattainment for this criteria pollutant. The coal from this region has low ash content and low sulfur content (U.S. EIA, 1989). The low ash content is expected to produce lower particulate emissions while the low sulfur content is expected to reduce the amount of coal cleaning necessary.

3.6.2.2.3 State and Local Air Quality Authorities

Each state in the Colorado Plateau has an EPA-approved SIP that grants permitting authority over their air management districts. In addition to state permitting authorities, the counties of Maricopa, Pima, and Pinal in Arizona have local permitting authorities that issue air permits within their jurisdiction (U.S. EPA, 2011c; National Atlas of the United States, 2005).

3.6.2.2.4 Federal Class I Areas

In the Colorado Plateau, there are numerous Class I areas around the Rocky Mountains and in the deserts of Arizona and New Mexico where air quality is subject to a higher level of protection. A mine subject to PSD regulation must review its impact on all Class I areas within 300 kilometers.

Figure 3.6- 6 depicts the locations of these Class I areas, with the numbers corresponding to the following sites. The numbered areas are presented in Table 3.6-3.

3.6.2.3 Gulf Coast Region

3.6.2.3.1 Nonattainment Areas

There are two NAAQS nonattainment areas in the Gulf Coast region. Pike County, Alabama is in nonattainment for lead (U.S. EPA, 2016). Shelby County, Tennessee is in nonattainment for ozone (U.S. EPA, 2016). Figure 3.6-7 shows these areas.

3.6.2.3.2 Pollutants of Concern

Throughout the Gulf Coast region, ample crops, forestland, and trees are a source of biogenic VOC, such that only NOx is the limiting factor for ozone formation. NOx is formed as a result of combustion, so any fuel combustion at a mine can potentially contribute to ozone formation.

The Gulf Coast region has surface mining and coal preparation plants only (U.S. EIA, 2011b). The coal from this region has very high ash content and median sulfur content (U.S. EIA, 1989). The high ash content would produce higher particulate emissions during handling, storage, and drying of coal, increasing the need for higher air pollution control at these sources.

3.6.2.3.3 State and Local Air Quality Authorities

Each state in the Gulf Coast region has an EPA-approved SIP that grants permitting authority over their air management districts (U.S. EPA, 2011c). No local air quality regulations exist in the Gulf Coast region coal-producing counties.

3.6.2.3.4 Federal Class I Areas

Federal Class I areas are designated federal lands, such as national parks and wilderness areas where air quality is subject to a higher level of protection. A mine subject to PSD regulation must review its impact on all Class I areas within 300 kilometers of the mine. In and around the Gulf Coast region, there are numerous Class I areas. These areas are depicted in Figure 3.6-8 and include (U.S. EPA, 2011e; National Atlas of the United States, 2005). The numbered areas are presented in Table 3.6-4.

3.6.2.4 Illinois Basin Region

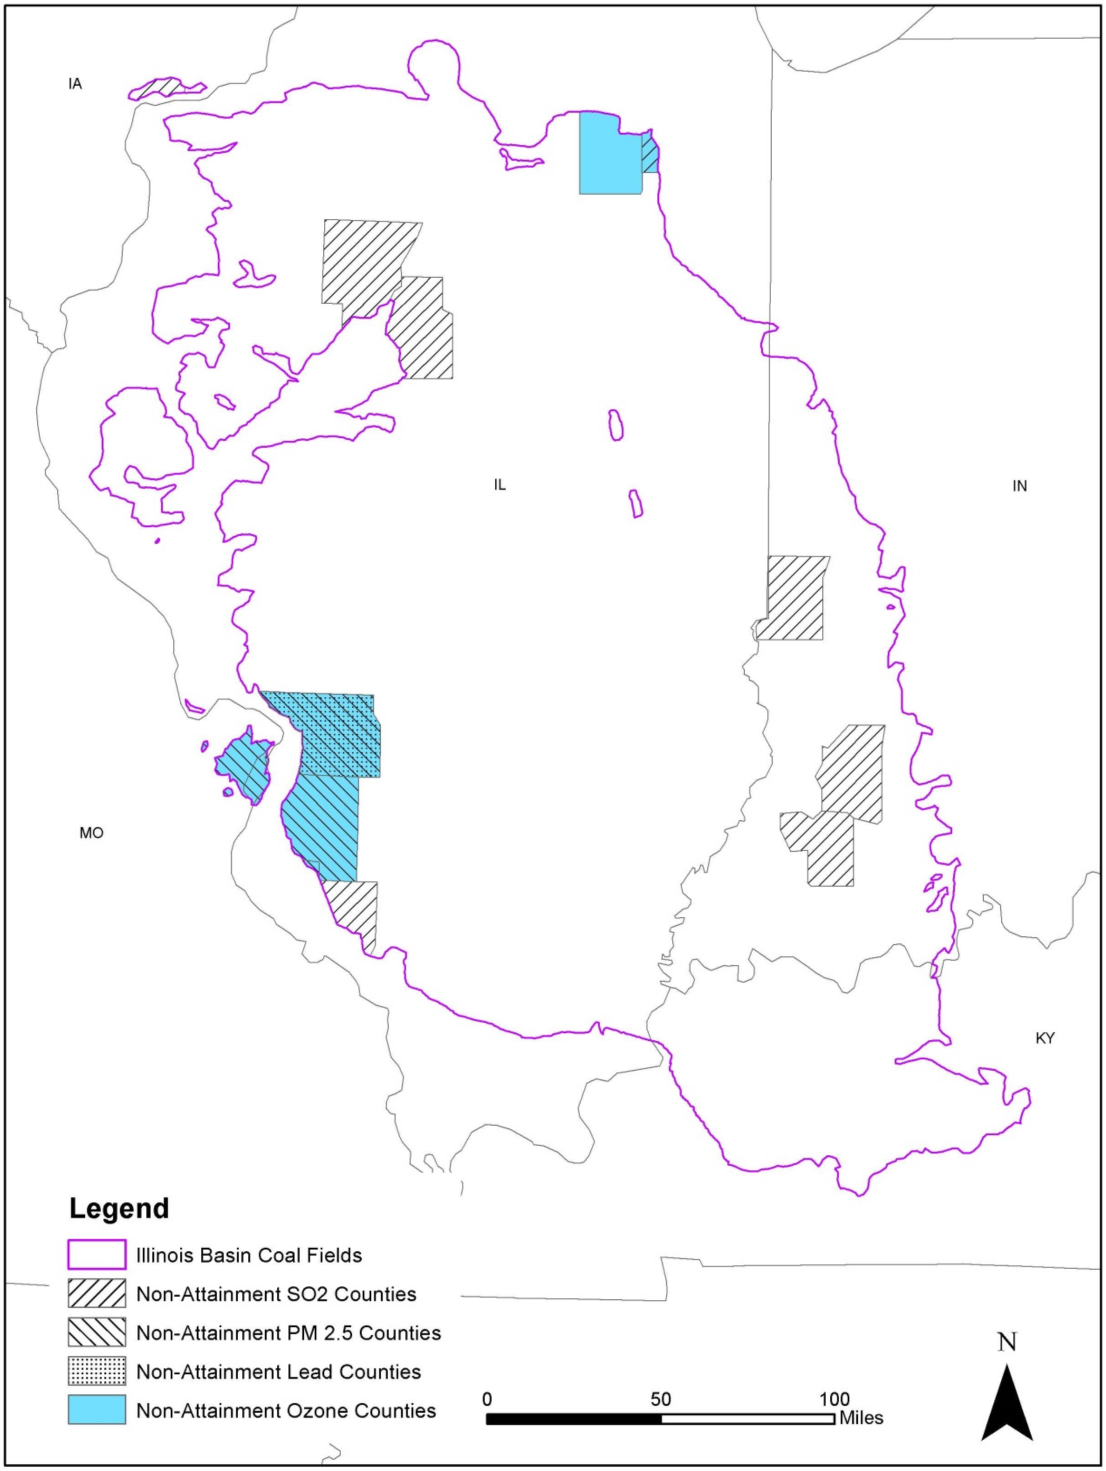
3.6.2.4.1 Nonattainment Areas

As of June 17, 2016 the following Illinois coal basin counties were listed as nonattainment counties for the specified criteria pollutants:

- Indiana:
  - SO_2: Daviess and Vigo Counties;
- Illinois:
  - Lead: Madison County
  - Ozone: Grundy, Madisoin, Monroe, and Will Counties;
  - $PM_{2.5}$: Madison, Randolph, St Clair, and Monroe Counties;
  - SO_2: Peoria, Tazewell and Vigo Counties;
- Missouri:
  - $PM_{2.5}$: St Charles, St Louis city, St Louis County;
  - Ozone: St Charles, St Louis city, St Louis County. (U.S. EPA, 2016).

Figure 3.6-9 shows these areas.

Figure 3.6-9. Nonattainment Areas in the Illinois Basin Region



Source: Data- U.S. EPA, 2016, The Green Book Nonattainment Areas for Criteria Pollutants, http://www.epa.gov/oar/oaqps/greenbk/index.html

3.6.2.4.2 Pollutants of Concern

Coal mined in the Illinois Basin generally contains a significant amount of sulfur. When burned, this sulfur is oxidized to sulfur dioxide, which contributes to fine particulate formation ($PM_{2.5}$) in the atmosphere. Therefore, when coal is burned at the mines for coal processing activities, air pollution controls or alternative fuels should be considered.

The Illinois Basin region has both surface mining and underground mining operations, as well as coal preparation plants (U.S. EIA, 2011b). The coal from this region has median ash content and very high sulfur content (U.S. EIA, 1989). This sulfur and ash content would increase the amount of coal cleaning necessary. As a result, the coal dryers may potentially cause greater particulate emissions (and possibly sulfur dioxide depending on the fuel) than at comparable mines in other regions.

3.6.2.4.3 State and Local Air Quality Authorities

Each state has an EPA-approved SIP that grants permitting authority over their air management districts. In addition to state permitting authorities, Jefferson County in Kentucky has a local permitting authority that issues air permits within its jurisdiction (U.S. EPA, 2011c).

3.6.2.4.4 Federal Class I Air Quality Areas

Federal Class I areas are designated federal lands where air quality is subject to a higher level of protection. In the Illinois Basin, there are numerous Class I areas. A mine subject to PSD regulation will need to review its impact on all Class I areas within 300 kilometers. Figure 3.6-10 shows the locations of the Class I areas within 300 kilometers of the region, which include (U.S. EPA, 2011e; National Atlas of the United States, 2005). The numbered areas are presented in Table 3.6-5.

3.6.2.5 Northern Rocky Mountains and Great Plains Region

3.6.2.5.1 Nonattainment Areas

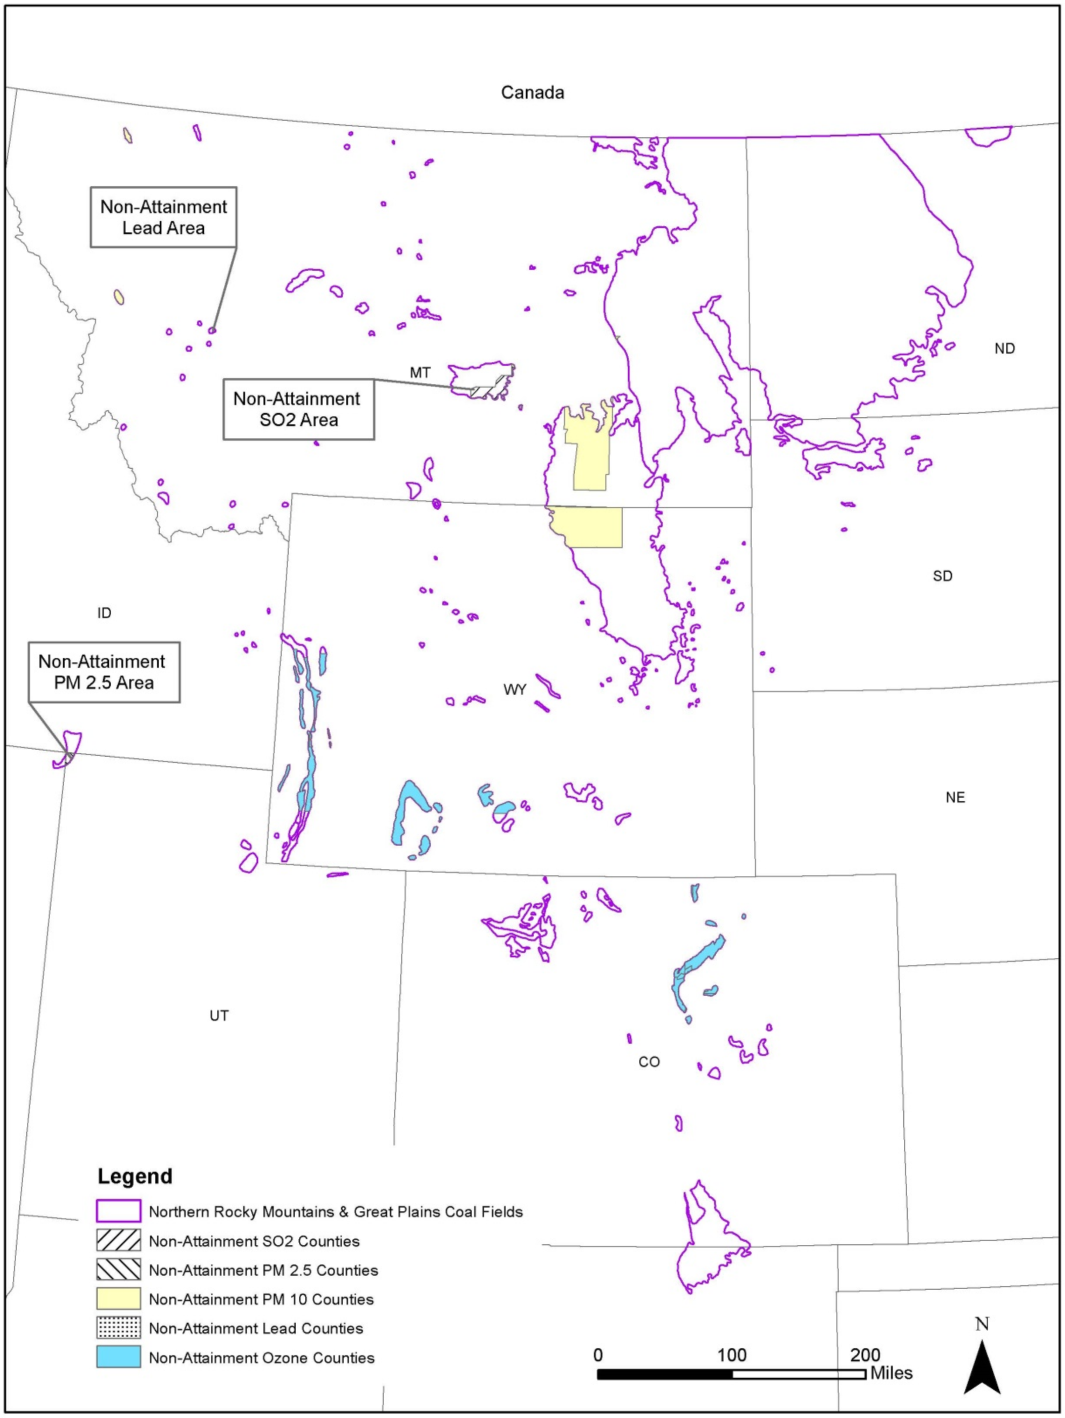
Coarse particulates (PM_{10}) and fine ($PM_{2.5}$), lead, ozone, and SO_2 currently exceed ambient air quality standards in certain counties of the Northern Rocky Mountains and Great Plains region (U.S. EPA, 2011b). Figure 3.6-11 depicts nonattainment areas within the Northern Rocky Mountains and Great Plains region.

Montana and Wyoming are the only two states within the Northern Rocky Mountains and Great Plains coal basin with counties that contain nonattainment PM_{10} areas (U.S. EPA, 2016). Several counties within Colorado are in nonattainment for the current 8-hour ozone standard. The Upper Green River Basin (Sublette County and portions of Lincoln and Sweetwater counties) in southwestern Wyoming was designated as marginal nonattainment for ozone effective July 20, 2012. Montana is the only state in this coal basin with counties that contain nonattainment SO_2 areas (U.S. EPA, 2016).

The following nonattainment areas (U.S. EPA, 2016) are within the Northern Rocky Mountains and Great Plains region:

- Colorado:
  - Ozone: Adams, Arapahoe, Boulder, Broomfield, Denver, Douglas, Jefferson, and Larimar Counties;
- Montana:
  - Lead: Lewis and Clark County
  - PM_{10}: Flathead, Missoula and Rosebud Counties;
  - SO_2: Lewis and Clark County, and Yellowstone County;
- Wyoming:
  - Ozone: Lincoln, Sublette, and Sweetwater Counties:
  - PM_{10}: Sheridan County.
- Utah:
  - $PM_{2.5}$: Box Elder County

Figure 3.6-11. Nonattainment Areas in the Northern Rocky Mountains and Great Plains Region



Source: Data- U.S. EPA, 2016, The Green Book Nonattainment Areas for Criteria Pollutants, http://www.epa.gov/oar/oaqps/greenbk/index.html

3.6.2.5.2 Pollutants of Concern

Most of the mining in this area is surface mining, which would generate more surface disturbance and result in more dust generation. While Wyoming Department of Environmental Quality requires the use of Best Available Control Technology to minimize air quality impacts (Wyoming Air Quality Standards and Regulations Chapter 6, Section 2), dust emissions from mining activities caused by haul roads and conveyors are a concern in this region. The coal from this region has relatively low ash and sulfur content (U.S. EIA, 1989). Less coal cleaning is needed and particulate emissions from coal are low relative to other regions.

3.6.2.5.3 State and Local Air Quality Authorities

Each state has an EPA-approved SIP that grants permitting authority over their air management districts. Therefore, air permits for mining operations are issued by the states (U.S. EPA, 2011c).

3.6.2.5.4 Federal Class I Air Quality Areas

Federal Class I areas are designated federal lands where air quality is subject to a higher level of protection. A mine subject to PSD regulation will need to review its impact on all Class I areas within 300 kilometers. In the Northern Rocky Mountains and Great Plains region, numerous Class I areas exist around the Rocky Mountains and in other areas. Figure 3.6-12 depicts the locations of these areas, which include the following (U.S. EPA, 2011e; National Atlas of the United States, 2005):

3.6.2.6 Northwest Region (Alaska) Regional Air Quality, Meteorology and Noise

Alaska is the only state in this region discussed in detail in the FEIS because it has an active coal mine with coal extraction. As discussed in 3.0, coal production is not predicted to occur in the reasonably foreseeable future in the other portions of the Northwest region, and, therefore, these areas are not included here in this discussion of air quality.

3.6.2.6.1 Nonattainment Areas

There are no NAAQS nonattainment areas within the counties of the Northwest region.

3.6.2.6.2 Pollutants of Concern

There are no specific pollutants of concern in the Northwest region. There are currently surface mining and coal preparation operations associated with the one actively producing mining area in the Northwest region. The coal from this region has low ash and sulfur content (U.S. EIA, 1989). The low ash content would produce lower particulate emissions while the low sulfur content would reduce the amount of coal cleaning necessary.

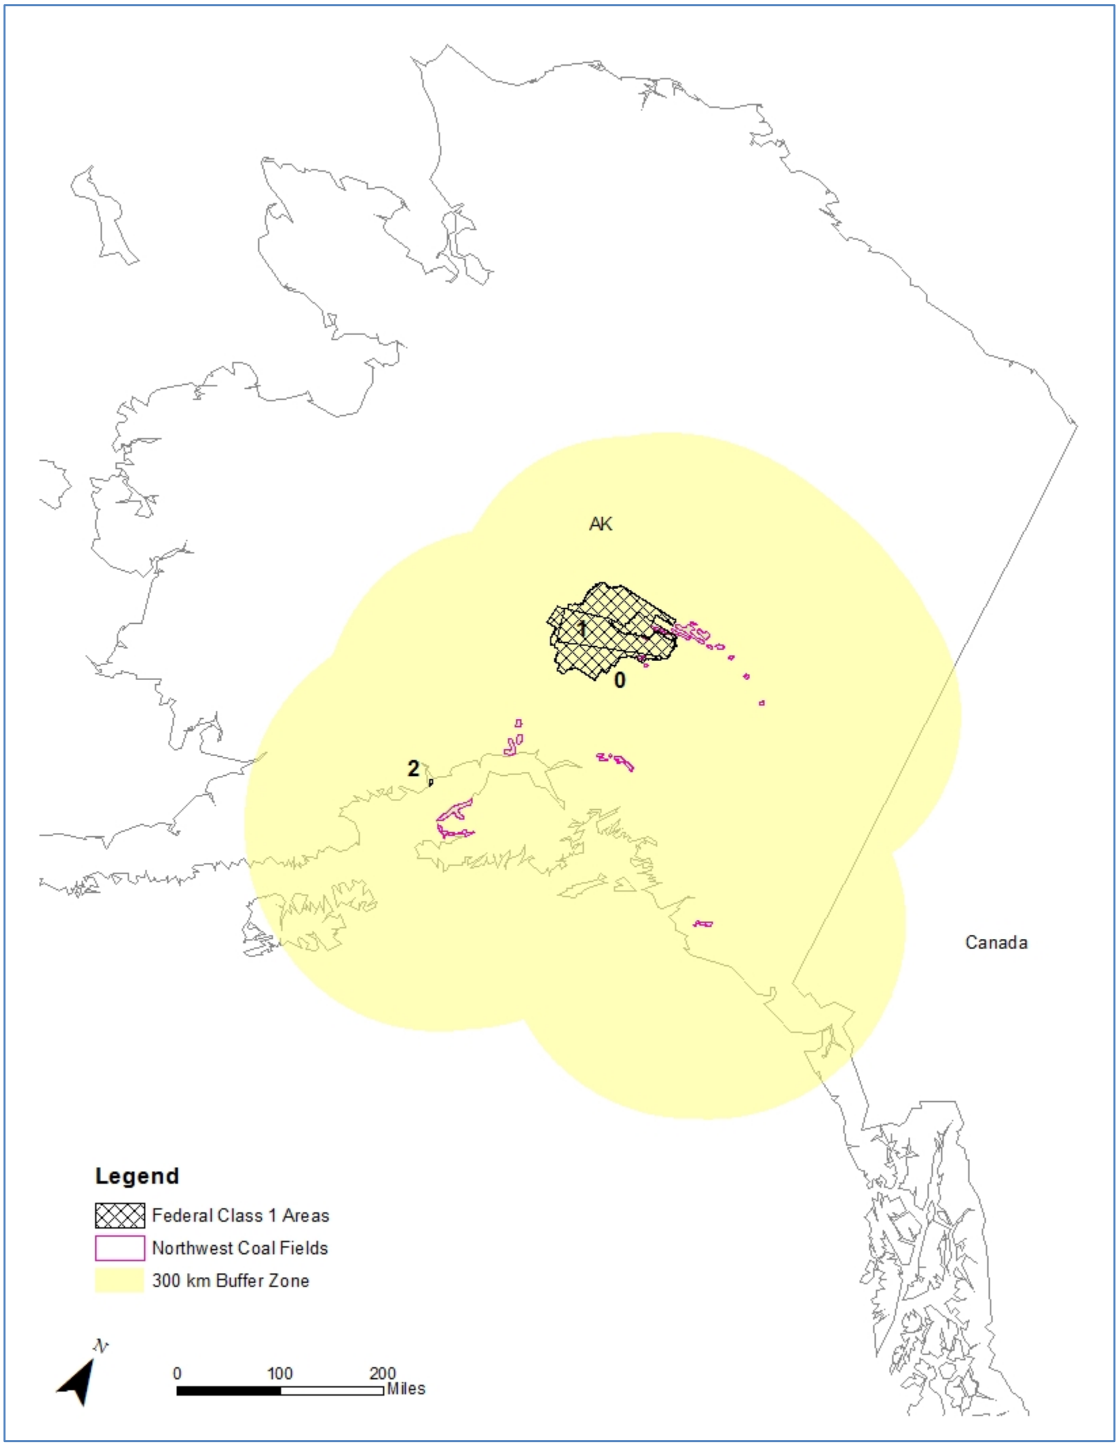
3.6.2.6.3 State and Local Air Quality Authorities

Alaska has an EPA-approved SIP that grants permitting authority over its air management districts. Therefore, any air permits for a mining operation would be granted by the state (U.S. EPA, 2011c). There are no local air quality authorities.

3.6.2.6.4 Federal Class I Air Quality Areas

Federal Class I areas are designated federal lands where air quality is subject to a higher level of protection. Denali National Park and Denali National Park and Wilderness are the only Class I areas within 300 kilometers of the subject coal fields. A coal mine permit would include a review of its impact on the Class I area (U.S. EPA, 2011e; National Atlas of the United States, 2005). Figure 3.6-13 shows the locations of these Class I areas.

Figure 3.6-13. Federal Class I Areas in the Northwest Region



Source: National Atlas of the United States, 2005, federal lands of the United States, USGS, U.S. DOI. http://nationalatlas.gov/atlasftp.html

3.6.2.7 Western Interior Region

3.6.2.7.1 Nonattainment Areas

There are three NAAQS nonattainment areas within the Western Interior region, Parker and Wise Counties in Texas for ozone and Jackson County Missouri for SO_2 (U.S. EPA, 2016). Figure 3.6-14 shows these areas.

3.6.2.7.2 Pollutants of Concern

There are no specific pollutants of concern in the Western Interior region. There are currently underground mining, surface mining, and coal preparation operations in the Western Interior region (U.S. EIA, 2016). The coal from this region has medium to high ash content and generally high sulfur content (U.S. EIA, 1989). This sulfur and ash content would increase the amount of coal cleaning necessary. As a result, coal dryers potentially could cause greater particulate emissions (and possibly sulfur dioxide emissions, depending on the fuel used in the dryers) than comparable mines in other regions.

3.6.2.7.3 State and Local Air Quality Authorities

Each state has an EPA-approved SIP that grants permitting authority over their air management districts. Therefore, air permits for mining operations are granted by the states (U.S. EPA, 2011c).

3.6.2.7.4 Federal Class I Air Quality Areas

Federal Class I areas are designated federal lands where air quality is subject to greater protection. A mine subject to PSD regulation will need to review its impact on all Class I areas within 300 kilometers. Within 300 kilometers of the Western Interior region, there are numerous Class I areas. Figure 3.6-15 shows the locations of these Class I areas, which include (U.S. EPA, 2011e; National Atlas of the United States, 2005):

Table 3.6-7. Federal Class I Areas in the Western Interior Region

FEATURE ID	NAME	STATE
0	Upper Buffalo Wilderness	AR
1	Hercules-Glades Wilderness	MO
2	Caney Creek Wilderness	AR
3	Wichita Mountains (North Mountain Unit)	OK
4	Wichita Mountains (Charons Garden Unit)	OK
5	Mingo Wilderness	MO

3.7 Land Use

3.7.1 Land and Mineral Ownership

Mineral ownership in the U.S. is often comprised of split estates, in which different parties own the surface and subsurface rights. Such estates are common throughout the coal-producing regions. In many instances, interests in the mineral estate (coal) were sold or otherwise severed long before the current surface owners acquired the land. State property law and legal instruments of conveyance determine the extent to which the owner of the mineral estate may exercise his or her rights to the detriment of the owner of the surface estate. Section 510 of SMCRA, however, requires that an applicant proposing to remove coal by surface mining methods must demonstrate a valid right of entry. In addition, Section 714 of SMCRA provides qualified surface owners, whose property overlies federal coal, with additional protections before the coal is leased for anticipated surface mining operations. Appendix G provides a detailed breakdown of land use percentages for the individual states and county study areas described by region below.

3.7.2 Federal and Indian Lands

The area of study includes seven coal-producing regions containing lands where the federal government holds title to the coal, the surface estate, or both. Recent USGS assessments estimate federally owned coal reserves in the U.S. at 957,000 million short tons (MMton), of which the Powder River Basin contains 58 percent (550,000 MMton) and the Colorado Plateau contains 38 percent (361,860 MMton). The remaining four percent of federally owned coal is distributed throughout other coal regions (USGS, 2007).

Federal surface lands in the eastern U.S. include National Forests, U.S. military properties, National Parks, water bodies, other recreational areas, and historical sites. In the coal-bearing area of the Appalachian Basin, about 90 percent of federal land is in National Forests.

USGS assessments of federally owned coal in the Northern and Central Appalachian coal regions indicated that federal coal ownership comprised 2 to 13 percent of the remaining reserves within those regions, while federal coal ownership in the West comprises approximately 70 percent to 80 percent of the total coal reserves in that region. (USGS, 2002b)

The Bureau of Land Management (BLM) has the authority to grant leases to operators wishing to mine federally owned coal. The Mineral Leasing Act of 1920 (MLA), as amended, and the Mineral Leasing Act for Acquired Lands of 1947, as amended, designates the BLM as the primary agency responsible for coal leasing on approximately 570 million acres of the 700 million acres of mineral estate owned by the federal government.

Not all federal lands are available for coal exploration or leasing. Under the BLM land use planning process, four land-use screening steps are used to identify which federal lands are acceptable for consideration for coal leasing and development:

- Identification of coal with potential for development;
- Determination if the lands are unsuitable for coal development;

- Consideration of multiple-use conflicts; and
- Surface owner consultation.

Specific coordination occurs during the review of permits for mining on federal lands and mining of federal coal. Mining of federal coal on lands where the surface is managed by a federal agency requires OSMRE to consult with the federal land managing agency during the permit application review. Mining of federal coal on lands where the surface is managed by a federal agency not within DOI requires OSMRE to consult with the managing agency to obtain consent on the terms of the mining plan prior to approval by the DOI Assistant Secretary, Land and Minerals Management (ALSM). Where the federal land is within a National Forest certain findings must be made before a permit for conducting surface coal mining operations on these lands may be issued. A prospective operator may assert valid existing rights to conduct surface mining of private coal on federal lands; in these instances it is ASLM and not the state regulatory authority that determines whether the operator has valid existing rights. 30 CFR 740.4(a)(4).

Prior to mining federal coal, a lessee/applicant must traverse a three step process: the BLM must issue a coal lease, the SMCRA regulatory authority must issue a surface mining permit, and the ALSM must approve a mining plan. Similarly, if an existing federal coal lessee seeks a surface mining permit revision, OSMRE must also determine whether the revision constitutes a mining plan modification that requires an additional ASLM mining plan approval.

As part of the first step—the federal coal leasing process—the BLM approves the applicant's Resource Recovery and Protection Plan (R2P2), which "show[s] that the proposed operation meets the requirements of the MLA for development, production, resource recovery and protection, diligent development, continued operation, [maximum economic recovery], and [other applicable regulations] for the life-of-the-mine." 43 CFR 3480.0-5(a)(34); see also 43 CFR 3482.1(b).

As part of the second step—the SMCRA permitting process—the applicant must submit a permit application package (PAP) to the SMCRA regulatory authority and to OSMRE, if OSMRE is not the regulatory authority. The identity of the regulatory authority is determined by whether a state has primacy and a formal State-Federal cooperative agreement that delegates the responsibility to regulate coal mining on federal lands to the State.

The requirements for the development, approval and administration of cooperative agreements are specified in 30 CFR Part 745—State-Federal Cooperative Agreements. Completed State-Federal cooperative agreements are found within 30 CFR 900 through 955. As of September 2016, fourteen states had cooperative agreements that designate them as the regulatory authority for federal lands: Alabama, Colorado, Illinois, Indiana, Kentucky, Montana, New Mexico, North Dakota, Ohio, Oklahoma, Utah, Virginia, West Virginia, and Wyoming. In most states this cooperative agreement allows the states to grant permits for federal leased coal; however, pursuant to the terms of West Virginia's cooperative agreement, OSMRE is the issuer of permits for federal leased coal. In the states of Tennessee and Washington, OSMRE is the regulatory authority for federal and non-federal lands.

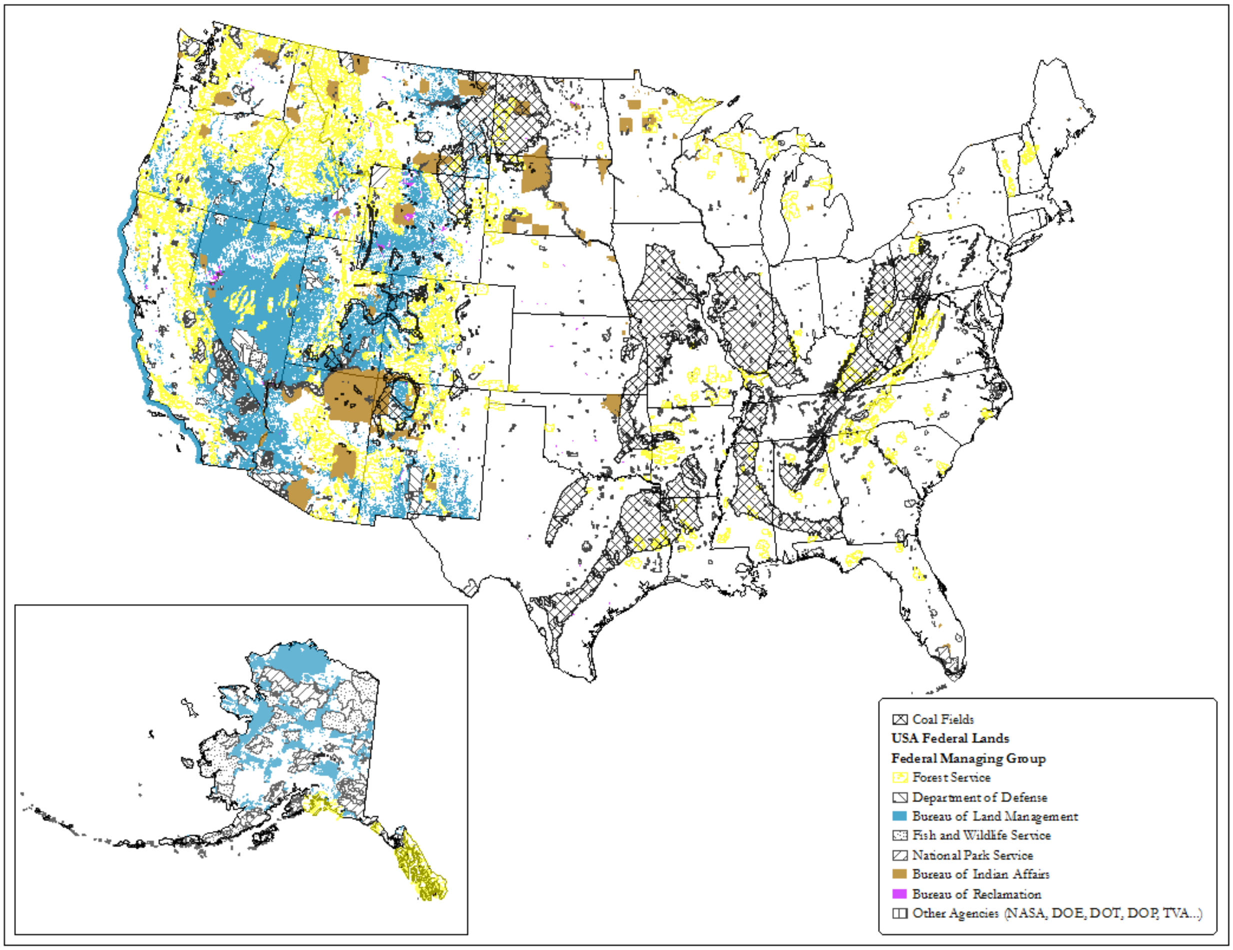
The SMCRA regulatory authority will review and approve, approve with conditions, or disapprove the proposed SMCRA permit application.

In most cases, the SMCRA permit will be approved prior to OSMRE beginning its development and review of the mining plan and the Mine Plan Decision Document (MPDD), the third step required by the MLA prior to extraction of federal coal. Once OSMRE, in consultation with other appropriate federal and state agencies, assesses the completeness and adequacy of the MPDD, OSMRE will recommend approval, approval with conditions, or disapproval of the mine plan to the ASLM. The MPDD is the document by which the ASLM will act on the mining plan. The ASLM is not required to follow OSMRE's recommendation.

The authorization for coal leasing on Indian lands is provided by the Indian Mineral Leasing Act of 1938 and the Indian Minerals Development Act of 1982 (IMDA). Most leasing on tribal land is currently done under the IMDA. This act establishes that tribes have the authority to enter into agreements to develop coal reserves on Indian lands independently without federal oversight. The IMDA also provides that the federal government will provide advice, assistance, and information during this process. The assistance to tribes is facilitated by the Bureau of Indian Affairs (BIA) in coordination with the BLM, the Office of Natural Resources Revenue (ONRR), OSMRE, and other agencies as necessary. Once leasing agreements have been approved by the Tribe and the BIA, the BLM must approve the mining plan, including the R2P2, and OSMRE must approve the SMCRA permit application for the proposed surface coal mining and reclamation operations. The BLM regulates coal exploration activities on Indian lands.

Figure 3.7-1 shows federal lands and Indian lands in the conterminous U.S. in relationship to the coal fields, (this map does not distinguish between mineable and non-mineable coal). However, this figure does not include lands where the federal government or Indian tribe owns the mineral resources but not the surface estate.

Figure 3.7-1. Federal Lands and Coal Fields in the Conterminous United States



Source: USGS, 2013d. Coal Fields and Federal Lands of the Conterminous United States. Open-File Report 97-461. U.S. Department of the Interior. http://pubs.usgs.gov/of/1997/ofr-97-0461/

3.7.3 Regional Land Use

3.7.3.1 Appalachian Basin Region

Approximately 60 percent of the premining land in the Appalachian Basin is deciduous forest. There are several large national forests within the area, including the Daniel Boone National Forest and the Monongahela National Forest. Most of the farmland in the Appalachian coal regions is in Northern Appalachia, with small agricultural areas in central and southern Appalachia. Approximately 10 percent of the land in the Appalachian Basin is pasture/hayland, and four percent is used for cultivated crops. Table 3.7-1 (see Appendix G) provides a detailed breakdown of land use percentages for the individual states and county study areas within this region (USGS, 2001b).

In 2003, OSMRE in conjunction with the EPA, U.S. Army Corps of Engineers (USACE), U.S. Fish and Wildlife Service (U.S. FWS), and West Virginia Department of Environmental Protection (WV DEP), prepared a programmatic Environmental Impact Statement (EIS) to evaluate the impacts of mountaintop mining and valley fills (U.S. EPA, et al., 2003). The purpose of the final EIS was: "to evaluate options for improving agency programs under the Clean Water Act (CWA), SMCRA and the Endangered Species Act (ESA) that will contribute to reducing the adverse environmental impacts of mountaintop mining operations and excess spoil valley fills in Appalachia" (U.S. EPA, et al., 2003). The study area for this EIS was approximately 12 million acres encompassing most of eastern Kentucky, southern West Virginia, western Virginia, and scattered areas of eastern Tennessee. The following information is derived from that study.

The overwhelming land use in the study area is forest, which covers approximately 11 million acres or 92 percent of the total 12 million acre study area. Deciduous forests cover over nine million acres or 79 percent of the study area. Mixed deciduous and evergreen forests encompass nine percent of the study area. Developed areas (residential, commercial and industrial) account for about one percent of the study area.

Under current practice, some post-mining land uses reflect a conversion from forested lands (with substantial carbon sequestration/storage) to other uses (ag, grasslands, urban) that have lower carbon sequestration/storage capacity (in addition to harvested wood/other vegetation that are, as discussed here, in some cases burned if not sold or turned into the soil).

3.7.3.1.1 West Virginia Study Area

The 2002 West Virginia University Land Use Assessment was conducted to examine land use issues associated with mountaintop mining[6] in the 14-county study region of southern West Virginia (Yuill, 2002). The results were derived from Landsat satellite data. The satellite data was classified and converted to Geographic Information System (GIS) coverage for analysis and display. Results confirmed the forested/lightly developed character of the West Virginia mountaintop mining region. Almost 88 percent, or slightly over four million acres, was classified as mature forest land, with the diverse mesophytic forest type, which was most prevalent at almost three million acres. All developed land uses (intensive urban, moderately intensive urban, light urban, populated areas, major roads, and infrastructure such as power lines) accounted for 155,000 acres or roughly three percent of the land area. Agricultural land uses were found on approximately a quarter of a million acres or five percent of the land area. Other general land use/land cover categories include: shrub land and woodland areas with slightly over 63,000 acres; water/wetlands with 56,000 acres or one percent of the land area; and barren land/mining with 74,000 acres or 1.5 percent of the study area.

[6] The term "mountaintop mining" used in the 2003 Mountaintop Mining-Valley Fills DEIS encompasses three different kinds of surface mining operations (contour mining, area mining, and mountaintop removal mining) that create valley fills. This is a broader definition than the legal definition used in SMCRA "mountaintop removal mining." Mountaintop removal mining totally extracts underlying coal seams, and the reclaimed land is left in a flat or gently rolling configuration capable of supporting certain postmining land uses, such as industrial, commercial, residential, agricultural, or public facilities (including recreational facilities). Mountaintop removal operations are subject to the approximate original contour (AOC) variance provisions of SMCRA, in order to provide for the development of such lands to alternative uses that could not otherwise be achieved if the lands were restored to AOC. Steep slope AOC variances are also allowed under SMCRA for the purpose of developing alternative land uses; however, unlike mountaintop removal AOC variances, agricultural land uses are not allowed.

3.7.3.1.2 Patterns of Land Use Changes, West Virginia Study Area

The general land use/land cover changes for the 14-county West Virginia study area were examined during three different time periods: 1950, 1976, and 2001.

- An analysis of the data from the three periods noted above revealed the following general patterns of land use change in the region:
- The acreage of developed area increased from 42,533 acres in 1950 to 154,966 acres in 2001. This acreage likely does not include much of the dispersed development that dominates the region.
- Agricultural acreage decreased from almost a million acres in 1950 to 188,000 acres in 1976, then increased to 246,000 acres by 2001. Much of the acreage increase in the second period is due to coal mining and reclamation that converted areas from existing forest land to grassland/pasture.
- Forest areas increased from under four million acres in 1950 to almost 4.5 million acres in 1976, and then fell to under 4.3 million acres by 2001. The current loss of forest land is due to mine reclamation that converted land from forest to grassland/pasture, as well as to new urban development.
- Disturbed areas increased from just over 3,000 acres in 1950 to a high of 85,000 acres in 1976 and are presently over 73,000 acres. This acreage is comprised of areas where vegetation was not established during those time periods. Lands which are not vegetated and otherwise do not fit into other categories are classified as "disturbed." Revegetated mined lands do not fall under this category.

A separate estimation of the extent of mining was developed by West Virginia University for the land use study. This is due to other sources significantly underestimating mined areas by placing reclaimed areas into other land use/land cover categories such as grassland/pasture and forest. A compilation of various data sources indicate that over 244,000 acres or approximately five percent of the West Virginia mountaintop mining study area contains evidence of disturbance from past or current mining practices. Mining-related land uses are the second most prevalent land use/land cover in the region, after forest land.

3.7.3.1.3 Current Studies of Postmining Land Use in the Appalachian Basin

Current studies indicate that the most common uses of reclaimed mine lands in the Appalachian coal region are hay and grass pastureland (Simmons et al., 2008). According to Burger et al., (2009), thousands of acres of Appalachian mined land that were originally forested have been reclaimed as hayland, pasture, or wildlife habitat. Grass and legume species used to revegetate reclaimed surface-mined lands in the Central Appalachian coal region are also used for cattle production (Ditsch et al., 2009).

Current regulations require revegetation in accordance with premining land use, unless an approved alternate Postmining Land Use (post mining land use) has been granted by the regulatory authority. Current practice often results in premining forested lands being converted to post mining land use designations as agriculture (i.e., pasture or hayland), fish and wildlife habitat (combined with another use), and commercial or industrial development, decreasing the percentage of forest lands while increasing the percentage of agricultural, grassland, or developed land. According to findings from the USGS's Land Cover Trends project, forested lands have decreased over the timeframe of 1973 through

2000. The results vary by ecoregion, and the ecoregions do not exactly overlay the coal resource regions. However, the data supports the hypothesis that forested land has been slowly converted to other land uses. Mining is not the sole reason for this trend because urban expansion and clearing for agricultural uses also contribute to the reduction in forested lands. This general trend does not imply that the reduction is consistent throughout each ecoregion given that various reclamation techniques are employed by different regulatory authorities. For example, in Virginia, a majority of reclaimed mine land is restored as unmanaged forest, and the overall area of hardwood forest types has increased steadily since the first forest inventory in 1940 (Burger and Zipper, 2009; Virginia DOF, 2013).

Forested mine sites (anywhere, not just in this region) must be logged before mining and economically recoverable forest products are removed from the site. The remaining forest material may be subsequently windrowed at the edge of the mine site to provide wildlife habitat enhancement. Some portion may be burned and/or buried beneath the backfill. Selection of ground cover species for reclamation within the Appalachian Basin region has typically been oriented to those species relatively easy to establish for maximum control of erosion, with minimal postmining maintenance or management costs required. Consequently, selected post mining land uses often minimize or eliminate the reestablishment of trees. post mining land uses without trees were historically perceived to be easier to achieve and less costly. In addition, they result in a shorter liability period for release of the performance bonds required by SMCRA.

3.7.3.1.4 Current Trends in Postmining Land Uses in Kentucky and West Virginia

In December 2009, the Government Accountability Office (GAO) completed a study titled "Characteristics of Mining in Mountainous Areas of Kentucky and West Virginia." Completed at the request of Congress, the study reported on the characteristics of surface coal mining and reclaimed lands that were disturbed by surface coal mining in the mountainous, eastern part of Kentucky and West Virginia. The study focused on approved post mining land uses, restoration of AOC and associated variances, and the number and size of excess spoil fills.

During the compilation of its report, GAO used data from the states for permits issued from January 2000 through July 2008. This data provided information on the approved post mining land use, the extent to which the land is restored to its AOC, and the number and size of fills created from excess spoil.

In addition to post mining land use types, the state data contained information on the type of land use associated with the permitted area immediately prior to mining or the premining land use. The most common types of premining land use in permits issued from January 2000 through July 2008 were the same for both states: forestland and previously mined but unreclaimed lands.

Kentucky's data shows that, for permits issued between January 2000 and July 2008, 415 permits had a premining land use of forestland, while 290 were previously mined (as with post mining land use, permits can identify more than one premining land use type). Moreover, 44 permits identified hay or pastureland, and 43 permits identified other types of premining land use, including 24 permits with undeveloped land.

Over the same period, West Virginia's data shows 174 permits had a premining land use of forestland, and 59 were previously mined. Additionally, 43 permits had a premining land use type of fish and wildlife/recreation, while 45 permits identified other types of premining land use, including 23 for hay or pastureland.

In Kentucky, between January 2000 through July 2008, 216 permits were approved for fish and wildlife habitat as a post mining land use, followed by 209 permits approved for hay or pastureland, and 109 permits approved for forestland. Fifty-nine permits issued during that time were approved for other post mining land use types including 22 residential, 19 industrial, and 12 commercial.

In West Virginia, between January 2000 through July 2008, 141 permits were approved for forestland as a postmining land use, followed by 46 approved permits for fish and wildlife habitat/recreation and 34 permits approved for hay or pastureland. Sixty permits issued during this time were approved for other post mining land use types, including 23 for commercial forestry or woodland, and 12 for industrial/commercial uses.

The most common postmining land uses approved for permits issued in January 2000 through July 2008 were fish and wildlife habitat in Kentucky and forestland in West Virginia.

3.7.3.1.5 Current Trends in AOC Variances

The 2009 GAO report on Surface Coal Mining (U.S. GAO, 2009) also provided data on Kentucky's and West Virginia's AOC variances. Between January 2002 and July 2008, Kentucky approved AOC variances for 24 percent of the permits issued, for a total of 99 variances. Of those AOC variances, 79 were for remining, five for mountaintop removal mining and 15 for steep slope mining. During the same period, West Virginia approved AOC variances for 15 percent of the permits issued, for a total of 33 variances. Of those AOC variances, nine were for remining, 18 were for mountaintop removal mining, and six for steep slope mining.

3.7.3.1.6 Mountaintop Removal and Steep Slope AOC Variance Postmining Land Uses

Between July 1, 2006 and June 30, 2012, OSMRE reviewed data from Tennessee, Virginia, Kentucky, and West Virginia regarding the approved post mining land use associated with MTR and steep slope AOC variances. Tennessee and Virginia did not have any MTR AOC variances approved within the six year review. Kentucky had one MTR AOC variance totaling 284 acres, with a Hay/Grazing post mining land use. West Virginia had four MTR AOC variances. Three had an industrial/commercial post mining land use totaling 3960 acres while the other had a commercial forestry post mining land use of 211 acres, totaling 4,171 acres. In addition, West Virginia had one combined variance (AOC/Steep Slope) with an industrial/commercial post mining land use for a 70-acre ATV trail park.

Tennessee did not have any steep slope mining AOC variances approved within the four year time period reviewed. Virginia had two steep slope AOC variances, with an industrial/ commercial post mining land use totaling 80 acres. Kentucky had five steep slope AOC variances with one industrial/commercial post mining land use of 553 acres, one public facility/recreation post mining land use of 111 acres and two residential post mining land use totaling five acres, for a total of 669 acres of steep slope AOC variances. West Virginia had one steep slope AOC variance, with an industrial/commercial post mining land use for a horse park/campground totaling 70 acres.

3.7.3.1.7 Economic Development of Mountaintop Mining Areas

In December 2009, a study was conducted concerning the reclaimed mountaintop sites in the coal surface mining regions of Kentucky, West Virginia, Virginia, and Tennessee (Geredien, 2009).[7] The study sought to determine how much of the postmining landscape was converted to new land uses such as industrial, commercial, or residential development. This study identified land uses that could be classified as "post-mining economic development" including "industrial, commercial, residential, or public" uses. Specific development sites were identified using information published by the National Mining Association.

The results of the study indicated the following:

- Twenty-seven sites revealed verifiable postmining economic development.
- Economic development projects included:
    - One federal prison;
    - Three oil/gas fields;
    - Two airports;
    - One hospital;
    - One ATV training center;
    - Three golf courses;
    - Four industrial/business parks;
    - Two county/municipal parks; and
    - One county fairground.
- Nine sites were developed for commercial agriculture or farming.

3.7.3.2 Colorado Plateau Region

A substantial percentage of the surface land in the Colorado Plateau coal region is federally owned. Additionally, most of the coal in the Colorado Plateau region is federally owned. A significant portion of the remaining coal (approximately 20 percent of western region coal) is non-federally owned but minable only in association with federal coal.[8]

As previously mentioned, surface features overlying federal coal reserves would be protected under BLM's land use planning procedures. Unique to the Colorado Plateau are significant areas of coal resources located on Indian Lands of the Hopi and Navajo reservations in Arizona and New Mexico. The Navajo Mine (owned by the Navajo Nation) is located on the Navajo Reservation in San Juan County, New Mexico. Approximately 50 percent of the surface of the coal-bearing area in this region is

---

[7] The study evaluated 410 known mountains and ridges within an existing geographic information system database where the elevation had been reduced by at least 50 feet due to mining. The authors assert that such elevation reductions constitute mountaintop removal operations, however such elevation changes may also represent areas mined that were returned to AOC, therefore any conclusions relative to mountaintop removal mining, as that term is used in SMCRA, are not presented here.

[8] Land ownership alternates in a checkerboard fashion throughout the western US due to 19th century federal land grants to railroads. Surface and mineral rights have been since been sold in many areas but alternating property owners often remains an impediment to economical mineral extraction.

administered by the federal government. Approximately 23 percent consists of Tribal lands. While these lands are held in trust by the U.S. government, they are not considered federal lands. The remaining percentage of approximately 26 percent is administered by state agencies or is privately owned (Kirschbaum et al., 2000).

Approximately 47 percent of the land in the Colorado Plateau consists of shrub/scrubland. Nearly 24 percent is evergreen forest. Less than three percent of the land in the Colorado Plateau is used for agricultural purposes (cultivated crops and pasture land). A large portion of this region is sparsely populated, and there are few urban areas.

The counties included in this table are not intended to represent all coal mining counties within the states or those that could occur in the future. However, they are considered representative of typical land uses that might be encountered within the coal region in those states.

Typical premining land uses in this coal-bearing region are agricultural activities (including cropland and livestock grazing lands), dispersed recreation, wildlife habitat, and industrial uses such as oil and gas development (U.S. BLM, 2009a). Typical postmining land uses in this region tend to mirror premining land uses mentioned above and would principally be approved as grazing land, wildlife habitat, and to a lesser degree pasturelands or croplands.

3.7.3.3 Gulf Coast Region

The Gulf Coast region is over 26 percent pastureland. Premining land use in Texas generally reflects agricultural activities identified by SMCRA as pasture/hayland and grazing land uses. Shrub/scrub land accounts for almost 16 percent of the land in the region. Compared to other regions in the study area, the Gulf Coast region has the highest percentage of wetlands at close to 11 percent of the total land. Much of these wetlands occur in Louisiana, which has two operating lignite mines. Mines located in Mississippi and Louisiana are predominantly located in areas with forestry premining land uses and some pastureland and cropland. Table 3.7-3 (see Appendix G) provides a detailed breakdown of land use percentages for the individual states and county study areas within this region (USGS, 2001b). The counties included in this table are not intended to represent all coal mining counties within the states or future coal mining counties. However, they are considered representative of typical land uses that might be encountered within the coal region in those states.

SMCRA postmining land uses in Texas are dominated by pasture/hay land and grazing land uses. Developed water in the form of final cut lakes also exists, with fish and wildlife land uses in areas adjacent to streams and lakes. In regions of Texas that receive more precipitation, forestry in upland areas has become an important post mining land use. At Mississippi and Louisiana lignite mines, approved forestry post mining land uses dominate with some pasture/hay land and occasional cropland uses.

3.7.3.4 Illinois Basin Region

The Illinois Basin covers the southern two-thirds of the state of Illinois, the southwestern portion of Indiana and parts of western Kentucky. In comparison to the other coal-producing regions in the study area, the Illinois Basin has the highest instance of cultivated cropland. Cropland accounts for over 48 percent of the land use in this region. The majority of the cropland is located in Illinois and Indiana.

Deciduous forest lands are also a predominant feature in this region, making up nearly 26 percent of the landscape. The third most common land use in this region is pasture and hay lands, which make up almost 11 percent of the area. Table 3.7-4 (see Appendix G) provides a detailed breakdown of land use percentages for the individual states and county study areas within this region (USGS, 2001b). The land uses included in this table are not intended to represent all coal mining counties within the states or those that could occur in the future. However, they are considered representative of typical land uses that might be encountered within the coal-producing regions in those states.

SMCRA postmining land uses in Illinois and Indiana are dominated by agricultural land uses, including cropland (much of it prime farmland) and pasture/hay land uses to a lesser extent. Fish and wildlife and developed water, from final cut lakes, are also important postmining land uses in both states. Recently, there has been a noticeable increase in forestry postmining land uses in Indiana. Kentucky postmining uses are largely pasture/hayland and fish and wildlife uses.

3.7.3.5 Northern Rocky Mountains and Great Plains Region

Like the Colorado Plateau, most of this region is federal land or federal mineral estate, and therefore subject to the restrictions outlined in subsection 3.7.3.2. To a much lesser extent than in the Colorado Plateau, areas of coal resources on Indian Lands in this region exist predominantly on Crow and Northern Cheyenne Tribal Lands. Approximately 80 percent of the available coal resources in the region are federally owned, and about 15 percent occur beneath federally managed lands. The rest of the coal occurs beneath state, tribal, or privately owned lands (USGS, 1999).

Similar to the Colorado Plateau, the Northern Rocky Mountains and Great Plains region is also predominantly shrub/scrublands. This feature makes up 45 percent of the regional land use. Wyoming accounts for a substantial part of this area, with 65 percent shrub/scrublands. Grasslands also provide a substantial percentage of the land use, nearly 30 percent for the region. This region is sparsely populated, with widely scattered population centers. All three categories of urban land use (low, medium and high intensity) collectively make up for only 0.36 percent of the total land use. Table 3.7-5 (refer to Appendix G) provides a detailed breakdown of land use percentages for the individual states and county study areas within this region (USGS, 2001b). The land uses included in this table are not intended to represent all coal mining counties within the states or those that could occur in the future. However, they are considered representative of typical land uses that might be encountered within the coal-producing region in those states.

Typical premining land uses in the Northern Rocky Mountains and Great Plains region include croplands, livestock grazing lands, and wildlife habitat, with gas production, recreation, and renewable energy being secondary uses (U.S. BLM, 2010a). In certain cases, additional secondary uses include communication/power lines and transportation (U.S. BLM, 2009b). Typical postmining land uses approved in this coal-bearing region generally mirror premining land uses. Most approved postmining land uses in this region include grazing land and wildlife habitat. In North Dakota, cropland postmining land uses are very common as well. However, in certain instances a post mining land use may differ from premining land use. For example, at the Dave Johnston Mine in Wyoming, portions of the reclaimed mine have been approved for an industrial post mining land use in support of wind energy development.

3.7.3.6 Northwest Region

The Northwest region currently has one active coal mine, the Usibelli Mine is southwest of Fairbanks, Alaska and northeast of Healey, Alaska. This area is surrounded by the Denali National Park and Denali State Wilderness to the west, the Tanana Valley State Forest to the north and east, and Nelchina Public Use Area to the south. Land use in Tanana Basin Subregion 4 includes commercial guiding, hunting, trapping, and recreation (AKDNR, 1991). There are several communities within this subregion: Nenana, Healy, McKinley Village, and Anderson. Other uses of land in the area have consisted of agriculture, forestry, and mineral mining (AKDNR, 1991). Premining land use in this coal-bearing state is typically dominated by wildlife habitat. A typical post mining land use in this coal-bearing region would include reclaiming the mined areas for wildlife habitat (Alaska Department of Natural Resources, 2013).

According to an October 1998 report by the BLM, approximately 65 percent of Alaska is owned and managed by the federal government as public lands, including a multitude of national forests, national parks, and national wildlife refuges. Of these, the BLM manages 87 million acres (350,000 km^2), or 23.8 percent of the state. The coal underlying the Usibelli Mine is owned by the State of Alaska and leased to the Usibelli Mining Company.

3.7.3.7 Western Interior Region

The dominant premining land use in the Western Interior region is pasture and grazing, accounting for over 38 percent of the landscape in Kansas and Oklahoma. Over one-quarter of Oklahoma and Arkansas is covered in deciduous forestlands. Missouri has a high occurrence of cultivated crops, which accounts for over 31 percent of the land use in that state. Table 3.7-6 (see Appendix G) provides a detailed breakdown of land use percentages for the individual states and county study areas within this region (USGS, 2001b). The land uses included in this table are not intended to represent all current or future coal mining counties. However, they are considered representative of typical land uses that might be encountered within the Western Interior coal region.

SMCRA postmining land uses in Oklahoma are dominated by pasture/hay lands, grazing land, fish and wildlife, and developed water from final cut lakes. Both Missouri and Kansas postmining land uses are similar, with mainly agricultural land uses of cropland and pasture/hay lands dominating. Some fish and wildlife and developed water land uses exist as well. Arkansas mines have generally been reclaimed to pasture/hay lands and forestry land uses.

3.8 Biological Resources (Excluding Wetlands)

3.8.1 Introduction

A wide variety of habitats are distributed throughout the coal regions of the U.S. This section presents a general description of the terrestrial and aquatic habitats occurring in the coal-producing areas that comprise the study area for this document. The discussion is organized around vegetative cover types for terrestrial systems and around flowing (lotic) versus pooled (lentic) water for aquatic systems.

The discussion is intended to describe general trends that apply across each region. It is not intended to present baseline environmental conditions for any particular mine site. Common names are used throughout the report to identify species found in the cover types and aquatic ecosystems of each coal region; within this section scientific names are provided at the first mention of each species.

The text below provides a general ecological discussion in the "General Ecological Setting" section of each region through the application of a system of description for ecological units adopted and maintained through the U.S. Department of Agriculture (USDA) – U.S. Forest Service (USFS). A discussion of representative species for each of the region, including common vegetative and animal communities, follows the discussion of ecological units.

A variety of other physical and chemical factors affect the biological resources of each coal region. Those are described elsewhere in this document; of particular importance are: topography (Section 3.4), meteorology (climate and precipitation) (Section 3.6), geology (Section 3.2), and soils (Section 3.3).

3.8.2 Biological Resource Topics

3.8.2.1 The USDA-Forest Service Terrestrial Ecological Units

The USDA-USFS adopted a national hierarchical framework of terrestrial ecological units to use an ecological approach to natural resource management (Bailey, 1995). The framework consists of seven levels of ecological units that are grouped into four application scales: ecoregions, sub-regions, landscapes, and land units (Cleland et al., 1997). The USFS Ecoregion Classification is useful in providing a general ecological description (Table 3.8-1) for the terrestrial and aquatic biology of each coal region. OSMRE has applied these ecological units to the coal regions to provide a general discussion of the ecological character of each region. Each region description below contains a figure depicting the extent of the ecological units across the respective region.

OMSRE reviewed Lewis et al., 2012, which parameterized an econometric model of land-use change to project future land use to the year 2051 at a fine spatial scale across the conterminous United States under several alternative land-use policy scenarios. Their results generally showed that alternative land use policy scenarios had little effect on future trends relative to business-as-usual. Other models may be available in the future that will assist with forecasting land use change at a fine scale over large areas.

The USDA-USFS classification system interchangeably uses the terms "cover type" and "potential natural communities" to describe predominant vegetation in a section. A potential natural community is defined as the ultimate biotic community that would become established on a site under the present environmental conditions, if all stages in the succession were completed without interference from humans. The narrative below uses the term cover type. In highly altered landscapes (e.g., agricultural areas, towns, and roads), natural cover types occur infrequently but understanding what cover types would occur in undisturbed conditions is helpful to understanding what conditions would be like in a given area if disturbance is avoided or restoration is achieved.

Table 3.8-1. USFS Ecoregion Classification System

Application Scale	Ecological Units (Map Scale Range)	Principal Map Unit Design Criteria
National (Ecoregions)	Domain (1:30,000,000 or smaller)	Broad climatic zones or groups (e.g., dry, humid, tropical)
National (Ecoregions)	Division (1:30,000,000 to 1:7,500,000)	Regional climatic types, vegetation affinities (e.g., prairie or forest), soil order
National (Ecoregions)	Province (1:15,000,000 to 1:5,000,000)	Dominant potential natural vegetation, highlands or mountains with complex vertical climate-vegetation-soil zonation
Regional (Subregions)	Section (1:7,500,000 to 1:3,500,000)	Geomorphic province, geologic age, stratigraphy and lithology, phases of soil orders, potential natural vegetation, potential natural communities (PNC)
Regional (Subregions)	Subsection (1:3,500,000 to 1:250,000)	Geomorphic process, surficial geology, phases of soil orders, subregion climatic data, PNC formation or series
Watershed/National Forest (Landscape)	Land Type Association (1:250,000 to 1:60,000)	Geomorphic process, geologic formation, surficial geology, and elevation, Phases of soil subgroups, families, or series, Local climate, PNC—series, subseries, plant associations
Project (Land Unit)	Land Type (1:60,000 to 1:24,000)	Landform and topography (elevation, aspect, slope gradient, and position), Phases of soil subgroups, families, or series, Rock type, geomorphic process, PNC—plant associations

Source: Cleland et al., 1997

3.8.2.2 Federally Protected and Regulated Species

The U.S. FWS administers a variety of laws protecting wildlife and plant species. These include the Endangered Species Act of 1973 (ESA) (16 U.S.C. 1531), the Migratory Bird Treaty Act (MBTA) (16 U.S.C. §§ 703-712), the Bald and Golden Eagle Protection Act (BGEPA) (16 U.S.C. §§ 668-668d). The MBTA prohibits the taking, killing, possession, and transportation of migratory birds, eggs, feathers (and other body parts), and nests without a permit. The BGEPA affords further protection of bald and golden eagles beyond the MBTA by making it unlawful to disturb eagles or destroy their nests.

Federal agencies have a responsibility to use their authorities to carry out programs for the conservation of listed species under section 7(a)(1) of the ESA. OSMRE has several programs that directly or indirectly support conservation of listed species, such as those that encourage the use of native plant species, pollinator-friendly plants and the Appalachian Regional Reforestation Initiative (www.arri.osmre.gov). Federal agencies must also consult with the U.S. FWS and the National Marine Fisheries Service (NMFS), under section 7(a)(2) of the ESA (16 U.S.C. § 1531 et seq.), on activities that may affect threatened or endangered species or designated critical habitat. These interagency consultations, or section 7 consultations, are designed to assist Federal agencies in fulfilling their duty to ensure federal actions do not jeopardize any endangered species or threatened species or result in the destruction or adverse modification of habitat of such species. The ESA makes it unlawful to "take" (defined at Section 3(19) of the ESA as "to harass, harm, pursue, hunt, shoot, wound, kill, trap, capture, or collect, or to attempt to engage in any such conduct") federally listed threatened or endangered species without a permit.

To determine which listed and proposed species might be affected by the proposed action, OSMRE provided FWS with maps of the coal basins affected by this action. Based on these maps FWS provided OSMRE with a list of proposed, threatened, and endangered species and proposed and designated critical habitat potentially occurring in the action area. FWS later provided OSMRE with maps of the species ranges and critical habitat on which these determinations were made. OSMRE calculated ranges for species that were not included on these maps using other data sources, primarily NatureServe. Those species whose range or critical habitat overlapped mineable coal were included in the analysis.

Since publication of the DEIS, OSMRE continued to update the list to reflect changes to the listing status of relevant species. The final list is included here in the FEIS in Appendix F along with the final Biological Assessment. The Biological Opinion, discussed in Chapter 4, is available on the OSMRE website at www.OSMRE.gov.

The final list contains 171 species, of which three are amphibians, eight are birds, four are crustaceans, 34 are fishes, two are insects, eight are mammals, 54 are mollusks, 50 are plants and eight are reptiles. The final list includes 47 species with designated critical habitat, and 5 species with proposed critical habitat. The critical habitat of 40 of these 47 species occurs partially or entirely within the coal resources areas studied in this EIS. As shown in appendix F, Table F-2 Critical Habitat Overlap with coal regions, 100% of the critical habitat for the Laurel dace (*Chrosomus saylori)* occurs in areas with mineable coal. Similarly 82% of the critical habitat for the Cumberland elktoe (*Alasmidonta atropurpurea),* and 55% of the habitat for the spotfin chub (*Erimonax monachus)* occur in areas with mineable coal. The degree to which critical habitat overlaps with mineable areas is less but still considerable (between 10–30%) for 17 other aquatic species.

Reasons for a particular species' decline are varied. Impacts to individuals are often natural (e.g., predation, succession, disease, etc.). However, impacts that affect the species at a population level are often attributable to human factors (e.g., development, resource extraction, the introduction of noxious weeds, over-hunting and/or collecting, pesticides and other pollutants).

Mining (including but not limited to coal mining) has been identified as a contributing factor in the past and ongoing decline of some species. For example, the U.S. FWS described a primary threat to greater sage grouse as ongoing loss and fragmentation of shrub-steppe habitats through a variety of mechanisms related to activity that transforms the land, including agriculture, oil and gas development, mining, urbanization, and infrastructure development that includes roads and power lines that convert or bisect habitats and introduce invasive species (75 FR 13909 (March 23, 2010).

Another recent issue of concern for species that overlap mining areas is white-nose syndrome, a syndrome caused by the white fungus (*Pseudogymnoascus destructans*), which is causing fatalities in hibernating bats from the northeastern to the central U.S. The USGS reports that northeastern U.S. bat populations have declined approximately 80% since the emergence of the disease (USGS, 2015).

Each of the regional discussions below provides a count of species by type (birds, mammals, plants, etc.). A general discussion of how each alternative would impact ESA listed species is included in the discussion of Environmental Consequences in Chapter 4.

In addition to these laws, migratory birds receive protection under Executive Order 13186 (Responsibilities of Federal Agencies to Protect Migratory Birds) (66 FR 3853), which promotes conservation of migratory birds. The Executive Order includes support for various conservation planning efforts already underway, such as the Partners in Flight initiative and North American Waterfowl Management Plan; incorporating bird conservation considerations into agency planning, including NEPA analyses; annual reporting on the level of take of migratory birds; and generally promotion of conservation of migratory birds where consistent with the agency mission. OSMRE is in the process of crafting a Memorandum of Understanding with the U.S. FWS to better implement the principles of Executive Order 13186 in its programs. Appendix D contains additional discussion of migratory flyways and describes how the flyways intersect with the coal regions in the U.S.

3.8.2.3 Additional Information

Additional detailed information on certain biological resource topics is included in the appendices. Appendix B provides a description of bioassessment methods used by federal and state agencies in the U.S. The appendix provides context for understanding the complex issues involved in studying and classifying aquatic resources (particularly stream ecosystems). A discussion of general ecological principles of running water, lakes, and reservoirs is contained in Appendix C.

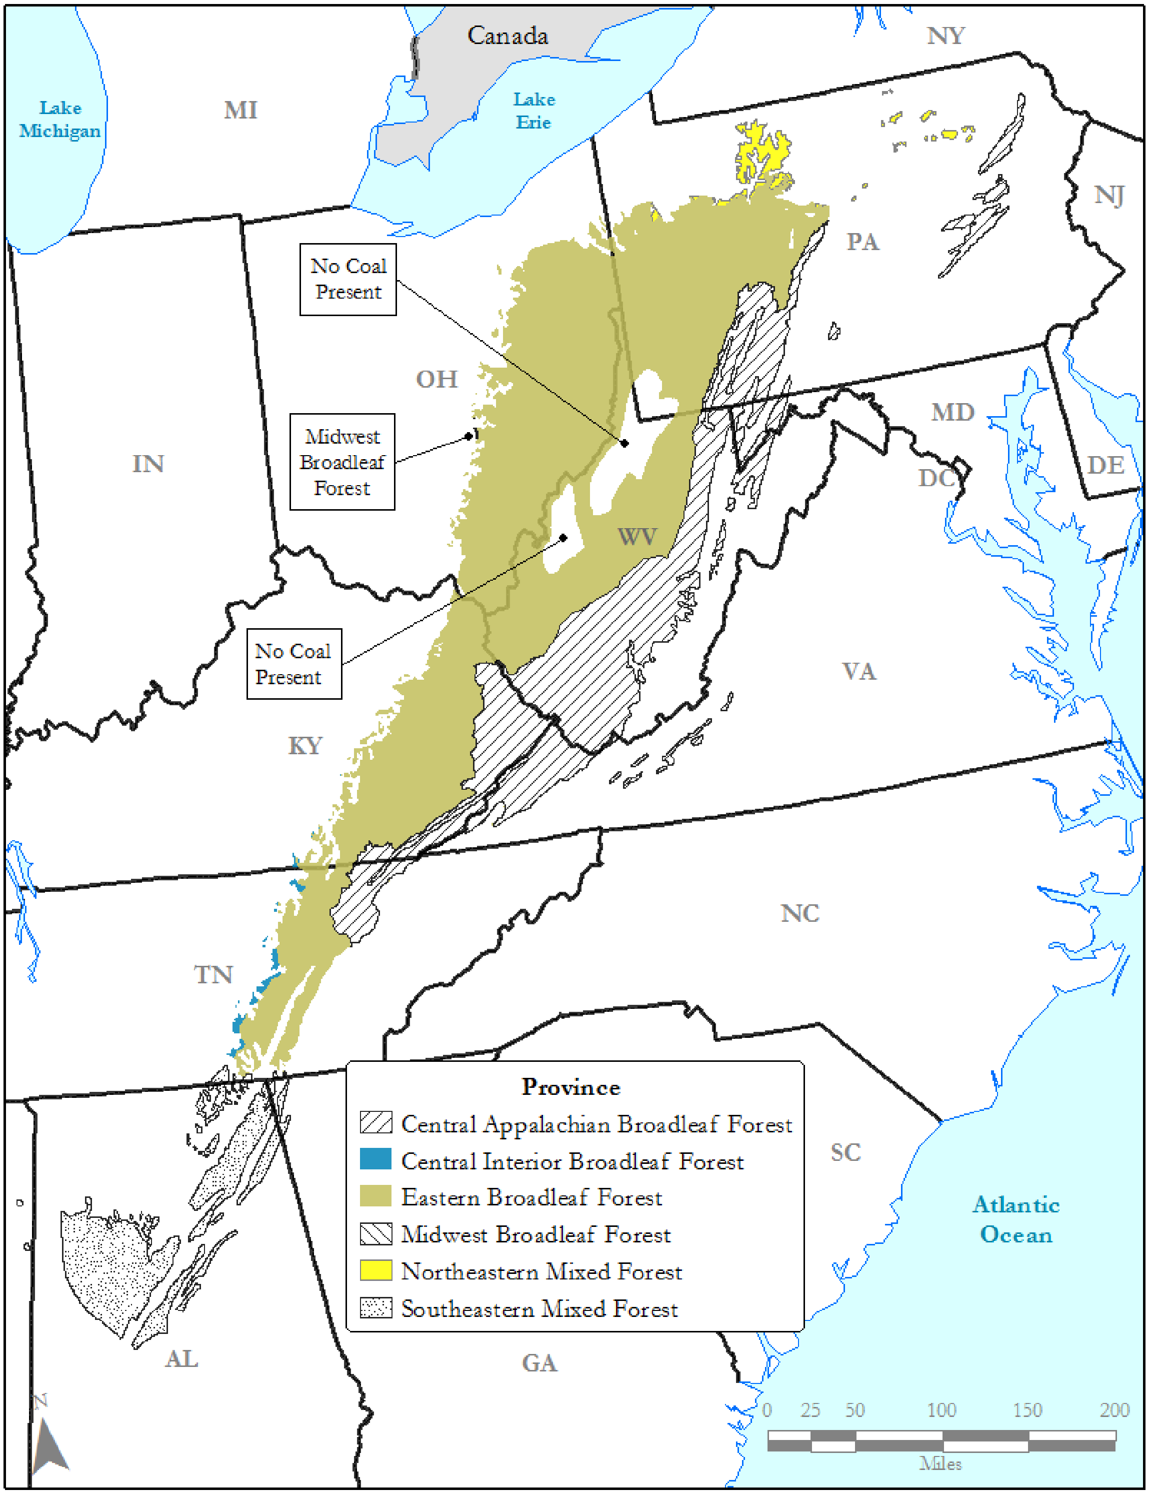
Appendix E provides information on invasive species and noxious weeds. A noxious weed is a term for an invasive plant that is designated and regulated by state and federal laws, such as the federal Plant Protection Act, 7 U.S.C. § 7701 et seq. Noxious weeds have biological traits that enable them to colonize new areas and successfully out-compete native species. They can transform the structure and function of ecosystems through: direct competition; changes in nutrient cycling, succession, and disturbance regimes; and shifts in evolutionary selection pressures (Mack and D’Antonio 1998). The spread of noxious weeds threatens the structure and function of many ecosystems worldwide, and certain species have the ability to spread over large areas or acutely threaten an ecosystem over its continental range (Hobbs and Humphries, 1995).

3.8.3 Appalachian Basin Region

3.8.3.1 General Ecological Setting

The Appalachian Basin encompasses significant portions of the states of Pennsylvania, Ohio, Kentucky, West Virginia, Virginia, Tennessee, and Alabama, including sizeable areas in which current coal mining activities take place (Figure 3.8-1). Table 3.8-2 shows the area of each ecological province within the Appalachian Coal Basin.

Figure 3.8-1, Ecological Provinces within the Appalachian Coal Basin Region



Source: USFS, 2015, Ecological Provinces, http://data.fs.usda.gov/geodata/;

USGS, 2011, Coal Fields, http://nationalatlas.gov/atlasftp.html?openChapters=chpgeol#chpgeol

Table 3.8-2. USFS Provinces Associated with the Appalachian Basin Region

Ecological Province	Area of Coal Region in Province (square miles)
Central Appalachian Broadleaf Forest-Coniferous Forest-Meadow	16,408
Central Interior Broadleaf Forest	238
Eastern Broadleaf Forest	37,887
Midwest Broadleaf Forest	5
Northeastern Mixed Forest	878
Southeastern Mixed Forest	5,789
Total	61,204

Unless otherwise noted, the following descriptions of the ecological provinces within the Appalachian Basin coal region come from Bailey (1995), McNab and Avers (1994), Cleland et al. (1997), and McNab et al. (2007).

3.8.3.1.1 Central Appalachian Broadleaf Forest-Coniferous Forest-Meadow Province

This province has a temperate climate with cool summers and short, mild winters. Annual precipitation is plentiful and evenly distributed with short, infrequent periods of water deficit. Landscapes of the province are predominantly mountainous, but sections vary in predominant elevation, geologic substrate, and physiography. The vegetation in this province is characterized by a tall, closed canopy of deciduous broadleaf forests with mesophytic and drought-tolerant species. Vegetation changes to coniferous forest or shrub lands at higher elevations. The Central Appalachian Broadleaf Forest-Coniferous Forest-Meadow province covers approximately 65,172 square miles in the U.S., a large portion of which is in the Appalachian Basin coal region.

3.8.3.1.2 Central Interior Broadleaf Forest Province

The vegetation in this province is broadleaf deciduous forests with somewhat open canopy and greater density of species tolerant of drought. The Central Interior Broadleaf Forest province covers approximately 119,790 square miles in the U.S., of which only a very small fraction is in the Appalachian Basin coal region.

3.8.3.1.3 Eastern Broadleaf Forest Province

The vegetation in this province is characterized by tall, cold-deciduous broadleaf forests that have a high proportion of mesophytic species. This province covers approximately 101,902 square miles in the U.S., of which about 25 percent is in the Appalachian Basin coal region.

This region contains some of the greatest aquatic animal diversity in North America, especially for species of amphibians, fishes, mollusks, aquatic insects, and crayfishes (U.S. EPA, 2006). This province contains many small natural lakes, small artificial ponds, and several large reservoirs which occur along perennial streams. Stream gradients in the western Alleghenies range from steep, headwater streams to low-gradient rivers that flow into larger bodies of water.

3.8.3.1.4 Midwest Broadleaf Forest Province

The vegetation in this province consists of cold-deciduous, hardwood-dominated forests with a high proportion of species able to tolerate mild, brief, periodic drought during the late summer. The Midwest Broadleaf Forest province covers approximately 141,746 square miles in the U.S., only a tiny fraction of which occurs in the Appalachian Basin coal region.

There is moderate to high density of streams in this province; low gradient streams and rivers are predominant, and typically have substrates composed of sand, gravel, bedrock, and boulders.

3.8.3.1.5 Southeastern Mixed Forest Province

The forest vegetation in this province is a mixture of deciduous hardwoods and conifers. The Southeastern Mixed Forest Province occurs mainly in Alabama and has a moderate density of small to medium size perennial streams and associated rivers, mostly with low to moderate rates of flow and moderate velocity (McNab and Avers, 1994). The streams of Alabama are noted for their diversity of native freshwater fishes, native freshwater gill-breathing snails, freshwater mussels, and native freshwater turtles.

3.8.3.1.6 Northeastern Mixed Forest Province

Among the coal-bearing states of Appalachian Basin region this province occurs only in Pennsylvania. The vegetation of this province consists of forests that provide a transition between boreal conifers and broadleaf deciduous. Streams in this province are characterized by deeply incised high-gradient and bedrock-controlled systems in the upland, and low and moderate-gradient, mature streams in the valleys. Numerous waterfalls and rapids exist where streams cross beds of resistant rock. There are a large number of rapidly moving streams and rivers that flow into the Allegheny and Susquehanna Rivers.

3.8.3.2 Terrestrial Resources

The Appalachian Basin coal region includes many different terrestrial habitats distributed over a broad area of the eastern U.S., extending from Mississippi northeast to Pennsylvania. The text below summarizes species presence with information adapted from Bailey (1995), McNab and Avers (1994), Cleland et al. (1997), and McNab et al. (2007).

In its southern range, this region is characterized by oak-pine, loblolly-shortleaf pine, and oak-hickory cover types. These forests are usually dominated by deciduous hardwood trees such as oak (*Quercus* spp.) and hickory (*Carya* spp.) and coniferous trees such as loblolly pine (*Pinus taeda*), shortleaf pine (*Pinus echinata*), or other southern yellow pines (*Pinus palustris*). Other common trees in these cover types include maple (*Acer* spp.), yellow-poplar (*Liriodendron tulipifera*), sweetgum (*Liquidambar styraciflua*), and red cedar (*Juniperus virginiana*).

Mature Appalachian Basin region forests typically have closed canopies, where the leaf cover of the trees rarely allow direct sunlight through to the forest floor. Younger forests have more open canopies with significant sunlight reaching the understory vegetation. In areas of open canopy, therefore, there is a thicker understory of young trees, shrubs, vines, and herbaceous plants. The major shrubs are blueberry (*Vaccinium* spp.), *Viburnum* spp., dogwood (*Cornus* spp.), *Rhododendron* spp., American beautyberry (*Callicarpa Americana*), and sumac (*Rhus* spp.). The major vines are woodbine (*Parthenocissus* spp.), grape *(Vitis* spp.), poison ivy (*Rhus radicans),* greenbrier (*Smilax* spp.), and blackberry (*Rubus* spp.). Important herbaceous plants are sedge (*Carex* spp.), *Panicum* spp., bluestem (*Andropogon* spp.), longleaf uniola (*Chasmanthium sessiliflora*), *Lespedeza* spp., tick clover (*Desmodium* spp.), goldenrod (*Solidago* spp.*)*, pussytoes (*Antennaria* spp.), and *Aster* spp.; many more are abundant locally.

Where the region extends to the north into Maryland, Tennessee, Kentucky, Ohio, West Virginia, and Pennsylvania, the vegetation is characterized by oak-pine, loblolly-shortleaf pine, maple-beech-birch, and aspen-birch cover types. Much of the vegetation is similar to the southern range of this region (described above), but also includes beech (*Fagus* spp.), yellow birch (*Betula alleghaniensis*), aspen (*Populus tremuloides*), balsam poplar (*Populus balsamifera*), paper birch (*Betula papyrifera*), and gray birch (*Betula populifolia*) as dominant tree species. Other common trees that differ from the southern zone description above include hemlock (*Tsuga* spp.), basswood (*Tilia Americana*), and white pine (*Pinus strobes*). In general, more maple species are found in this area as well.

Common mammal species that extend throughout this region include the white-tailed deer (*Odocoileus virginianus*), black bear (*Ursus americanus*), bobcat (*Lynx rufus*), raccoon (*Procyon lotor*), gray fox (*Urocyon cinereoargenteus*), gray squirrel (*Sciurus carolinensis*), eastern chipmunk (*Tamias striatus*), white-footed mouse (*Peromyscus leucopus*), and Northern Long-Eared Bat (*Myotis septentrionalis*). Mammals once thought to extend throughout this range but that are now considered either extirpated or extremely rare include two predators; the eastern cougar (*Puma concolor couguar*) and wolves (*Canis rufus, Canis lupus rufus*); as well as the American bison (*Bison bison*) and eastern elk (*Cervus canadensis canadensis*).

Bird species that extend throughout this region and use this region for breeding and/or wintering range include turkey (*Meleagris gallopavo*), mourning doves (*Zenaida macroura*), ruffed grouse (*Bonasa umbellus*), bobwhite (*Colinus virginianus*), northern cardinal (*Cardinalis cardinalis*), tufted titmouse (*Parus bicolor*), pine warbler (*Dendroica pinus*), wood thrush (*Hylocichla mustelina*), ruby-throated hummingbird (*Archilochus colubris*), red-tailed hawk (*Buteo jamaicensis*), and barn owl (*Tyto alba*).

Common reptiles include the box turtles (*Terrapene spp.*), painted turtle (*Chrysemys picta*) common garter snake (*Thamnophis sirtalis*), eastern fence lizard (*Sceloporus undulatus*), and copperhead (*Agkistrodon contortrix*). An example of a rare but widespread species is the timber rattlesnake (*Crotalus horridus*).

Common amphibians with distributions across this region include red-spotted newt (*Notophthalmus viridescens*), dusky salamanders (*Desmognathus spp*.), and American toad (*Anaxyrus americanus*).

3.8.3.3 Aquatic Resources

3.8.3.3.1 Lotic Systems (Rivers and Streams)

Most of the major rivers and tributaries in the U.S. east of the Mississippi originate in the mountains of the Appalachian region (U.S. EPA et al., 2003). First- through twelfth-order streams (as defined by Vannote et al., 1980), ephemeral streams, and intermittent streams occur in the Appalachian region, with headwater streams generally originating at higher elevations (U.S. EPA et al., 2003). Major rivers that originate in this region include, but are not limited to; the Cumberland, Ohio, Susquehanna, James, Potomac, and New Rivers, and rivers that contribute to the Chesapeake Bay watershed.

A variety of flowing-water habitats are present in the Appalachian Basin coal region. These include ephemeral, intermittent, low order (first through third) and higher order (fourth through sixth) streams as well as rivers. As described in Section 3.5 (see Table 3.5-5) there are a total of 69,798 miles of intermittent streams, and 56,929 miles of perennial streams in this coal region. A more detailed discussion about the general habitat features of these types of streams is presented in Appendix C.

3.8.3.3.1.1 Energy Flow/Primary Production

Organic materials that fall into, and are transported in, streams provide energy to the stream. Leaf litter fall and lateral movement of leaves and wood have been found to be the predominant energy source in high-gradient streams of the southern Appalachians; however, stream width affects the amount of input. Woody debris comprises about 25 percent to 50 percent of total input. Dissolved organic carbon (DOC) is also another potential energy source and may include groundwater inputs, leaching from detritus stored in the streambed, and dissolved exudates from biota (Wallace et al., 1992).

Primary production rates in high-gradient Appalachian streams have been shown to vary with stream order, season, degree of shading, nutrients, and water hardness (Wallace et al., 1992). Plant and algal communities of high-gradient streams in the Appalachian Basin are reduced compared to low-gradient streams and lentic systems as these high-gradient stream communities are typically densely shaded and subject to high current velocities (Wallace et al., 1992). As a result, plant and algal communities occurring along high-gradient streams contain flora uniquely adapted to this type of environment (Wallace et al., 1992), and many species are considered to be endemic to this region (Patrick, 1948). Hornleaf riverweed (*Podostemum ceratophyllum*) is an example of a vascular plant found along high-gradient streams (Wallace et al., 1992), and is broadly distributed in the southern Appalachian Mountains (Meijer, 1976). Water willow (*Justicia americana*), another important vascular plant found in southeastern streams, is the dominant emergent plant of the New River, contributing approximately 12 percent of the aquatic macrophyte biomass (Hill, 1981).

Mosses and liverworts are among the dominant flora in turbulent flows. Four bryophytes dominate Appalachian streams: fontinalis moss (*Fontinalis dalecarlica*), streamside hygroamblystegium moss (*Hygroamblystegium fluviatile*), Lescur’s platylomella moss (*Sciaromium lescurii*), and Chokai marimo (*Scapania undulate*) (Glime, 1968).

Endemic and unique species of algae are common to the high-gradient streams of the southern Appalachians. Like bryophytes, these algae are also attached to stable substrates. Dominant algal flora in the high-gradient streams of the southeast U.S. include filamentous red algae, filamentous green algae, and diatoms (Wallace et al., 1992). Camburn and Lowe (1978) described a diatom from high-gradient streams in the Great Smokies (*Achnanthes subrostrata* var. *appalachiana*) which comprised as much as 73 percent of the algal community. Diatoms are a major group of algae, and are one of the most common types of phytoplankton. Diatoms have been used as indicators of stream condition and water quality, reflecting parameters such as pH, trophic status, metal concentrations, and other environmental conditions, especially in lakes. Diatoms can also be used as quantitative indicators of ecological conditions in lotic systems (Pan et al., 1996).

3.8.3.3.1.2 Invertebrates

Appalachian headwater streams support an abundant and diverse epibenthic fauna, although they are subject to seasonal flow and occasionally to large storm events (Angradi et al., 2001). Typical benthic macroinvertebrates found in headwater streams in the Appalachian coal region include mayflies (Ephemeroptera), stoneflies (Plecoptera), caddisflies (Trichoptera), dragonflies and damselflies (Odonata), beetles (Coleoptera), dobsonflies and alderflies (Megaloptera), true bugs (Hemiptera), springtails (Collembola), and true flies (Diptera) (U.S. EPA et al., 2003). Other macroinvertebrates that have been collected include crayfish (Decapoda), isopods (Isopoda), worms (Oligochaeta and Annelida) and snails (Gastropoda) (U.S. EPA et al., 2003). Many streams in the Central Appalachian Basin region harbor a diverse and unique array of invertebrates. This has been attributed to the unique geological, climatological and hydrological features of this region. A number of the unique species are known from only one or two isolated locations in the Appalachians. In the southern Appalachian Mountains, macroinvertebrates in the Ephemeroptera, Plecoptera, and Tricoptera (EPT) taxonomic groups have been found to be rich in species, including many endemic species and species considered to be rare (U.S. EPA et al., 2003). The proportion of the macroinvertebrate assemblage made up by species in the EPT taxonomic group is used as an indicator of stream condition, with a higher proportion of EPT representatives expected in less impacted streams. Other biological indices which are used to describe stream condition in the states of the Appalachian Basin coal region are provided in Appendix B.

There are few differences between the numbers of invertebrate taxa in permanent streams versus those found in intermittent stream reaches in several northern Alabama streams (Feminella, 1996). Similar trends have been observed for other stream systems in the Appalachian Basin region (Stout and Wallace, 2003). This suggests that there may be sufficient water present in the headwaters for long-lived taxa with multi-year life cycles to complete their juvenile development prior to reaching the aerial adult stage. During periods of no visible stream flow, interstitial water flows through the material below the stream. This special hydrology creates a unique habitat, called the hyporheic zone. Specially adapted macroinvertebrates are able to continue their life cycles by burrowing into the hyporheic zone, especially in times of drought. Other macroinvertebrates live completely within the hyporheic zone (see Appendix C for further discussion of the biota of the hyporheic zone).

There are about 390 native crayfish species (primarily Cambaridae) in North America, with most restricted to eastern North America (Lodge et al., 2000). Crayfish are important in that they can regulate periphyton standing crops, are often a large portion of fish diets, and are a component in the processing of leaf litter (Seiler and Turner, 2004). Based on the important role that crayfish play in the stream food web, any disturbance to crayfish abundance may have a negative impact on the stream ecosystem (Seiler and Turner, 2004).

Many crayfish species have small ranges in the southeastern U.S., making their persistence vulnerable, primarily due to non-native crayfish species. As documented in Lodge et al. (2000) and Loughman and Welsh (2010), non-native crayfish species have negatively impacted North American lake and stream ecosystems and fisheries, and have led to the extirpation of many populations of native crayfishes. Lodge et al. (2000) also listed the impacts of several species of introduced crayfishes have been documented and include: reduction of the abundance of macrophytes by more than 80 percent; reduction in the abundance of algae through direct consumption/destruction of macrophytes on which some algae grow; reduction in the abundance of some macroinvertebrates (particularly snails); and the reduction in the abundance of native crayfishes, often to the point of local extirpation. Lodge et al. (2000) also listed other studies showing the impacts of non-native crawfish species on amphibians and fishes. The mechanisms by which native crayfishes are impacted include competition, predation, and reproductive interference.

The central and southern portions of the Appalachian Basin region also contain substantial freshwater mussel (Bivalvia: Unionidae) populations. Approximately 70 percent of the approximately 300 North American mussel taxa are endangered, threatened, or locally at risk (Strayer et al., 2004). Declines in mussel populations have resulted from factors such as impoundments, exotic species, and degraded water quality (Lydeard et al., 2004).

Freshwater mussel communities are important components of food webs; they are omnivores that feed across trophic levels on bacteria, algae, detritus, and zooplankton (Vaughn et al., 2008). Mussel communities link and influence multiple trophic levels, and effect nutrient translocation and cycling depending on their abundance, species composition, and environmental conditions (Vaughn et al., 2008). The dispersal ability of mussels is limited by their reproductive cycle. The larval stage (called the glochidium) of mussels is an obligate parasite on the gills or fins of host fishes; thus mussel dispersal is linked to the mobility of the host fishes. Consequently, the presence and abundance of certain host fishes is an important component of the life cycle of freshwater mussels. A study conducted by Haag and Warren (1998) indicated that patterns of mussel community variation were correlated with patterns of fish community variation, but not with habitat.

Non-native mussel species introduced and spread within the southeastern U.S. have been adversarial to native mollusk assemblages (Neves et al., 1997). The greatest threat to southeastern mollusk populations comes from the non-native zebra mussel (*Dreissena polymorpha*). This species has made its way up the Tennessee River to Knoxville, Tennessee (Neves et al., 1997).

3.8.3.3.1.3 Vertebrates

Many types of amphibians are unique to the Appalachian Mountain region. Salamanders are a significant component of high-gradient stream communities in the Appalachians. Typically, salamanders are the predators that occupy small, high-gradient headwater streams, while predatory fish occur farther downstream. Predation by fish is believed to restrict salamanders to smaller streams or the banks of large streams (Wallace et al., 1992). The most common aquatic salamanders in the Appalachian Basin region include those of the genus *Desmognathus*, with two-lined salamanders (*Eurycea bislineata*) and shovel-nosed salamanders (*Leurognathus marmoratus*) also being common (Wallace et al., 1992).

Aquatic salamanders may spend a portion of their life cycle within adjacent terrestrial habitats. According to a study conducted along streamside forests in western North Carolina and eastern Tennessee (Petranka and Smith, 2005), the overall abundance of aquatic-breeders (primarily *Desmognathus* spp.) within adjacent terrestrial habitat (118 to 125 feet from aquatic habitat) declined with elevation. Further, this study found that the number of aquatic breeders were most abundant within eight meters of aquatic habitats (49 percent of total terrestrial catch of aquatic-breeders), particularly at low elevation sites. The terrestrial zone provided core habitat to six semi-aquatic species (*Desmognathus* spp., *Gyrinophilus* *porphyriticus*, and *Eurycea wilderae*) that were broadly distributed throughout the study plots and acted as an aquatic buffer for four highly aquatic species (*Desmognathus* spp.).

Based on studies conducted by the West Virginia Division of Natural Resources (2003), there are 87 known species of amphibians and reptiles in West Virginia. Less common salamanders (e.g., the Blue Ridge two-lined salamander, *Eurycea wilderae*), skinks (e.g., the coal skink, *Eumeces anthracinus*), frogs (e.g., the cricket frog, *Acris crepitans*), turtles (e.g., the spotted turtle, *Clemmys guttata*), and snakes (e.g., the Eastern black kingsnake, *Lampropeltis getula niger*) are all associated with aquatic habitats. Amphibian species found in the Northern Cumberland Plateau section (eastern Tennessee and Kentucky) include the green salamander, Kentucky spring salamander (*Gyrinophilus porphyriticus duryi*), Black Mountain salamander (*Desmognathus welteri*), seal salamander (*Desmognathus monticola*), slimy salamander (*Plethodon glutinosus*), spotted salamander (*Ambystoma maculatum*), American toad (*Bufo americanus*), mountain chorus frog (*Pseudacris brachyphona*), green frog (*Rana clamitans*), pickerel frog (*Lithobates palustris*), and wood frog (*Rana sylvatica*) (OSMRE, 2008).

The fish assemblages of the Central Appalachian area tend to contain a relatively large number of endemic and unique species (U.S. EPA et al., 2003). In the southern Appalachian Mountains south of the Roanoke and New Rivers, there are about 350 fish species, 64 of which are considered imperiled (Walsh et al., 1995). Both fish and mollusks exhibit high degrees of endemism in the southeast, which is a major contributing factor to species endangerment (Dobson et al., 1997; Warren and Burr, 1994).

The diversity and distribution of fishes in West Virginia is related to drainage divides (Stauffer and Ferreri, 2002). Kanawha Falls is the primary physical barrier that divides the distinct fish fauna of the New River System from that of the Upper Ohio River system (Hocutt et al., 1986). The Kanawha/New River system above the Kanawha Falls has a unique fauna with up to 45 native species, including eight endemic species (Messinger and Chambers, 2001). Fish species found in the upper Kanawha/New River system include bigmouth chub (*Nocomis platyrhynchus*), New River shiner (*Notropis scabriceps*), Kanawha minnow (*Phenacobius teretulus*), candy darter (*Etheostoma osburni*), Kanawha darter (*Etheostoma kanawhae*), and Appalachia darter (*Percina gymnocephala*), with all but the Kanawha darter occurring in West Virginia (Stauffer and Ferreri, 2002). Common fish on the Ohio River and lower portions of its tributaries include black bass (*Micropterus* spp**.)**, sunfish (*Lepomis* spp.), sauger (*Sander* spp.), catfish (order Siluriformes), the hybrid saugeye (*Sander vitreus x Sander canadense*), and striped bass (*Morone saxatilis*) (McNab and Avers, 1994; OSMRE, 2008).

Many high-altitude (headwater) streams are cold and support trout populations, particularly where these streams are draining areas larger than 100 square miles (Messinger and Chambers, 2001). In Appalachia, high elevation streams are often headwaters, but not all headwaters are high gradient, high elevation streams. Fish species collected in headwaters of West Virginia include rainbow trout (*Oncorhynchus mykiss*), brown trout (*Salmo trutta*), brook trout (*Salvelinus fontinalis*), blacknose dace (*Rhinichthys atratulus*), creek chub (*Semotilus atromaculatus*), and slimy sculpin (*Cottus cognatus*) (Stauffer and Ferreri, 2002). In general, common fish species found in smaller streams in Appalachia include southern redbelly dace (*Phoxinus erythrogaster*), creek chub, barred fantail darter (*Etheostoma flabellare*), and greenside darter (*Etheostoma blennioides*), whereas largemouth bass (*Micropterus salmoides*), bluegill (*Lepomis macrochirus*), channel catfish (*Ictalurus punctatus*), and crappie (*Pomoxis* spp.) are found in the large, man-made reservoirs (McNab and Avers, 1994; OSMRE, 2008).

Brook trout, a native salmonid species of streams in the southern Appalachian Mountains, is found mainly in small headwater streams. The distribution of brook trout is thought to be influenced by the presence of the non-native rainbow trout, as documented in the in Great Smoky Mountains National Park (Larson et al., 1995). Within the Park, the competitive advantage of rainbow trout over brook trout was evident when rainbow trout were removed and the abundance and biomass of brook trout populations rebounded (Moore et al., 1983).

According to a study conducted in the Southern Unglaciated Allegheny Plateau (Clear Fork or Spruce Laurel Fork), fish commonly collected include mottled sculpin (*Cottus bairdii*), bluebreast darter (*Etheostoma camurum*), river carpsucker (*Carpiodes carpio*), blacknose dace, and longnose dace (*Rhinichthys cataractae*) (Messinger and Chambers, 2001).

Studies conducted in Central Appalachian drainages of eastern Kentucky have found approximately 277 native freshwater fish species distributed among 22 families, with minnows (Cyprinidae), suckers (Catostomidae), catfishes (Ictaluridae), sunfishes, and perches (*Perca* spp.) being the most predominant (U.S. EPA, 1983). A diverse fish assemblage is found in eastern Kentucky due to the numerous geological, climatic, and hydrological events (U.S. EPA, 1983). Uncommon fish species found in the Northern Cumberland Plateau section (Tennessee and Kentucky) include the paddlefish (*Polyodon spathula*), sturgeon (Acipenseridae), eastern sand darter (*Ammocrypta pellucida*), spotted darter (*Etheostoma maculatum*), Tippecanoe darter (*Etheostoma tippecanoe*), and the redside dace (*Clinostomus elongatus*) (OSMRE, 2008). Larger populations of redside dace are found within a small range in Kentucky (OSMRE, 2008).

3.8.3.3.2 Lentic Systems (Ponds, Lakes and Reservoirs)

The following discussion of lentic systems in the Appalachian basin is divided into discussions of small ponds/impoundments and reservoirs. Natural lakes are largely absent in the Appalachian coal region. Small ponds/impoundments are common in the southeastern portion of the U.S.; most are formed by damming small streams (Wallace et al., 1992).

3.8.3.3.2.1 Energy Flow/Primary Production

Submersed macrophytes (macroscopic algae and aquatic vascular plants), periphyton (attached algae), and phytoplankton (suspended algae) communities are closely linked in small impoundments (Wallace et al., 1992). In the Appalachian Basin region, small lentic systems tend to be highly productive, eutrophic systems (high in nutrients, low in dissolved oxygen), although some small ponds and impoundments may be oligotrophic where there are low concentrations of plant nutrients and low productivity (Wallace et al., 1992). The main source of primary production (production of organic matter) in these smaller lentic systems is submergent or emergent vegetation (Menzel and Cooper, 1992). Floating macrophytes such as duckweed (*Lemna* spp.), spatterdock (*Nuphar* spp.), and yellow lotus (*Nelumbo* spp.), are widely distributed in the southeastern U.S. (Wallace et al., 1992). If floating macrophytes cover an entire surface area of a pond, photosynthesis will be greatly reduced in the water column, resulting in decreased dissolved oxygen concentrations that may inhibit fish populations. Fungi and bacteria are the primary decomposers of organic matter in small impoundments.

In reservoirs, as with other smaller impoundment types, phytoplankton, periphyton, and macrophytes supply most of the organic matter to the food web. Due to fluctuating water levels, phytoplankton production dominates most impoundments; however, rooted and floating macrophytes can dominate where water levels are stable in a reservoir. Reservoirs in the Appalachian Basin region are generally nutrient rich and productive. Nutrient loads to downstream aquatic systems are higher than that in most natural lakes.

3.8.3.3.2.2 Invertebrates

Common invertebrate species found in Appalachian ponds include rotifers, protozoans, and crustaceans (Cladocera and Copepoda). Within the benthos of most ponds and reservoirs in the southeastern U.S., larvae of true midges (Diptera: Chironomidae) and oligochaete worms are the dominant macroinvertebrates (Diggins and Thorpe, 1985).

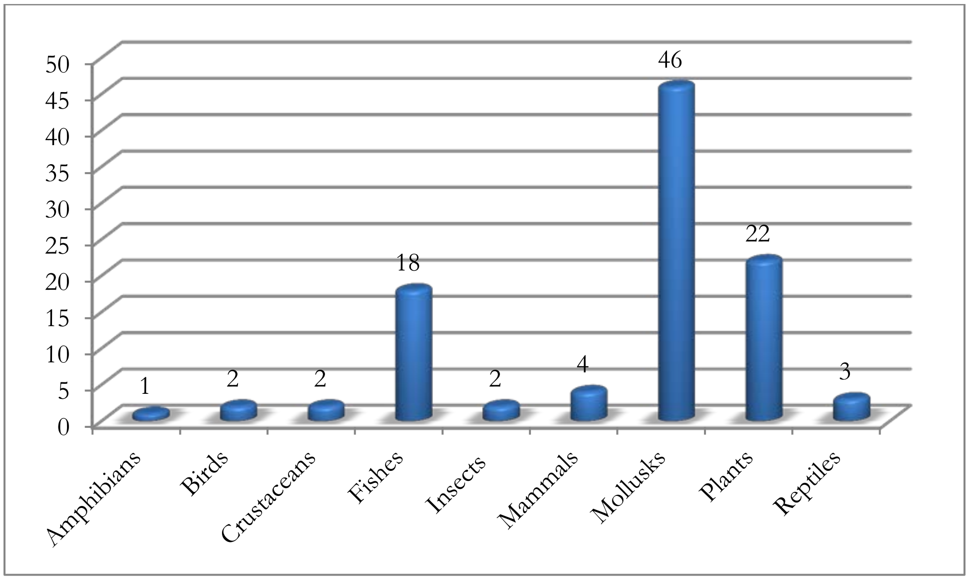
3.8.3.3.2.3 Vertebrates

Fish, amphibians, reptiles, birds, and mammals are the main groups of vertebrates associated with ponds and reservoirs in the Appalachian basin. These vertebrates may be present throughout their lifecycles, or may occupy the area only during a portion of their life cycle (Wallace et al., 1992). Fish populations are mainly comprised of forage fishes, including shads (*Alosa* spp.) and silversides (order Atheriniformes) in reservoirs, and sunfishes in ponds (Noble, 1981). The dominant predators in ponds are typically largemouth bass.

3.8.3.4 Protected Species in the Coal Mining Areas of the Appalachian Basin

The Appalachian Basin coal region supports nearly 100 federally listed and proposed species. These species include birds, fish, insects, mammals, mollusks, amphibians, reptiles, and vascular plants (see Appendix F for species names). Figure 3.8-2 depicts the number of species and relative proportion for each taxonomic group in the Appalachian Basin region.

Figure 3.8-2. Count of Federally Listed and Proposed Species in the Appalachian Basin Coal-Producing Region



Mollusks are of particular concern within the Appalachian Basin region. Mollusks account for nearly 50 percent of the total federally listed species within the Appalachian Basin coal region. Only seven of the forty seven mollusk species listed are freshwater snails; the remaining listed mollusks are freshwater mussels. Freshwater mussels are in decline nationwide and particularly in the Southeast. According to Neves et al. (1997):

The current status and prognosis for the Southeast region's mussel fauna is grim. Of the 269 species in the Southeast, 13 percent are presumed extinct, 28 percent are endangered, 14 percent are threatened, 18 percent are of special concern, and only 25 percent are considered stable at this time.

According to this study, as of 1997 up to 75 percent of the mussel species native to the Southeast had been ecologically impacted, and a significant concern remained regarding the vulnerability of these species due to their limited geographic distribution of many mussel species; many are endemic to small areas, and some limited to single watersheds (Neves et al., 1997). Therefore, these mussel species are extremely vulnerable to extirpation as a result of single catastrophic events. Regardless of the nationwide decline in mussel species, Appalachia is a mussel biodiversity "hotspot" in the United States, as demonstrated by the 43 federally listed freshwater mussel species reported for the Appalachian Basin coal region. Thirty-eight of the freshwater mussel species are listed as Endangered, while five mussel species are listed as Threatened.

Among the listed mammals, bats are also of particular concern in the Appalachian Basin region. White nose syndrome is a disease named after the white fungus, *Pseudogymnoascus destructans*, which infects the skin of hibernating bats on the muzzle, ears, and wings. White-nose syndrome has already caused population declines in northeastern U.S. bat populations of approximately 80%, and it continues to spread to other areas. According to the USGS National Wildlife Health Center, the disease continues to spread with new confirmed occurrences reported in Alabama, Indiana, Kentucky, Tennessee, and Missouri http://www.nwhc.usgs.gov/disease_information/white-nose_syndrome).

The remaining federally listed and proposed listed non-mollusk species that occur in the Appalachian Basin coal mining areas include: twenty species of vascular plants, seventeen species of fish, three species of birds, four species of mammals, two species of insects, two species of reptiles, and one species of amphibian.

3.8.4 Colorado Plateau Region

3.8.4.1 General Ecological Setting

The Colorado Plateau coal region encompasses coal-bearing areas of Arizona, Colorado, New Mexico, and Utah (Figure 3.8-3). Table 3.8-3 shows the area of each ecological province within the Colorado Plateau coal region.

The descriptions provided below for the ecological provinces within the Colorado Plateau coal region come from Bailey (1995), Cleland et al. (1997), McNab and Avers (1994), McNab et al. (2005), and McNab et al. (2007).

Figure 3.8-3. Ecological Provinces Located Within the Colorado Plateau Region

USGS, 2011, Coal Fields http://nationalatlas.gov/atlasftp.html?openChapters=chpgeol#chpgeol

Table 3.8-3. USFS Provinces Associated with the Colorado Plateau Region

Ecological Province	Area of Coal Region in Province (square miles)
Arizona-New Mexico Mountains Semi-Desert - Open Woodland - Coniferous Forest - Alpine Meadow	263
Colorado Plateau Semi-Desert	10,853
Intermountain Semi-Desert	15
Intermountain Semi-Desert and Desert	958
Nevada-Utah Mountains Semi-Desert - Coniferous Forest - Alpine Meadow	3,687
Southern Rocky Mountain Steppe - Open Woodland - Coniferous Forest - Alpine Meadow	1,602
Chihuahuan Semi-Desert	36
Southwest Plateau and Plains Dry Steppe - Open Woodland - Coniferous Forest - Alpine Meadow	252
Total	17,666

3.8.4.1.1 Arizona-New Mexico Mountains Semi-Desert-Open Woodland-Coniferous Forest-Alpine Meadow Province

This province consists mostly of steep foothills and mountains but includes some deeply dissected high plateaus. The vegetation varies by elevation zones and, from low to high, ranges from herbaceous to shrubland, to woodland, to forest. The province is approximately 34,439 square miles; the Colorado Plateau coal region is only a small amount of this province.

Several large perennial streams exist in this province. Much of the water is stored in reservoirs, small impoundments, and ponds. Ground water usually occurs at great depths. This province contains land in the watershed of the Rio Grande and Pecos Valley basins.

3.8.4.1.2 Colorado Plateau Semi-Desert Province

This province consists of tablelands with moderate to considerable relief in Arizona, New Mexico, and Utah. The vegetation in this province varies by altitude and varies from herbaceous and dwarf-shrubland at low elevation, shrubland and woodland at moderate elevation, to needleleaf forest at upper elevations. Water is scarce in the Colorado Plateau Semi-Desert Province. The Colorado River and its tributaries drain the coal-bearing areas of this region. The largest river in the province is the Colorado River, which crosses the northern part of the province in Arizona to Utah. Many other streams and rivers flow year-round, but the volume of water fluctuates considerably. These streams and rivers are narrow and located in deep, widely spaced valleys. Ground water supplies are deep and limited. Smaller lakes, impoundments, and reservoirs are present; Lake Powell is the largest.

3.8.4.1.3 Intermountain Semi-Desert and Desert Province

The vegetation in this province consists of shrubland on plains and woodlands on steeper slopes. Water is scarce in this province. The lands of the province are eroded by the Colorado River and its tributaries and are located in parts of Colorado, Arizona, and Utah. Few lakes and reservoirs occur, and the area is drained by the Colorado and Green Rivers and their tributaries. A small portion of Lake Powell occurs in Northern Canyonlands in this province. In the Uinta Basin in northeast Utah, some streams and rivers bring water into the surrounding areas from adjoining mountains. Major rivers that flow through the Uinta Basin are the Green, Duchesne, and Strawberry. Few lakes and reservoirs occur in the Uinta Basin; examples are the Strawberry reservoir, Starvation reservoir, and Steinaker reservoir.

3.8.4.1.4 Intermountain Semi-Desert Province

This province covers the plains and tablelands of the Columbia-Snake River Plateaus and Wyoming Basin. The vegetation in this province is herbaceous and dwarf-shrubland on plains, changing to shrubland and woodland on higher slopes.

In northeast Utah, there is a low to moderate frequency of rapidly flowing rivers and streams. Streams generally flow into the Great Basin or Snake River drainage. Few lakes and wet meadows are associated with higher areas above 5,000 feet (1,500 meters). Large lakes include Bear Lake, Gray's Lake, Palisades Reservoir, and Blackfoot Reservoir. The portions of the Intermountain Semi-Desert province in northwest Colorado are part of the Green River basin ecological subregion. Water is scarce in the Green River Basin, but some major rivers (e.g., Green and Lower Snake Rivers) and small streams flow through here. Part of the Flaming Gorge Reservoir is also found in this area.

3.8.4.1.5 Nevada-Utah Mountains-Semi-Desert-Coniferous Forest-Alpine Meadow Province

Vegetation is stratified by altitude, ranging from herbaceous and dwarf-shrubland on plateaus to woodlands at middle slopes and needleleaf evergreen forests on higher mountain slopes. Although some valleys are closed, none contain perennial lakes.

Generally, streams in this province are rare. Few are perennial, except in the southern Utah High Plateau Section. In the Tavaputs Plateau Section of this province, which is found in eastern-central Utah and in western Colorado, water is confined to the Green and White Rivers. Smaller drainages such as Timber, Sowards, and Indian Canyon deliver water to the Green River system after flowing into the Strawberry River in the Uinta Basin. There are few lakes and reservoirs in the Tavaputs Plateau Section, and many water developments exist on public lands to distribute to livestock and to provide water for wildlife. In the areas of the province found in south-central Utah, streams, lakes, and ground water supplies provide adequate water for grazing and forest growth. Perennial streams in southern Utah are more common and drain into the Sevier, Virgin, or Colorado Rivers. Some of the major lakes are larger impoundments of perennial streams: Piute Reservoir, Panguitch Lake, Scofield Reservoir, Joes Valley Reservoir, Fish Lake, and Otter Creek Reservoir.

3.8.4.1.6 Southern Rocky Mountain Steppe-Open Woodland-Coniferous Forest-Alpine Meadow Province

The vegetation of this province is mainly evergreen, needleleaf forest that varies in composition with altitude and aspect. In northern New Mexico and southwest Colorado, the landscape is rugged with high, steeply crested mountains etched with deep valleys. The northwestern areas of Colorado within this province have topography dominated by flat-topped mountains that are dissected by narrow stream valleys. Snowfields exist on higher-elevation upper slopes and crests, which provide a source of water into the summer months. The Rio Grande, Animas, Gunnison, Yampa, White, Colorado, Eagle, Arkansas, Taylor, Crystal, Roaring Fork, San Miguel and Frying Pan are the larger perennial rivers flowing through here. Water from streams and lakes is abundant in this province and ground water is also plentiful.

3.8.4.1.7 Chihuahuan Semi-Desert Province

This province has a subtropical arid climate of short winters and long, hot summers. It includes isolated embedded areas of mountain climates of cooler temperatures, lower relative humidity, and increased orographic precipitation. Most precipitation occurs during mid to late summer, mainly as thunderstorms that cause rapid runoff. Vegetation is almost entirely dwarf-shrubland and sparse coverage, although small areas of woodland do occur on higher mountains.

3.8.4.1.8 Southwest Plateau and Plains Dry Steppe and Shrub Province

A description of the Southwest Plateau and Plains Dry Steppe and Shrub province is provided below in the discussion of Gulf Coast provinces.

3.8.4.2 Terrestrial Resources

The Colorado Plateau coal region encompasses coal-bearing areas of Arizona, Colorado, New Mexico, and Utah. The text below summarizes aspects of terrestrial resources in areas of the region as classified under the USDA-USFSTerrestrial Ecological Unit designation (see also Figure 3.8-3) and adapted from Bailey (1995), McNab and Avers (1994), Cleland et al. (1997), and McNab et al. (2007). Table 3.8-3 lists the aerial extent of each unit within the Colorado Plateau coal region.

Vegetation

In Utah, most of the coal region is associated with the Intermountain Semi-desert and Desert Province and the associated Nevada-Utah Mountains Semi-desert-Coniferous Forest-Alpine Meadow Province. Cover types include: desert shrub; pinyon-juniper; sagebrush and chaparral-mountain shrub desert grasslands; ponderosa pine; western hardwoods; and Douglas-fir. The common vegetation and fauna in each cover type described in this report are described briefly in Appendix G.

Along its northern edge in Utah and extending across Colorado south into New Mexico, the coal region is located within the Southern Rocky Mountain Steppe-Open Woodland-Coniferous Forest-Alpine Meadow Province. This area is characterized by the following cover types: lodgepole pine; fir-spruce; sagebrush; alpine tundra chaparral-mountain shrub; ponderosa pine; and pinyon-juniper.

In the four corners area at the intersection of Utah, Colorado, Arizona, and New Mexico, the coal region is within the Colorado Plateau Semi-desert Province. This area is characterized by sagebrush, pinyon-juniper, ponderosa pine, southwestern shrub-steppe, desert grasslands, and desert shrub cover types.

South of the Four Corners area in central-eastern Arizona and into central New Mexico, the coal region is located within the Arizona-New Mexico Mountains Semi-desert-Open Woodland-Coniferous Forest-

Alpine Meadow Province. Ecoregion sections are characterized by ponderosa pine, pinyon-juniper, desert grasslands, and southwestern shrub-steppe cover types.

The fauna that occur in the arid and semi-arid areas of this coal region have adapted to its harsh climatic conditions. The composition of animal communities in and surrounding the lotic systems of this region are influenced by the vegetative communities that occur. Compared to the rest of the landscape, microclimates in and around the streams support the greatest concentrations of wildlife and provide the primary: habitat; predator protection; breeding and nesting sites; shade; movement corridors; migration stopover sites; and food sources (Levick et al., 2008).

Some physical features of wildlife habitat along ephemeral and intermittent streams include: the deposits of river material (sediment and debris); rock and subsurface soil layers exposed by erosion; the provision of shade through topographic relief; the creation of microclimatic zones; and the sequestration of moisture and nutrients in alluvium. River bank material provides shelter for numerous wildlife species including reptiles, amphibians, birds, mammals, and invertebrates. Specifically, dry wash embankments can contain numerous small caves and crevices that provide critical shelters from predators and the harsh environmental conditions for a variety of species (Van Devender, 2002; Levick et al., 2008).

Major wildlife species in the coal-bearing areas of southeastern Utah, southwest Colorado and northern New Mexico include mule deer (*Odocoileus virginianus*), elk (*Cervus canadensis*), coyote (*Canis latrans*), black bear, mountain lion (*Puma concolor*), black-tailed jackrabbit (*Lepus californicus*), Gunnison's prairie dog (*Cynomys gunnisoni*), badger (*Taxidea taxus*), piñon jay (*Gymnorhinus cyanocephalus*), black-billed magpie (*Pica hudsonia*), mountain chickadee (*Poecile gambeli*), red-breasted nuthatch (*Sitta Canadensis*), white-breasted nuthatch (*Sitta carolinensis*), collared lizard (*Crotaphytus collaris*), western fence lizard (*Sceloporus occidentalis*), and western rattlesnake (*Crotalus viridis*).

Some of the major wildlife species occurring in east central Utah to mid-central Colorado include coyote, kit fox (*Vulpes macrotis*), white-tailed prairie dog (*Cynomys leucurus*), white-tailed jackrabbit (*Lepus townsendii*), pronghorn (*Antilocapra americana*), mule deer, elk, American kestrel (*Falco sparverius*), sage grouse (*Centrocercus* spp.), turkey vulture (*Cathartes aura*), screech owls (*Megascops* spp.), mourning dove, piñon jay, common raven (*Corvus corax*), sage sparrow (*Artemisiospiza nevadensis*), bald eagle (*Haliaeetus leucocephalus*), golden eagle (*Aquila chrysaetos*), western rattlesnake, bullsnakes (*Pituophis* spp.), western fence lizard, and sagebrush lizard (*Sceloporus graciosus*).

Faunal communities are highly related to the habitat as influenced by altitude. Rocky Mountain bighorn sheep (*Ovis canadensis*) and white tailed ptarmigan (*Lagopus leucura*) inhabit the higher elevations of some portions of the region. In desert shrub communities common wildlife species include rock wren (*Salpinctes obsoletus*), lark sparrow (*Chondestes grammacus*), loggerhead shrike (*Lanius ludovicianus*), horned lark (*Eremophila alpestris*), green-tailed towhee (*Pipilo chlorurus*), Brewer's sparrow (*Spizella breweri*), red-tailed hawks, golden eagle, northern harrier (*Circus cyaneus*), and the American kestrel. In pinyon-juniper and mountain brush habitats mountain bluebird (*Sialia currucoides*), blue-gray gnatcatcher (*Polioptila caerulea*), red breasted nuthatch, flycatchers (Family Tyrannidae), great horned owl (*Bubo virginianus*) and red-tailed hawk are common. Mountain bluebirds are common summer nesters. The piñon jay and piñon mouse (*Peromyscus truei*) are obligate species in the pinyon-juniper and mountain brush habitat.

In the high elevation sagebrush communities typical species include sage grouse, mule deer, pronghorn, mountain lion, black bear, California myotis (*Myotis californicus*) and pygmy faded rattlesnake (*Crotolus viridis concolor*). Typical forest-dwelling avifauna include Clark's nutcracker (*Nucifraga columbiana*), gray jay (*Perisoreus canadensis*), northern flicker (*Colaptes auratus*), and Steller's jay (*Cyanocitta stelleri*). Bird species representative of aspen and coniferous forest specifically can include brown creeper (*Certhia americana*), western wood peewee (*Contopus sordidulus*), warbling vireo (*Vireo gilvus*), MacGillivray's warbler (*Geothlypis tolmiei*), Townsend's solitaire (*Myadestes townsendi*), three-toed woodpecker (*Picoides dorsalis*), red-naped sapsucker (*Sphyrapicus nuchalis*), hairy (*Leuconotopicus villosus*) and downy woodpeckers (*Picoides pubescens*), red-tailed hawk, goshawk (*Accipiter gentilis*), Cooper's hawk (*Accipiter cooperii*), and sharp-shinned hawk (*Accipiter striatus*). Typical mammal species in these aspen and coniferous forests include red squirrel (*Sciurus vulgaris*), northern flying squirrel (*Glaucomys sabrinus*), deer, elk, mountain lion, bear, coyote, and hoary bat (*Lasiurus cinereus*).

In the riparian areas bird species can include yellow warbler (*Setophaga petechia*), tree swallow (*Tachycineta bicolor*), western kingbird (*Tyrannus verticalis*), house wren (*Troglodytes aedon*), rufous-sided towhee (*Pipilo erythrophthalmus*), song sparrow (*Melospiza melodia*), loggerhead shrike, hairy woodpecker, red-tailed hawk, and golden eagle. Riparian areas also support a variety of mammals including deer, elk, moose (*Alces alces*), mountain lion, bear, beaver (*Castor canadensis*) and silver-haired bat (*Lasionycteris noctivagans*), along with amphibians such as the Utah tiger salamander (*Ambystoma Tigrinum*). Two common amphibian species include chorus frogs (*Pseudacris* spp.), and leopard frogs (*Rana* spp.).

Soil salinity also affects this region's vegetative communities and the fauna that use them. Within southeast Utah, northeastern Arizona, and northwest New Mexico high elevation desert shrub and woodland vegetation the plant and animal communities change. High elevation pinyon-juniper woodland and sagebrush have an understory of galleta (*Hilaria* spp.), blue grama (*Bouteloua gracilis*), black grama (*Bouteloua eriopoda*), and western wheatgrass (*Pascopyrum smithii*). Galleta grass, alkali sacaton (*Sporobolus airoides*), Indian ricegrass (Oryzopsis hymenoides), bottlebrush squirreltail (*Elymus elymoides*), and needlegrasses (*Achnatherum* spp.) intermixed with fourwing saltbush (*Atriplex canescens*) and winterfat (*Krascheninnikovia lanata*) are at the lower elevations. Greasewood (*Sarcobatus* spp.) and shadscale (*Atriplex confertifolia*) are part of the plant community on salty soils. Blackbrush (*Coleogyne ramosissima*) may be dominant at the lower elevations.

3.8.4.3 Aquatic Resources

In the Colorado Plateau coal region, each province has unique climatic, physiographic, and geologic properties that influence the types of aquatic systems and biota that occur within them.

3.8.4.3.1 Lotic Systems (River and Streams)

Major perennial rivers that run through the provinces found in the coal region include the Green, Yampa, White, Little Colorado, Colorado, Rio Grande, Pecos, Gila, San Juan, San Francisco, and Little Snake. The largest watershed in this coal region is the Colorado River watershed.

Over 81 percent of streams in the Southwest (Arizona, New Mexico, Nevada, Utah, Colorado and California) are ephemeral or intermittent, according to the USGS National Hydrography Dataset (NHD) (USGS, 2011a). Ephemeral and intermittent streams in the desert and semi-desert areas of this coal region are unique in their function when compared to perennial streams located in wetter, more humid mountainous provinces. Most streams in the more xeric, desert-like areas of the coal region drain erodible sedimentary rock, making the waters turbid, and sudden rains flush sediments down smaller streams to the perennial reaches (U.S. EPA, 2006). These smaller streams in the xeric regions are often subject to rapid change as a result of flash floods and debris flows (U.S. EPA, 2006). In the southern areas, the extreme xeric conditions and water withdrawals produce internal drainages that end in saline lakes (U.S. EPA, 2006) or desert wallows called playas (Levick et al., 2008). The seasonal rainfall patterns in this coal region vary, which as a result have an effect on stream flows throughout.

A variety of flowing water habitats is present in the Colorado Plateau coal region. These include ephemeral, intermittent, low order (first through third) and higher order (fourth through sixth) streams as well as rivers. As listed in Table 3.5-5, there are a total of 43,482 miles of intermittent streams, and 2,811 miles of perennial streams, in this coal region. A more detailed discussion about the general habitat features and hydrology of these different types of streams is presented in Appendix C.

Ephemeral and intermittent stream channels provide critical wildlife movement corridors in arid and semi-arid regions because they often contain continuous chains of vegetation that provide food and cover for wildlife. Small floods that occur during the summer monsoons create corridors of water that allow the dispersal of herpetofauna such as garter snakes and various amphibians (Levick et al., 2008).

3.8.4.3.1.1 Energy Flow/Primary Production

The riparian areas surrounding lotic systems in this coal region are vital to the persistence of biota. Riparian ecosystems occupy small portions of the landscape in arid and semi-arid areas of the coal region, yet they exert substantial influence on hydrologic, geomorphic, and ecological processes (Shaw and Cooper, 2008), and typically support the great majority of biodiversity in these regions (Levick et al., 2008). Plant communities along ephemeral and intermittent streams of this coal region provide food, cover, nesting and breeding habitat, and movement/migration corridors for wildlife that are not as available in the adjacent uplands (Levick et al., 2008). Furthermore, these plant communities moderate soil and air temperatures, stabilize channel banks and interfluves, provide seed banks, trap silt and fine sediment favorable to the establishment of diverse floral and faunal species, and dissipate stream energy, which aids in flood control (Levick et al., 2008). Ephemeral streams in this region provide support to aquatic species within their own reaches and transfer nutrients, food, and other materials to the more perennial downstream reaches, aiding the biota in these habitats as well.

Algal communities comprised of diatoms, filamentous algae, and cyanobacteria are the predominant primary producers in intermittent and ephemeral streams of the more arid areas of the Colorado Basin coal region. These algal communities are prolific due to the high levels of sunlight. After flood events, algal blooms can occur in areas with stored water and provide the base of the food chain in these systems. When stored water is accessible, primary production can be high for much of the growing season (Atchley et al., 1999; Levick et al., 2008).

As the hydrologic regime shifts from perennial to ephemeral, the presence of drought-tolerant species increases, vegetative cover declines, riparian areas transition from forests to shrublands, and canopy height and upper canopy vegetation volume decline (Leenhouts et al., 2006; Stromberg et al., 2007; Levick et al., 2008). Ephemeral streams with intermediate water availability support drought-tolerant shrubs such as wolfberry (*Lycium* spp.), brickellbush (*Brickellia* spp.), and small-leaved trees such as velvet mesquite (*Prosopis velutina*) (Hardy et al., 2004; Levick et al., 2008). Along the intermittent and perennial streams, riparian scrublands include seepwillow or batamote (*Baccharis glutinosa*), broom (*Baccharis sarothroides* or *B. emoryi*), arrowweed (*Pluchea sericea*), and tamarisk (*Tamarix chinensis*) (Brown et al., 1977; Levick et al., 2008). Hydro-obligate broad-leaved trees (e.g., the mesoriparian species Arizona walnut, *Juglans major*, and the Fremont cottonwood, *Populus fremontii*) are typically sustained on large washes by floodwater stored in perched ground-water reservoirs (Levick et al., 2008).

3.8.4.3.1.2 Invertebrates

Aquatic invertebrates are important contributors to the biological integrity of stream networks throughout this coal region. Invertebrates constitute a majority of faunal diversity, and aquatic invertebrates are a significant component of the food chain. Many invertebrates require a hydrologic connection for their spatial dispersal, even if the connection is ephemeral or intermittent (Nadeau and Rains, 2007). Ephemeral streams in this coal region can contain rich assemblages of invertebrates. Microinvertebrates in these ephemeral systems include copepods, ostracods, and cladocerans (Levick et al., 2008). Intermittent streams in the Southwest provide food sources for numerous macroinvertebrates found within them and in surrounding areas. For example, Graham (2002) studied temporary pools in watercourses in Wupatki National Monument, Arizona, and found 22 taxa of aquatic macroinvertebrates and two taxa of amphibians. Disturbances caused by intermittent flows may actually improve production and food quality and consequently increase insect production in warm-temperate desert streams (Fisher and Gray, 1983; Jackson and Fisher, 1986; Grimm and Fisher, 1989; Huryn and Wallace, 2000; Levick et al., 2008). Whiles and Goldowitz (2005) investigated macroinvertebrate diversity across a hydrologic gradient from ephemeral to perennial streams and found the highest taxa richness and diversity at intermittent sites (Levick et al., 2008). Del Rosario and Resh (2000) compared species richness and abundance of invertebrates in the hyporheic zones of intermittent and perennial streams, and found that intermittent streams had lower densities, similar richness, but higher species diversity than perennial streams.

Various mollusks are found within this coal region and function as filter feeders that eat algae, detritus, and other submersed items on the rocks and substrate within the streams. Mollusks are important sources of food for fish, birds, and some mammals. Mussels rely on specific fish species as hosts for their larvae (called glochidia) to complete their life cycle, and removal of these hosts has led to the decline of some species (Harrold and Guralnick, 2010). Specifically, as of 2010, Colorado has 83 mollusk species (eight gastropod families and three bivalve families) known to occur in various waters throughout the state (Harrald and Guralnick, 2010).

Crustaceans that occur in the Colorado Plateau are various crayfish and freshwater shrimp, and many species are imperiled by pollution, habitat loss, and invasive species. Exotic mollusks have been a threat to ecological communities in Utah (Sutter et al., 2005). Native crustacean species are rare in Utah and of limited distribution (Sutter et al., 2005). Invasive crayfish populations' effects on streams, especially in sensitive headwater areas, are receiving increased attention. Crayfish, such as the rusty crayfish (*Orconectes rusticus*), are omnivorous and aggressively consume submerged aquatic vegetation, other macroinvertebrates, and fish species, and they compete for habitat and resources with fish, frogs, reptiles, and snails (Arizona Invasive Species Advisory Council, 2008).

3.8.4.3.1.3 Vertebrates

Fish communities in the Colorado Plateau coal region range from assemblages of warm water fish (e.g., centrarchids, cyprinids, topminnows, catfishes, perches, catostomids) in the lower elevations to assemblages of more coolwater species (e.g., darters, sculpins, cyprinids, and salmonids) in the higher gradient streams in the upper elevations. However, the Southwest has among the greatest species endemism in the U.S. Cyprinids and cyprinodontids appear to be the most specious groups of fishes that occur in the various lotic systems in the coal region, and some of the largest members of the family Cyprinidae occur in this coal region. The southwestern deserts of the Basin and Range Province, which encompasses some of the coal region, contain 182 native species of fish, of which 149 are endemic. In these areas, the fish occupy isolated pools within streams that are supplied by underground springs, intermittent marshes, and arroyo habitats which are supplied by water that originates in the wetter mountainous areas (Helfman et al., 1997). Fish communities in the desert areas tend to belong to five major families: Poeciliidae, Cyprinodontidae (e.g., desert pupfish), Cyprinidae, Catostomidae, and Salmonidae (Helfman et al., 1997). Populations of native desert fishes are rapidly dwindling due to destruction of aquatic habitats from urbanization, channelization, land-use change, over grazing by cattle, ground-water pumping, dams, water diversions, and pollution (Rinne and Minckley, 1991).

Fish in the extremely arid areas of this coal region are adapted to harsh and variable desert conditions. For this reason (and others) the ephemeral and intermittent streams, and the isolated pools within them, are important. For example, pupfish (*Cyprinodon* spp.) can withstand the high temperatures, alkalinity, and salinity of small desert pools (Pister, 1995; Levick et al., 2008). Another example, longfin dace (*Agosia chrysogaster*) have the most widespread distribution of any native fish in the Southwest and are highly adapted to drought (Rinne and Minckley, 1991). Longfin dace can survive in relatively high water temperatures, poor water quality and availability, and have been found alive in moist algal mats where there was not enough water to swim (Hulen, 2007; Rinne and Minckley, 1991; Levick et al., 2008).

Larger fishes of the coal region occur in the larger, higher-order perennial streams and rivers, including the Green, Colorado, Yampa, and San Juan Rivers; many are highly threatened as a result of anthropogenic disturbances and invasive species.

Cutthroat trout (*Oncorhynchus clarkii*) serve as an important recreation species in Utah (Sutter et al., 2005). The historical distribution of cutthroat trout covers the broadest range of any stream-dwelling trout in the Western Hemisphere. The rugged topography of their range has led to isolation, which in turn has given rise to fourteen recognized subspecies. Four of these evolved in Colorado and three are of particular interest: the Colorado River cutthroat trout (*O. clarkii pleuriticus)* in drainages west of the continental divide, Greenback cutthroat trout (*O. clarkii stomias*) in the South Platte and Arkansas River drainages, and the Rio Grande cutthroat trout (*O. clarkii virginalis*) in streams that drain into the San Luis Valley (Colorado Division of Wildlife, 2010).

The greenback cutthroat trout was thought to be extinct in 1937; however, numerous pure populations have since been discovered. The historic range for greenback cutthroat trout lies in the headwaters of the South Platte and Arkansas Rivers. Many of those waters have been reclaimed and restocked with pure greenback cutthroat trout. The success of those projects led to the 1978 down listing of greenback cutthroat trout from endangered to threatened under the ESA (Colorado Division of Wildlife, 2010).

The Colorado River cutthroat trout historically occupied portions of the Colorado River drainage in Wyoming, Colorado, Utah, Arizona, and New Mexico. Widespread introductions of non-native salmonids over the last century have served to limit current distributions primarily to isolated headwater streams and lakes. As such, the Colorado River cutthroat trout is designated as a species of special concern in Colorado, and significant resources have been dedicated to conservation of the subspecies. The Conservation Agreement for Colorado River cutthroat trout is a collaborative effort among state and federal resource agencies designed to provide a framework for the long-term conservation of Colorado River cutthroat trout and to reduce or eliminate the threats that warrant its status as a species of special concern (Colorado Division of Wildlife, 2010).

The Rio Grande cutthroat trout is the third subspecies of native trout found in Colorado. They range further south than any other cutthroat trout, historically occupying waters down to southern New Mexico. As with other subspecies of cutthroat trout, widespread introductions of non-native salmonids over the last century have served to limit their current distribution to isolated headwater streams and lakes. A conservation plan developed in 2004 has been used to guide conservation efforts thus far. A Conservation Agreement (Rio Grande Conservation Team, 2009) provides a collaborative framework among state, federal, and tribal resource agencies outlining long-term conservation objectives for this subspecies.

The Colorado Plateau coal region has high herpetofauna diversity, most of which are reptiles. However, there are some introduced species such as the bullfrog (*Lithobates catesbeianus*) that have imperiled other species in some areas of the coal region (Arizona Invasive Species Advisory Council, 2006). Bullfrogs, which are aggressive predators, have been introduced into many locations in the Colorado Plateau coal region and have locally depleted and displaced populations of native amphibians, reptiles, fish, and even small mammals and birds (Arizona Invasive Species Advisory Council, 2008).

3.8.4.3.2 Lentic Systems

Lentic systems in the Colorado Plateau coal region tend to be smaller intermittent or ephemeral wallows called playa lakes, or larger reservoirs created by impoundment of stream flow. Of the 802 lakes surveyed in the "Xeric ecoregion" of the EPA's National Lakes Assessment (U.S. EPA, 2009b), which includes the Colorado Plateau coal region, 91 percent were constructed reservoirs. Damming the Colorado River has created large man-made lakes and reservoirs (e.g., Lake Powell) (U.S. EPA, 2009b). Smaller impounded streams comprise numerous man-made lentic systems that provide energy and water supply for various municipalities.

Playas fill with water after seasonal rainstorms when freshwater collects in the round depressions of the generally flat landscape. Some saltwater-filled playas are also found in the region and these systems are fed by water from underlying aquifers that transfer salt as water percolates upward through the soil (U.S. EPA, 2012). The saline environment in these playas is inhospitable to many organisms and results in a fauna uniquely adapted to these conditions. Playas are important because they store water in areas commonly subjected to drought, where there are no permanent rivers or streams. Consequently, playas create an oasis-like area that provides habitat for a variety of species, especially in the more arid areas of the coal region. Because playa lakes support such a wide variety of animals, they contribute significantly to the biodiversity of this coal region.

3.8.4.3.2.1 Energy Flow/Primary Production

Flora found in and surrounding the playas can be variable depending upon the periodicity of rain events, agriculture, and substrate (Bolen et al., 1989). During wetter periods, emergent vegetation such as bulrushes (family Cyperaceae), cattails (*Typha* spp.), pondweeds and smartweeds (family Polygonaceae), and barnyard grasses (*Echinochloa* spp.) can be present (Bolen et al., 1989).

Energy flow and primary production in lentic systems within the Colorado Plateau coal region are variable by location but are similar to those described for the semi-arid provinces in the Other Western Interior, Northern Rocky Mountains and Great Plains, and Gulf Coast coal regions.

3.8.4.3.2.2 Invertebrates

Invertebrate populations are heavily exploited by the animal community. During their breeding season, various waterfowl and their broods rely on aquatic macroinvertebrates as important sources of protein. Invertebrates in the littoral zones of playas also provide food for a number of shorebirds (Baldassarre and Fischer, 1984; Bolen et al., 1989). Merickel and Wangberg (1981) collected more than 60 species of macroinvertebrates in playa lakes; however, such biodiversity will vary depending on location, type of playa, and surrounding flora (Bolen et al., 1989).

In some communities of playas, biotic interactions are thought to lead a relatively ordered and predictable succession of organisms (MacKay et al., 1990). MacKay et al. (1990) also noted that after flood events, macroinvertebrate productivity increased with the oviposition of flying insects such as mosquitoes (*Aedes* spp.). Immediately following these floods, mosquito larvae pupated and left the playa within eight days; simultaneously, freshwater shrimp (*Eulimnadia* spp., *Streptocephalus* spp., *Triops* spp., and *Thamnocephalus* spp.) densities increased and then dissipated as the playa dried. This provides evidence that such species in playa lakes likely have adapted quick life cycles to avoid direct competition and predation by other organisms.

3.8.4.3.2.3 Vertebrates

Amphibian species and their dependence on playas are poorly understood. However, multiple species have been documented to use playas, primarily during periods of peaked rainfall that triggers their breeding activities (Bolen et al., 1989). Tiger salamanders (*Ambystoma tigrinum*) use playas in the Southern High Plains to spawn, and leopard frogs (*Rana pipiens*), bullfrogs, cricket frogs (*Acris* spp.), spotted chorus frogs (*Pseudacris* spp.), Great Plains toads (*Bufo cognatus*) and spadefoot toads (*Scaphiopus* spp.) also occur in these playas (Bolen et al., 1989; MacKay et al., 1990).

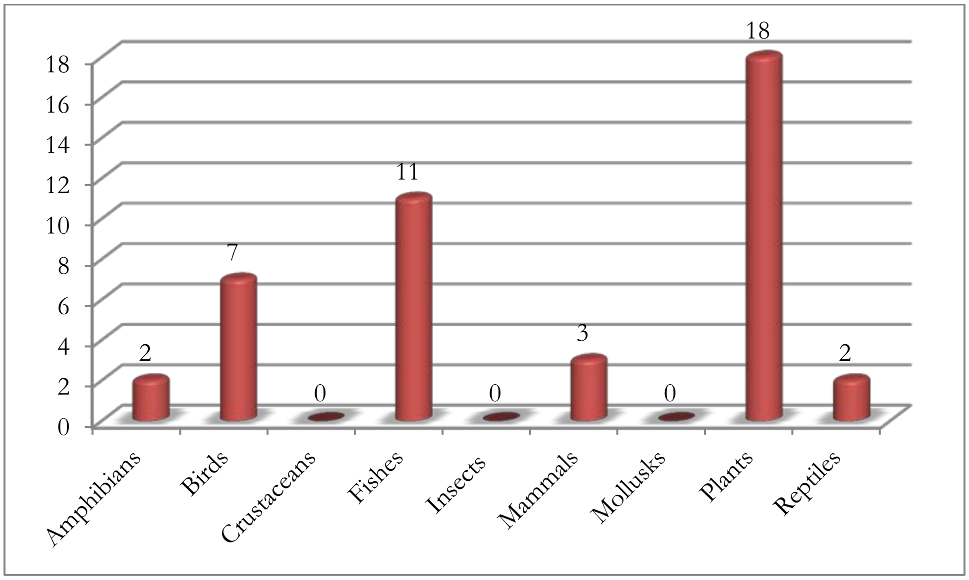
Fish do not commonly inhabit playas because they are ephemeral bodies of water. Playas that have been altered for irrigation and agriculture have had introductions of various fish species to support some angling activity. Bolen et al. (1989) noted that playas that historically contained no fish populations now support black bullhead (*Ameiurus melas*).

Waterfowl commonly winter in the playa lakes of the region (Bolen et al., 1989); the EPA (2012) noted up to two million waterfowl can use playas. Whooping cranes (*Grus americana*) and up to 400,000 sandhill cranes (*G. canadensis*) have been documented to use the playas as wading and feeding habitat (Bolen et al., 1989). Ring-necked pheasants (*Phasianus colchicus*) also use playa lakes as wintering habitat in this region (Bolen et al., 1989). Species native to areas surrounding these systems survive because of the existence of playa lakes.

3.8.4.4 Protected Species in the Coal Mining Areas of the Colorado Plateau

In the Colorado Plateau coal region, there are a total of 43 federally listed (and proposed listed) species. See Appendix F for the species names and status information. Figure 3.8-4 depicts the number of listed species and relative proportion for each taxonomic group in the Colorado Plateau coal region.

Figure 3.8-4. Count of Federally Listed and Proposed Species in the Colorado Plateau Region



Of the listed species, the fishes are of particular concern in the Colorado plateau region due to the intense demands on water. The region is impacted by dam construction and water withdrawals to ensure supplies for agriculture, industry and human consumption. As a result fish species and their habitats are affected by changing water temperature, water depletions, blockage of fish passage, transformation of riverine habitat, changes in the timing and magnitude of high and low flows, and changes in channel morphology and water quality. Introduced species are a significant threat in addition to water development (Rondeau et al., 2011).

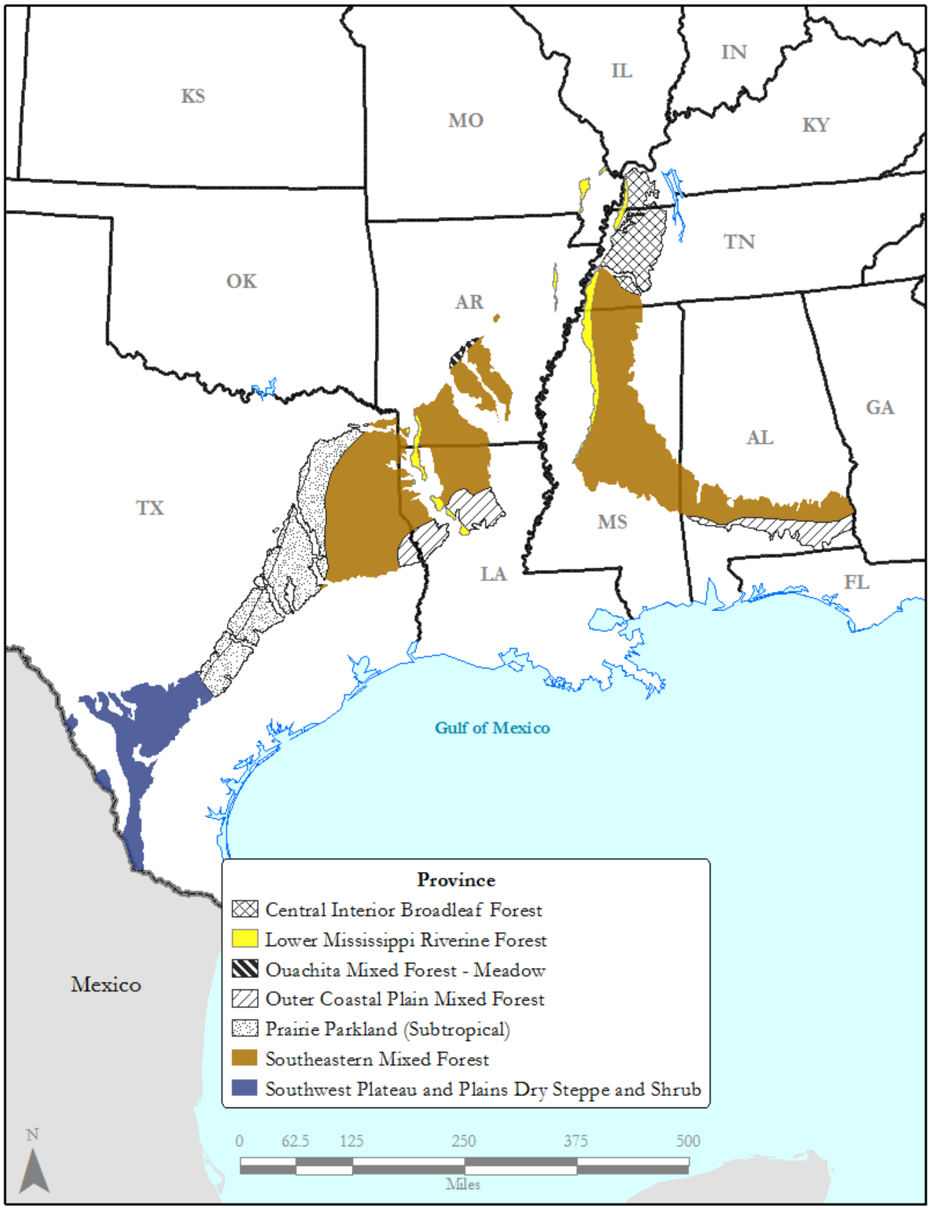
While the absolute number of listed plant species is higher than the number of other groups for this region, that may be a factor of the higher number of plant species in general, as was determined to be the case for Colorado (Rondeau et al., 2011). The primary factors affecting listed bird species in Colorado are habitat loss due to conversion to cropland, forestry, energy development and wetland/riparian alteration (Rondeau et al., 2011).

3.8.5 Gulf Coast Region

3.8.5.1 General Ecological Setting

The coal region of the Gulf Coast is an area of approximately 9,735 square miles and includes the coal mining areas located in Texas, Louisiana, and Mississippi (Figure 3.8-5). A variety of physical and chemical factors affect the biological resources of this coal region. Table 3.8-4 lists the ecological provinces located within this coal region and the approximate area of each.

Figure 3.8-5. Ecological Provinces Located Within the Gulf Coast Region



Source: USFS, 2015, Ecological Provinces, http://data.fs.usda.gov/geodata/;

USGS, 2011, Coal Fields, http://nationalatlas.gov/atlasftp.html?openChapters=chpgeol#chpgeol

Table 3.8-4. USFS Provinces Associated with the Gulf Coast Region

Ecological Province	Area of Coal Region in Province (square miles)
Outer Coastal Plain Mixed Forest	12,107
Prairie Parkland (Subtropical)	12,258
Southeastern Mixed Forest	46,193
Southwest Plateau and Plains Dry Steppe and Shrub	9,566
Lower Mississippi Riverine Forest	623
Central Interior Broadleaf Forest	27
Ouachita Mixed Forest-Meadow	101
Total	80,876

The descriptions provided below for the ecological provinces distributed within the Gulf Coast coal region come from Bailey (1995), Cleland et al. (1997), McNab and Avers (1994), and McNab et al. (2007).

3.8.5.1.1 Outer Coastal Plain Mixed Forest Province

Most of the province's numerous streams are intermittent to perennial, and sluggish; marshes, swamps, and lakes are numerous. Major rivers that run through the province in the coal region include the Sabine, Red, Mississippi, Mobile, Chattahoochee, and the Flint. Few natural lakes and reservoirs are present, but small ponds and impoundments are abundant.

3.8.5.1.2 Prairie Parkland (Subtropical) Province

This province is a region of gently rolling to flat plains. The vegetation is mainly herbaceous with areas of deciduous broadleaf woodland, particularly along floodplains. In the central Texas area of the province, there is a low to moderate density of perennial streams and associated rivers that form dendritic drainage patterns. These streams mostly have low to moderate rates of flow and moderate velocity. One of the major rivers draining this area is the Red River. A relatively large number of water reservoirs have also been constructed. Along the Texas coast, fluvial deposition and shore-zone processes are active in developing and maintaining beaches, swamps, and mud flats. There is a low density of small to medium size perennial streams and associated rivers, most with moderate volume of water flowing at low velocity. A major river draining this area is the Trinity. In the southern areas of the province small to medium size perennial streams and a low density of associated rivers occur, most with moderate volume of water flowing at very low velocity. Approaching the coast, the water table is high, resulting in poor natural drainage and abundance of wetlands. A poorly defined drainage pattern has developed on very young plains near the coast. An abundance of palustrine (non-tidal wetlands) systems are present, having seasonally high water levels.

3.8.5.1.3 Southeastern Mixed Forest Province

In eastern Texas, northwest Louisiana, and eastern Mississippi small to medium size perennial streams and associated rivers occur, most with a moderate volume of water flowing at low velocity. These lotic systems form a dendritic (branching) drainage pattern and tend to lack bedrock control. Major rivers in this ecological province within the Gulf Coast coal region are the Arkansas, Red, and Ouachita.

3.8.5.1.4 Southwest Plateau and Plains Dry Steppe and Shrub Province

This is a region of flat to rolling plains and plateaus occasionally dissected by canyons at the western end of the Gulf Coastal Plain and the southern end of the Great Plains. The vegetation of this province is mainly herbaceous with shrubland increasing to woodland on steeper slopes. Aquatic systems in the Edwards Plateau consist of small intermittent and occasional perennial streams forming a dendritic drainage pattern. All streams generally have a low volume of water flowing at low velocity, except along the plateau escarpment, where flow rates can be high. In the southern portion of this province, small to medium intermittent streams are present in a dendritic drainage pattern, and major rivers include the Rio Grande and Nueces.

3.8.5.1.5 Central Interior Broadleaf Forest Province

A description of the Central Interior Broadleaf Forest province is provided above in Section 3.8.2.

3.8.5.1.6 Lower Mississippi Riverine Forest Province

The climate of this province is characterized by warm winters and hot summers. Precipitation occurs throughout the year, although least in fall. Much of this subregion is influenced by periodic flooding of the Mississippi River. Vegetation was initially forests of cold-deciduous, mesophytic hardwoods, which have now largely been cleared and cultivated.

3.8.5.1.7 Ouachita Mixed Forest-Meadow Province

This province has a continental climate, with short, cool winters and long, hot summers. Precipitation occurs throughout the year, but summers are dry. Vegetation consists of mixed needle leaf and cold-deciduous broadleaf forests.

3.8.5.2 Terrestrial Resources

The Gulf Coast coal region study area includes many different terrestrial habits over a broad area of the southeastern United States, ranging from desert habitats in west Texas to coastal areas of the Florida panhandle. The coal counties with active mines extend from Texas to Mississippi. Except as noted, all of the ecoregion descriptions and vegetation cover type descriptions are taken from McMahan et al. (1984) and McNab et al. (2007).

In central Texas, the Gulf Coast coal belt consists of three ecoregion sections: the Rolling Plains Section; the Southwest Plateau and Plains Dry Steppe; and Shrub Province (characterized by Great Plains grasslands, prairie cover types, and oak-hickory). The eastern portion of this coal region is within the Prairie Parkland Province, characterized by cropland; mesquite-lotebush shrub areas with *Yucca* spp., juniper (*Juniperus* spp.), bluestems and snakeweed (*Gutierrezia sarothrae*); and mesquite brush (*Prosopus* spp.) areas with yucca (*Yucca* spp.), prickly pear (*Opuntia* spp.), and grama (*Bouteloua* spp.).

The most significant portion of the Gulf Coast coal belt crosses numerous ecoregions. The eastern portion is characterized by cropland; mesquite-lotebush shrub areas with *yucca*, juniper, bluestems and snakeweed; and mesquite brush areas with yucca, prickly pear, and grama. In southern Texas, the coal region includes the Southwest Plateau and Plains Dry Steppe and Shrub Province and associated with the Texas savanna and oak-hickory cover types, including with extensive cropland, mesquite-blackbrush brush, and mesquite-Granjeno parks. Common wildlife species include white-tailed deer, coyote, bobcat, beaver, raccoon, cottontail rabbit (*Sylvilagus* spp.), fox squirrel (*Sciurus niger*), turkey, bobwhite, and mourning dove.

East of Texas, the coal region is characterized by oak-hickory, oak-gum-cypress, oak-pine, loblolly-shortleaf pine, prairie, and longleaf-slash pine cover types. Further east, the coal region is within the Prairie Parkland Province, characterized by oak-hickory and oak-pine cover types. There are also extensive areas of including extensive cropland, post oak woods/forest, and post oak woods/forest/grassland. The Mississippi River and its associated environments have been a large contributing factor to the development of ecosystems in these regions. Natural vegetation in these areas varies with topography and hydrology and is incorporated into a patchwork of a predominantly open, agricultural landscape (Lower Mississippi VJV, 2007).

Common wildlife species occurring in the coal-bearing areas of Tennessee, Louisiana, Mississippi, and Alabama include white-tailed deer, black bear, bobcat, gray fox, raccoon, gray squirrel, fox squirrel, eastern chipmunk, white-footed mouse, pine vole (*Microtus pinetorum*), northern short-tailed shrew (*Blarina brevicauda*), and cotton mouse (*Peromyscus gossypinus*). The turkey, ruffed grouse, bobwhite, and mourning dove are common game birds. Typical songbirds include the red-eyed vireo (*Vireo olivaceus*), cardinal (*Cardinalis spp.*), tufted titmouse, wood thrush, summer tanager (*Piranga rubra*), blue-gray gnatcatcher, hooded warbler (*Setophaga citrina*), and Carolina wren (*Thryothorus ludovicianus*). Common reptiles include box turtles, common garter snake, and timber rattlesnake. In flooded areas, such as those of the lower coastal plain in Louisiana, migratory waterfowl and colonial nesting birds such as herons (family Ardeidae) are common.

Areas of eastern Texas, Louisiana and Arkansas support loblolly-shortleaf pine, oak-pine, oak-hickory, oak-gum-cypress cover, and longleaf-slash pine types, including young forest/grassland, loblolly pine-hardwood forest, and native/introduced grasses. Common mammals include white-tailed deer, raccoon, skunk (*Mephitis* spp.), opossum (*Didelphis virginiana*), muskrat (*Ondatra zibethicus*), mink (*Neovison vison*), coyote, ringtail (*Bassariscus astutus*), ocelot (*Leopardus pardalis*), and collard peccary (*Pecari tajacu*). Smaller herbivores include plains pocket gopher (*Geomys bursarius*), fulvous harvest mouse (*Reithrodontomys fulvescens*), northern pygmy mouse (*Baiomys taylori*), southern short-tailed shrew (*Blarina carolinensis*), and least shrew (*Cryptotis parva*). Birds include many wide-spread species, such as eastern bluebird (*Sialia sialis*), eastern meadowlark (*Sturnella magna*), grasshopper sparrow (*Ammodramus savannarum*), mourning dove, Cooper's hawk and mockingbird (*Mimus* spp.). Common amphibians and reptiles include eastern spadefoot toad (*Leptobrachium* spp.), Great Plains narrow mouthed frog (*Gastrophryne olivacea*), green toad (*Anaxyrus debilis*), yellow mud turtle (*Kinosternon flavescens*), Texas horned lizard (*Phrynosoma cornutum*), Texas spiny lizard (*Sceloporus olivaceus*), and Texas blind snake (*Leptotyphlops dulcis*).

3.8.5.3 Aquatic Resources

Aquatic systems within the Gulf Coast coal region range from arid western Texas to the subtropical Mississippi lowlands. Aquatic systems within this coal region are diverse in structure, flows, composition, and biota. Major rivers include the Chattahoochee, Mobile, Mississippi, Red, Brazos, and the Rio Grande Rivers.

3.8.5.3.1 Lotic Systems

A variety of flowing water habitats is present in the Gulf Coast coal region. These include ephemeral, intermittent, low order (first through third) and higher order (fourth through sixth) streams as well as rivers. A more detailed discussion about the general habitat features of these different types of streams is presented in Appendix C.

Streams in the Gulf Coast coal region create riparian habitat for plants and animals (U.S. EPA, 2006; Levick et al., 2008). Prairie streams found in this coal region tend to be either sand-bottomed or clay-bottomed; water in clay-bottomed prairie streams tends to have longer residence time and less water exchange with substrate when compared to sand-bottomed streams (Matthews, 1988). During summer months, the drying up of intermittent clay-bottomed streams creates small pools that provide habitat for aquatic fauna. Streams towards the humid-subtropical coastal areas of the coal region can be described as small to medium size perennial streams adjacent to larger rivers, and their arrangement within the watersheds follows a dendritic pattern. These are warm water streams, which have lower-gradient, moderate to high discharges, low turbulence, and rubble-sand-mud substrates (Winger, 1981; Felley, 1992; Hackney et al., 1992). Streams in the Gulf Coast tend to be acidic and low in conductivity, salinity, hardness, and nutrient levels, except in regions where streams drain over limestone bedrock high in phosphate (e.g., Peninsular Florida) (Felley, 1992). Streams in this region are also subject to pulsed floods that are crucial for moving nutrients and particulates downstream (Livingston, 1992).

Blackwater streams are more common along the coast than whitewater streams and alluvial rivers, and are unique in that they often contain more dissolved organic compounds than other streams (Smock and Gilinsky, 1992). The dissolved oxygen levels in medium to low gradient whitewater and alluvial streams tend to be high throughout most of the year, not dropping below 70 percent saturation (Felley, 1992; Hackney et al., 1992). Blackwater streams often face oxygen depletion during summer months as a result of increased temperatures. Furthermore, the oxygen concentrations in the hyporheic zones of smaller blackwater streams are low to anoxic during the warmer months (Smock and Gilinsky, 1992). Most upstream reaches and smaller streams are sand-bottomed. Discharge of streams in this province is seasonally variable and dependent on stream order (Felley, 1992; Hackney et al., 1992). Often, low flows occur from June through October. A period of higher flows occurs from November to May, where flows are highest from January to March (Felley, 1992; Smock and Gilinsky, 1992). Many headwater streams in this region tend to be intermittent and dry during the summer, leaving only isolated pools (Smock and Gilinsky, 1992). During the winter rains, most discharge flows through the floodplains surrounding the streams.

As described in Section 3.5 (see Table 3.5-5), it is estimated that there are a total of 175,925 miles of intermittent streams and 46,695 miles of perennial streams in this coal region. A more detailed discussion about the general habitat features and hydrology of these different types of streams is presented in Appendix C and Section 3.5.

3.8.5.3.1.1 Energy Flow/Primary Production

The productivity of lotic systems in the Gulf Coast varies spatially and temporally. Prairie streams exhibit productivity patterns similar to desert streams. Headwater streams of southern prairies are sunlit and lack forest cover. Matthews (1988) stated that these systems may be somewhat autochthonous in that filamentous algae may serve as significant primary producers. Bott et al. (1985) found higher rates of autochthonous production in prairie streams similar to desert streams, and Matthews (1988) further noted that streams that rely on allochthonous inputs obtain them from detritus from decaying grasses surrounding the streams.

The algal community of streams in the Gulf Coastal plain is dominated by diatoms and filamentous algae. Seasonal algal blooms often occur during the late winter and early spring months (Smock and Gilinsky, 1992). The distribution of filamentous algae and its extensive growth within the blackwater streams in the Gulf Coast region is related to the presence of beavers (*Castor canadensis*) and their effects on the local habitat (Smock and Gilinsky, 1992). Unicellular producers tend to be more important in slower moving waters in the downstream reaches of streams and are rare in areas with flowing water and dense, surrounding vegetative cover (Felley, 1992). Light is a limiting factor to primary production in blackwater streams; they also tend to have low rates of primary production and are primarily heterotrophic systems (Smock and Gilinsky, 1992). Animals in these systems exploit dissolved organic compounds as their primary source of food, and Smock and Gilinsky (1992) noted that detritus processing is dependent on hydrologic events that move organic material (e.g., leaves and debris) downstream to leaf-shredding macroinvertebrates. For blackwaters, these organisms are generally found in the perennial streams. In intermittent streams, isopods and amphipods are the predominant shredders. Floodplains serve as the functional headwaters of river systems in the Gulf Coast (Smock and Gilinsky, 1992).

Submerged plants are important contributors to the primary production of streams in the Gulf Coastal plain, providing food and also cover for various aquatic animals. Typically, submerged vegetation is not as abundant in headwater streams but becomes more common in higher-order streams of the province. Water nymphs (*Najas* spp.), coontails (*Ceratophyllum* spp.), bladderworts (*Utricularia* spp.), eel grass (*Vallisneria* spp.), exotic hydrilla (*Hydrilla verticillata*) and water hyacinth (*Eichoria crassipes*) are some submerged plant species found in the province (Felley, 1992; Hackney et al., 1992). A majority of the primary production in the low-order and upstream reaches of streams occurs in the riparian or wetland areas surrounding these streams.

Emergent plants are also important lotic producers found in this region, especially those surrounding headwater streams. Many species of emergent vegetation in the Gulf Coastal plain have adapted to periodic flooding and drought conditions and can grow on saturated and drying soil (Hackney et al., 1992). Tree species such as bald cypress (*Taxodium distichum*) and water tupelo (*Nyssa aquatica*), and various grasses and rushes (*Cladium* spp., *Juncus* spp., *Rynchspora* spp., etc.), grow along the edges of low gradient streams that may remain wet for most of the year. Such species are important because they stabilize the banks of these streams as well as supply cover and food for animals, influence stream temperature, and provide nutrient input to the streams (Felley, 1992). Floating plants such as duckweed, water lettuce (*Pistia stratiotes*), water hyacinth, and alligator weed (*Alternanthera philoxeroides*) are also common (Livingston, 1992). The U.S. EPA (2006) indicated that the streams assessed in the Gulf Coastal Plains ecoregion had good condition of vegetative cover on 52 percent of stream length. Floodplains of the streams in this region also have distinctive vegetation communities. Cypress swamps can be found along the coast from Florida to Texas, as can southern bottomland hardwood swamps (Livingston, 1992).

3.8.5.3.1.2 Invertebrates

The continental and subtropical areas of the Gulf Coast coal region contain high aquatic invertebrate diversity. Multiple studies have characterized the diverse arthropod communities found in the various small and mid-sized streams in the coastal plains (Berner, 1950; Beck, 1980; Barr and Chapin, 1988; Berner and Pescador, 1988; Felley, 1992). Berner (1950) found that southeastern coastal areas of the region had more mayfly genera than any other physiographic region of the U.S. The ephemeral and intermittent streams of prairie provinces tend to support lower aquatic macroinvertebrate diversity than coastal and temperate areas of the coal region (Matthews, 1988). The lack of aquatic macroinvertebrate diversity is likely attributable to unpredictable flows, homogenous substrates, and the prevalence of mud and sandy stream bottoms. In the prairie provinces, riffles in streams serve as optimal habitat for macroinvertebrates. Furthermore, spring-fed streams in prairie regions often have higher macroinvertebrate diversity than other prairie streams (Matthews, 1988).

Invertebrate biomass varies seasonally in Gulf Coastal streams, and seasonal biomass varies among drainages (Bass and Hitt, 1977, 1978; Bass et al., 1980; Felley, 1992). Smaller streams (orders 1 through 4) have lower biomass in the summer than larger streams (order 5 or greater) which tend to have peak biomass during these months (Felley, 1992). Furthermore, Felley (1992) noted that variations in invertebrate productivity within drainages are associated with habitat types. The more productive streams in coastal areas are those with vegetation or fine sand/mud substrates with detritus; productivity is lower in streams with clean, sandy bottoms (Felley, 1992).

The primary food source exploited by the invertebrates in smaller to medium streams in this coal region is detritus, which enters coastal plain streams during the fall, winter and early spring, and enters prairie streams in the spring and early summer. In headwaters, invertebrates tend to be collectors/gatherers and scrapers; further downstream, these organisms are important, but lower in numbers as predator abundance gradually increases (Felley, 1992). Prairie streams tend to have a lower abundance of shredders than those with abundant broad-leaved riparian vegetation, and much of the processing of particulate organic matter is done by microbes (Matthews, 1988). In the extreme headwaters of coastal areas, invertebrates (e.g., copepods, cladocerans, and rotifers) are abundant and restricted to pools and temporary ponds (Felley, 1992). Larger arthropods such as odonates, culicids, isopods, and amphipods are common throughout the various reaches of streams, including the headwaters. Oligochaetes and chironomids are the dominant taxa found in the more permanent streams, but ephemeropterans, ceratopogonids, and gastropods are also abundant (Felley; 1992). Riffle beetles (Elmidae) and trichopterans tend to be abundant in sand-bottom streams (Felley, 1992).

Crayfish species are extremely diverse in the southeastern U.S., especially within the Gulf Coast region. Crayfish found in the aquatic systems of the Gulf Coast coal region are ecologically important as predators, processors of organic materials, and as food sources for a variety of fish and terrestrial species (Taylor et al., 2007).

Most of the freshwater mussel species known to occur in the U.S. are distributed in the Southeast. Fifty-three of the 300 species known to occur in the U.S. occur in Texas, 175 occur in Alabama, 84 occur in

Mississippi, 63 occur in Louisiana, and 51 occur in Florida (Neves et al., 1997). The dominant mussel species in most Gulf Coastal streams are introduced Asiatic mussels (*Corbicula* spp.), but multiple native species reside in the larger perennial streams, some of which are endemic to the waters in which they are found.

3.8.5.3.1.3 Vertebrates

The southeastern U.S. is one of the most diverse regions for species of reptiles and amphibians. Snakes (*Nerodia* spp., *Farancia* spp., *Regina* spp., *Agkistrodon* spp.), turtles (*Sternotherus* spp., *Kinosternon* spp., *Clemmys* spp., *Chelydra* spp., *Pseudemys* spp., *Apalone* spp., *Graptemys* spp.), and alligators (*Alligator mississippiensis*) are some of the common reptile genera that can be found in small and medium-sized Gulf Coastal plain streams and their floodplains. Various frogs (*Rana* spp., *Pseudacris* spp., *Hyla* spp., *Acris* spp.), amphiuma (*Amphiuma* spp.), sirens (*Siren* spp.), waterdogs (*Necturus* spp.), and Ambystomatid and Plethodontid salamanders can be found as well. Many species are widely distributed and are represented by several subspecies. Felley (1992) noted that many species of map turtles (*Graptemys* spp.) found in this region are confined to particular drainages. Over half of the amphibian genera in the Southeast have species that live in small streams, seeps, bogs or swamps (Dodd, 1997; Meyer et al., 2003). Multiple species of stream salamanders require headwater seeps and small streams in forested habitats to maintain viable populations (Petranka, 1998; Meyer et al., 2003).

Fish assemblages in the Gulf Coast region tend to be very diverse. In a study conducted in prairie streams, stream size was the most important factor influencing the structure of fish assemblages (Fischer and Paukert, 2008). Spatially, fish communities of the coal region tend to become relatively more diverse from the arid western areas eastward to the more humid-subtropical areas. However, the diversity of fish communities is suspected to have decreased and become more homogenized over time (Hubbs et al., 1997).

Fish communities in the western plains tend be composed of species that have adapted to harsh seasonal conditions and are represented by generalists (e.g., cyprinids, catostomids, centrarchids, ictalurids, topminnows, etc.) (Fischer and Paukert, 2008). Fish diversity in prairie streams tends to be low because of higher saline waters and frequent droughts (Matthews, 1988). Cyprinids tend to be the dominant group of fish in prairie streams.

Fish communities of the coastal provinces are diverse and are comprised of warm water fish species such as sunfishes and black basses (Centrarchidae), darters (Percidae), minnows, suckers, and catfishes. In larger streams, black basses, gar (Lepisosteidae), bowfin (Amiidae), and catfishes are the dominant predators in these fish communities. Anadromous fishes include sturgeons (Ascipenseridae), shad (Clupeidae), and striped bass (Moronidae). There are few endemic freshwater fish species limited to the medium-low gradient streams of the province. Blackwater streams in this region are said to be more diverse than piedmont or mountain streams (Smock and Gilinsky, 1992). Ross and Baker (1983) noted that 42 species were found within a small Mississippi stream. Fish diversity increases with stream order (Livingston, 1992). Most species that are limited to the small to medium streams belong to genera that are considered to speciate readily: shiners (*Notropis spp.*), topminnows (*Fundulus spp.*), and darters (*Etheostoma spp.*) (Felley, 1992). Such species are considered to produce many eggs and have a protracted spawning season to assure that reproduction is successful despite dry periods or sudden disturbances (Heins and Clemmer, 1976; Heins and Rabito, 1986; Heins and Baker, 1987; Felley, 1992).

Coastal Plain streams and their floodplains are important spawning and nursery grounds for a variety of fish species.

3.8.5.3.2 Lentic Systems

Lentic systems in the Gulf Coast coal region tend to be variable. They are more ephemeral and intermittent in the arid and semi-arid provinces in the West, and are more permanent in the more humid, eastern provinces. Lentic systems in the Southwest Plateau and Plains Dry Steppe Province tend to be smaller intermittent or ephemeral wallows (called playa lakes) as well as some larger reservoirs. Lentic systems in the subtropical provinces (e.g., Prairie Parkland, Lower Mississippi Riverine Forest, Southeast Mixed Forest, and Outer Coastal Plain Mixed Forest) are mostly man-made impoundments and private ponds. Natural lentic systems in this coal region are fluvial lakes (Crisman, 1992). A subset of major lakes of the region includes the Toledo Bend (TX) and Sam Rayburn Reservoirs (TX/LA), and the massive lake-wetland complexes north of the Gulf Coast (U.S. EPA, 2009b). The Coastal Plains province is also home to a variety of lakes and ponds such as southeastern blackwater lakes, Carolina "Bays," and the limestone-rich clear lakes of the Florida peninsula (U.S. EPA, 2009b). Small impoundments and farm ponds are common in the coal region, and they are formed by impounding small perennial or intermittent streams (Menzel and Cooper, 1992).

The biotic communities of smaller ponds and impoundments in the region are more affected by natural and artificial outside influences as a result of their isolation from other water bodies. Generally, the small impoundments are constructed for water supply, recreation, and flood control. Water temperatures in these small ponds and impoundments often approximate that of the air temperature because of their small volume and shallow depth, resulting in seasonal stratification (Menzel and Cooper, 1992).

Natural lakes in the coal region usually discharge by simple overflow of surface water, whereas reservoir discharge is controlled by outlet structures that can be located at various depths. Southeastern reservoirs tend to be deep and stratify seasonally. Water released from these reservoirs is typically released from the dense bottom layer (Soballe et al., 1992). Released water can vary in nutrient content, but it tends to have cooler temperatures and the releases can have significant ecological effects on the receiving streams.

3.8.5.3.2.1 Energy Flow/Primary Production

Plants surrounding lentic systems in this coal region provide a significant amount of allochthonous energy input through leaf litter fall. The ponds, lakes, and reservoirs also receive sediments and additional nutrients from surface runoff during precipitation events, which can contribute to the energy balance. The species of phytoplankton found in lentic systems and their distribution depends on the size and location of the system. Often, smaller impoundments are dominated by benthic forms of algae that detach and become a part of the planktonic population (Menzel and Cooper, 1992). More planktonic forms and diatoms are more prevalent in larger systems. Stable water levels and prolific macrophytes prevent higher rates of primary production from occurring in reservoirs, but overall these systems tend to be nutrient-rich and moderately productive (Soballe et al., 1992). Seasonally, the algal community shifts from diatoms or green algae in the winter and spring, to blue-green algae during the summer and fall (Menzel and Cooper, 1992). Blue-green algae often become a dominant primary producer in areas that receive higher levels of nutrient inputs such as fertilizers with nitrogen and phosphorus or organic manures. Primary production by macrophytes is more important within smaller ponds and impoundments in this coal region compared to more northern latitudes, whereas phytoplankton provide much of the primary production in larger systems (Menzel and Cooper, 1992). Floating plants in lentic systems can become so dense that they shade out phytoplankton in the water column, which can lead to oxygen depletion and fish kills.

Emergent vegetation in the littoral zone varies across the coal region. Common herbaceous plants surrounding lentic systems include rushes, grasses, beggarticks (*Bidens* spp.), sedges, cattails, spikerush (*Eleocharis spp.)*, and marsh-purslane (*Ludwigia* spp.) (Menzel and Cooper, 1992). Trees such as red maple (*Acer rubrum*), hazel alder (*Alnus* spp.), sweetgum, willows (*Salix* spp.), and tupelo are common near the shores of lentic systems in this coal region.

3.8.5.3.2.2 Invertebrates

Cladocerans and copepods are major biomass contributors in lentic systems in this coal region, and they filter a significant amount of the detritus and serve as a critical link in the food chain between primary producers and fish (Menzel and Cooper, 1992; Soballe et al., 1992). Common genera of zooplankton include *Daphnia*, *Bosmina*, and *Mesocyclops*. Rotifers and protozoans also can be found, but tend to comprise a smaller percentage of biomass (Menzel and Cooper, 1992; Soballe et al., 1992). Chironomids also serve as an important food source for many species in lentic systems, including bluegill, brown bullhead, and golden shiner (*Notemigonus crysoleucas*) (Mozley, 1968; Menzel and Cooper, 1992).

3.8.5.3.2.3 Vertebrates

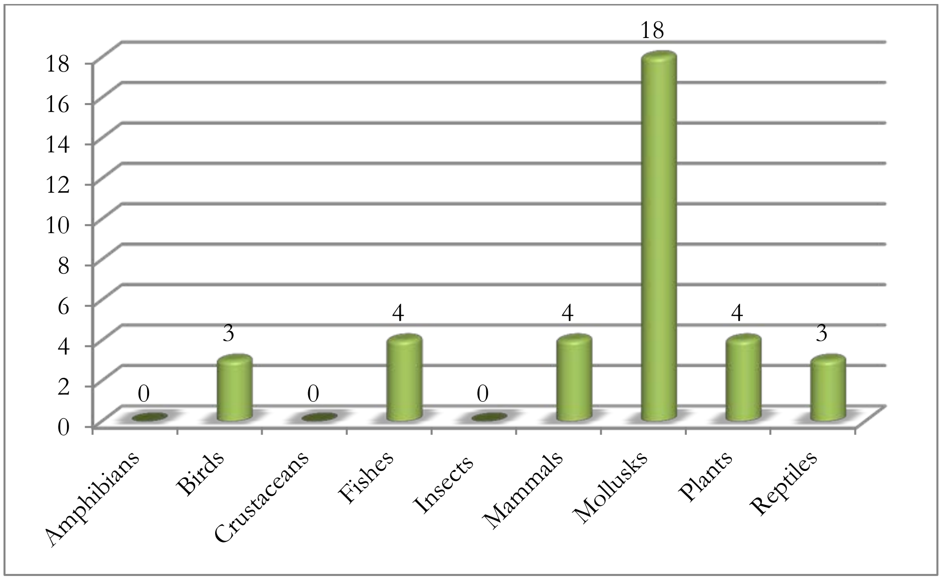
Lentic systems in the Gulf Coast coal region tend to have fish communities comprised of generalist species such as sunfishes, black basses, white bass (*Morone chrysops*), catfishes, perches, and suckers. In smaller impoundments, largemouth bass is the top predator and will eat many species of sunfishes, amphibians, reptiles, and even small birds and mammals (Menzel and Cooper, 1992). Sunfishes are important forage fish in lentic systems in the southeast, but they have the ability to overpopulate smaller systems and produce stunted individuals. Other common fish species that occur in lentic systems in this coal region are gar, bowfin, minnows, golden shiners (*Notemigonous crysoleucas*), topminnows, and introduced species such as the common carp (*Cyprinus carpio*). Many centrarchids, moronids, and ictalurids found in the lentic systems in the continental and subtropical areas support popular sport fisheries. Clupeid species (e.g., shads) are important prey for a number of the predatory fish in these lentic systems.

Reptiles and amphibians rely heavily on the littoral habitats of the lentic ecosystems for food and cover. Various species of snakes, lizards, and turtles also use littoral areas of lentic systems for foraging sites. Presence of reptiles in or near the aquatic systems in this coal region is positively correlated with increasing sedimentation, decreasing water depths, and increasing abundance of prey species (Menzel and Cooper, 1992). Amphibians, especially salamanders, tend to avoid lentic systems populated by predatory fish species (Kats et al., 1988; Figiel and Semlitsch, 1990; Kats et al., 1992). Ephemeral and intermittent ponds are especially important for breeding sites for ambystomatids like the marbled (*Ambystoma opacum*), spotted, and mole (*A. talpoideum*) salamanders, and various frog species during the fall, winter, and spring seasons.

3.8.5.4 Protected Species in the Coal Mining Areas of the Gulf Coast

In the Gulf Coast coal region, there are a total of 36 federally listed (and proposed listed) species. See Appendix F for the species names and status information. Figure 3.8-6 depicts the number of listed species and relative proportion for each taxonomic group.

Figure 3.8-6. Count of Federally Listed and Proposed Species in the Gulf Coast Region



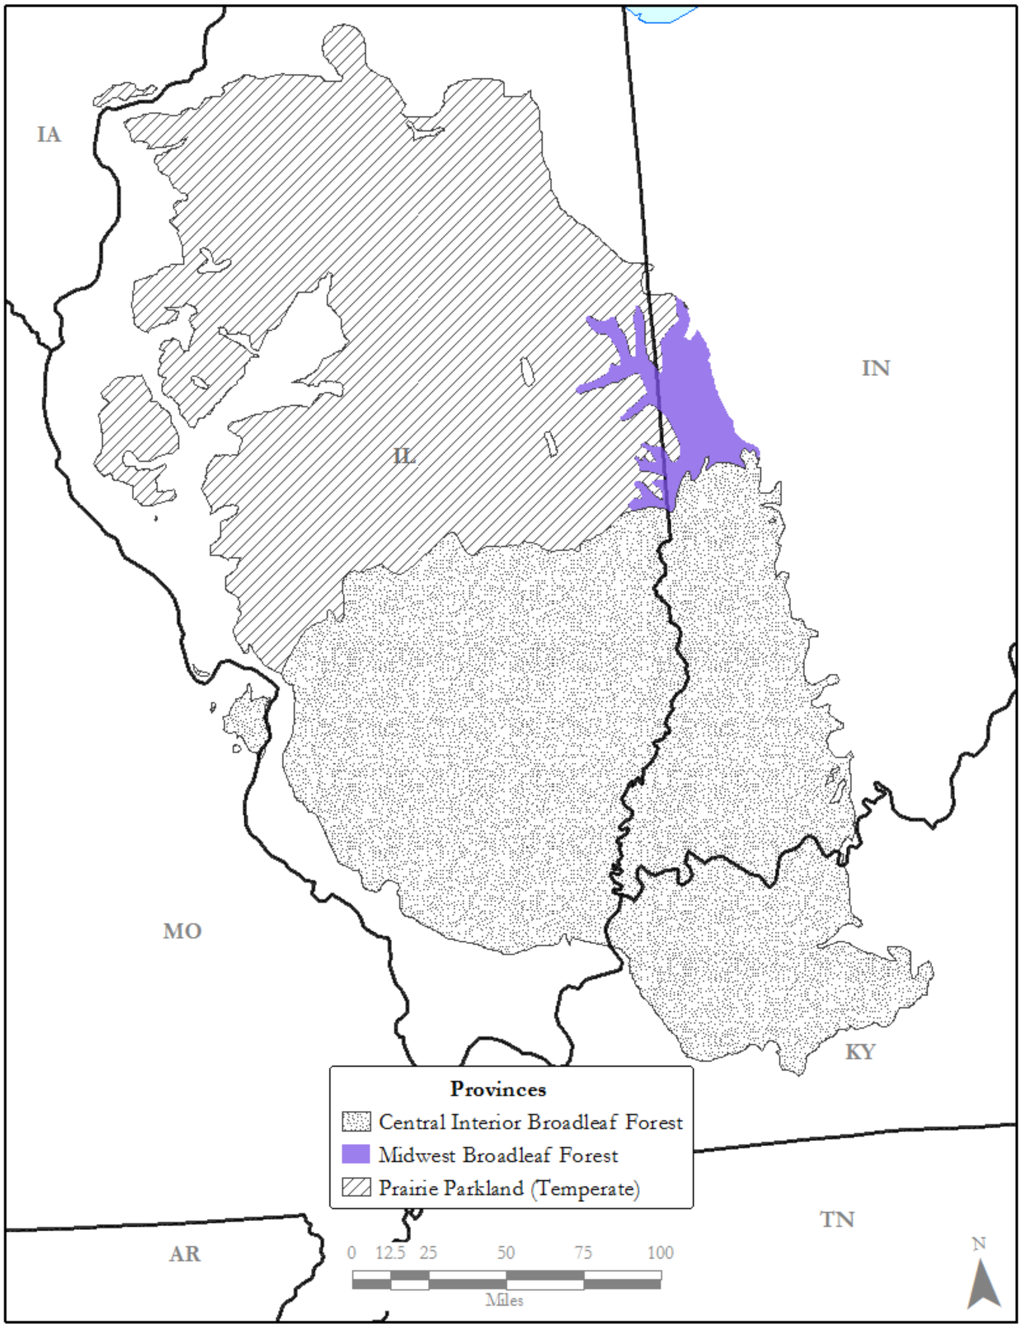
Mollusk species represent 50 percent of the total listed species in the Gulf Coast coal region. Mussels are sensitive to habitat alterations and dependent on flow conditions, which make their populations patchily distributed in rivers and streams. Within this region, there is fragmentation of streams and rivers from channeling, and impounding water that can eliminate subpopulations. The increase in distance between other populations can have major consequences for the metatpopulation structure of the species and diminish their resilence (*Muhlop and Vaughn, 1994*). Mollusks in this region are particularly impacted by changes in stream habitats caused by commercial fishing and invasive species. Hydrologic changes and habitat fragmentation increases their vulnerability to these stressors.

3.8.6 Illinois Basin Region

3.8.6.1 General Ecological Setting

The active mining in the Illinois Basin coal region stretches across three primary states: Illinois, Indiana, and Kentucky. Most of the coal region lies within the state of Illinois (Figure 3.8-7). Table 3.8-5 lists the ecological provinces located within this coal region and the approximate area of each.

Figure 3.8-7. Ecological Provinces Located within the Illinois Basin Region



Source: USFS, 2015, Ecological Provinces, http://data.fs.usda.gov/geodata/;

USGS, 2011, Coal Fields, http://nationalatlas.gov/atlasftp.html?openChapters=chpgeol#chpgeol

Table 3.8-5. USFS Provinces Associated with the Illinois Basin Region

Ecological Province	Area of Coal Region in Province (square miles)
Central Interior Broadleaf Forest	24,673
Midwest Broadleaf Forest	1,366
Prairie Parkland (Temperate)	21,936
Total	47,975

The descriptions provided below for the ecological provinces distributed within the Illinois Basin coal region come from Bailey (1995), Cleland et al. (1997), McNab and Avers (1994), and McNab et al. (2007). The common vegetation and fauna in each cover type are described briefly in Appendix G.

3.8.6.1.1 Prairie Parkland (Temperate) Province

This province covers an extensive area from Canada to Oklahoma, with alternating prairie and deciduous forest. The vegetation was once herbaceous with woodland of scattered deciduous broadleaf trees along floodplains of major rivers; almost all woodland has now been cleared for agriculture.

Stream and river systems in this province are well developed and have integrated dendritic drainage networks that are carved into the land surface. Allochthonous energy sources for streams in this province include plains with native vegetation of herbaceous prairies and woodlands (McNab et al., 2005). Illinois has a system of lakes dominated by manmade bodies of water ranging in scale from huge flood control reservoirs to worked-out stone quarries, gravel pits, and farm ponds (Illinois DNR, 1994a). Natural lakes and ponds are rare or non-existent in this province.

3.8.6.1.2 Midwest Broadleaf Forest Province

A description of the Midwest Broadleaf Forest province is provided above in Section 3.8.2. Streams in the Indiana portion of this province are in the Ohio River watershed. Lakes in this province are generally small to medium size. Wetlands are formed in extensive low-lying areas in former glacial lakebeds. There is moderate to high density of streams in this province; low gradient streams and rivers predominate, and typically have substrates composed of sand, gravel, bedrock, and boulders. Vegetation in this province consists of cold-deciduous, hardwood-dominated forests with a high proportion of species able to tolerate mild, brief, periodic drought during the late summer.

3.8.6.1.3 Central Interior Broadleaf Forest Province

A description of the Central Interior Broadleaf Forest province is provided above in Section 3.8.2. The geomorphology of the province leads to drainage areas of shallow entrenchment, and in some local areas, exposed limestone and sandstone bedrock. There is a moderate density of medium to large perennial streams, most with moderate volume of water at low velocity, composed of dendritic drainage patterns. This area has a handful of natural lakes from previous glacial events; however, most of the lakes in the region are manmade (Illinois DNR, 1994a). The few natural lentic systems in the Central Interior

Broadleaf Forest Province predominantly consist of lakes and wetlands in oxbows along the Kaskaskia, Big Muddy, and Wabash river flood plains.

3.8.6.2 Terrestrial Resources

The coal-producing portions of the Illinois Basin are characterized by mostly agricultural land, with natural vegetation consisting of oak-hickory, elm-ash-cottonwood, oak-gum-cypress, prairie, oak-pine, maple-beech-birch, and aspen-birch cover types. As mentioned above in the introduction to Section 3.8, native cover types in highly altered landscapes, like those found in the Illinois basin, can be rare.

Beginning in the northern portion of this coal region in central Illinois and Indiana, this area originally supported prairie vegetation with hardwood forests on scattered upland sites. Areas of tall prairie grasses are characterized by big bluestem (*Andropogon gerardii*), Indiangrass (*Sorghastrum nutans*), prairie dropseed (*Sporobolus heterolepis*), and switchgrass (*Panicum virgatum*). White oak (*Quercus alba*), shingle oak (*Quercus imbricaria*), black oak (*Quercus velutina*), hickory, white ash (*Fraxinus americana*), basswood, sugar maple (*Acer saccharum*), and walnut (*Juglans* spp.) grow on the better drained soils. Silver maple (*Acer saccharinum*), black willow (*Salix nigra*), cottonwood (*Populus* spp.), and sycamore grow on flood plains.

Some of the common wildlife species include white-tailed deer, jack rabbits (*Lepus* spp.), cottontails, opossum, and many small rodents. Common predators include swift foxes (*Vulpes velox*), kit foxes, bobcats, and coyotes. Grassland dwelling species are plentiful, for example bobwhites, horned larks, and meadowlarks (*Sturnella* spp.). Cooper's hawks, barred owls (*Strix varia*), and long-eared owls (*Asio otus*) are examples of year round residents. Common reptiles include snapping turtles (*Chelydra serpentina*), box turtles, bullfrogs, ringneck snakes (*Diadophis punctatus*), and bull snakes. Other common wildlife species include coyote, turkey, red fox (*Vulpes vulpes*), beaver, raccoon, skunk, muskrat, opossum, cottontail rabbit, fox squirrel, Canada goose (*Branta canadensis*) (*Ardea Herodias*), wood duck (*Aix sponsa*), mallard duck (Anas platyrhynchos), redheaded woodpecker (*Melanerpes erythrocephalus*), quail (*Coturnix coturnix*), and ring-necked pheasant.

Areas of southeastern Illinois originally supported tall prairie grasses, mainly big bluestem (*Andropogon gerardii*), Indiangrass (*Sorghastrum nutans*), prairie dropseed (*Sporobolus heterolepis*), and switchgrass (*Panicum virgatum*). The present potential for natural vegetation on these soils is unknown. Forests of post oak (*Quercus stellata*), swamp white oak (*Quercus bicolor*), blackjack oak (*Quercus marilandica*), and pin oak (*Quercus palustris*) grow on poorly drained soils. White oak (*Quercus alba*), shingle oak (*Quercus imbricaria*), black oak (*Quercus velutina*), hickory (*Fraxinus americana*), white ash, basswood (*Acer saccharum*), sugar maple (*Acer saccharum*), , and walnut (*Juglans spp.)* grow on the better drained soils. Species such as silver maple (*Acer saccharium*), black willow (*Salix nigra*), cottonwood (*Populus spp*.), and sycamore grow on the flood plains.

Some of the major wildlife species in this area are white-tailed deer, coyote, turkey, and bobwhite. Small mammals include masked shrew (*Sorex cinereus*), meadow vole (*Microtus pennsylvanicus*), and western harvest mouse (*Reithrodontomys megalotis*). Common avian species include black-capped chickadee (*Poecile atricapillus*), northern harrier, upland sandpiper (*Bartramia longicauda*), long-eared owl, and Henslow's sparrows (*Ammodramus henslowii*). Sora (*Porzana carolina*), black-crowned night herons (*Nycticorax nycticorax*) and veery (*Catharus fuscescens*) are found in sedge meadows and swamps.

Common amphibians include the Illinois chorus frog (*Pseudacris illinoensis*) and the Plains leopard frog (*Lithobates blairi*); common reptiles include the Kirtland's snake (*Clonophis kirtlandii*), and Illinois mud turtle (*Kinosternon flavescens*).

Areas of southwest Illinois, Missouri, southwest Indiana and Kentucky support natural hardwoods. Oak, hickory, beech, and sugar maple are the dominant species in the forest overstory. Native grasses grow in some scattered areas between the trees including big bluestem and little bluestem (*Schizachyrium scoparium*). The soils on lowlands support mixed forest vegetation. Pin oak, shingle oak, hickory, sweetgum, and black oak are the dominant species on the wetter sites. White oak, black oak, red oak (*Quercus rubra*), hickory, yellow-poplar, ash, sugar maple, and black walnut (*Juglans nigra*) grow on the better drained sites. Honeylocust (*Gleditsia triacanthos*) is dominant on soils that formed in shaly limestone residuum. Red cedar commonly grows on the shallower soils overlying limestone. Silver maple, cottonwood, sycamore, pin oak, river birch (*Betula nigra*), pecan (*Carya illinoinensis*), willow, cherrybark oak (*Quercus pagoda*), Shumard oak (*Quercus shumardii*), and sweetgum grow along rivers, streams, and floodplains. Black walnut is abundant on deep, well drained soils on some small flood plains. Sedge and grass meadows and scattered trees are on some lowland sites.

Some of the major wildlife species in this area are white-tailed deer, coyote, gray fox, red fox, beaver, raccoon, skunk, muskrat, opossum, mink, rabbit, fox squirrel, gray squirrel, Canada goose, turkey vulture, turkey, woodcock (*Scolopax* spp.), ruffed grouse, great horned owl, wood duck, pileated woodpecker (*Hylatomus pileatus*), red-bellied woodpecker (*Melanerpes carolinus*), ring-necked pheasant, and bobwhite. Canada geese and other waterfowl winter in large concentrations in the broader valleys and flat low lands. Forest–interior birds such as the Cerulean warbler (*Setophaga cerulea*) and the wood thrush live in the forested uplands, while the Swainson's warbler (*Limnothlypis swainsonii*) nests in the bottomland forests. Two common amphibians include the central newt (*Notophthalmus viridescens louisianensis*), zigzag salamander (*Plethodon dorsalis*). Eastern mud turtle (*Kinosternon subrubrum*) and worm snake (*Carphophis amoenus amoenus*) are important reptiles of the area.

3.8.6.3 Aquatic Resources

3.8.6.3.1 Lotic Systems

A variety of flowing water habitats is present in the Illinois Basin coal region. These include ephemeral, intermittent, low order (first through third) and higher order (fourth through sixth) streams as well as rivers. A more detailed discussion about the general habitat features of these different types of streams is presented in Appendix C.

The major rivers in the coal region include the Illinois, Ohio, Wabash, and the Upper Mississippi Rivers. The flat and rolling topography of the Illinois Basin has facilitated the development of these rivers and streams into predominantly dendritic drainage patterns. Historically, streams in this basin, particularly in Illinois, have been heavily impacted by anthropogenic manipulation and influence. Channelization has profoundly affected the function of many streams. More than 25 percent of the total length of sizeable streams in the Rock, Sangamon, Fox/Des Plaines, and Kankakee/Vermilion/Mackinaw basins has been straightened (Illinois DNR, 1994b). In addition, nearly every sizeable stream in Illinois is dammed in at least one spot, creating a total inventory of nearly 1,200 dams (Illinois DNR, 1994b). In large rivers, dams combined with high levees have prevented the natural flooding and drying cycle in the floodplains which formerly maintained a highly productive and diverse biota (Illinois DNR, 1994b). Physical changes remain a perturbing force in Illinois Basin stream ecology, with erosion and sedimentation among the current regional problems. Much of this sedimentation and erosion is attributed to agricultural activities and the lack of riparian vegetation.

The rivers and streams of the Illinois Basin coal region are affected by the surrounding land uses. Nutrient inputs (e.g., nitrogen and phosphorus) from terrestrial sources are important to aquatic systems as a unit of nutrient cycling. The transport of nutrients into aquatic systems in the Illinois Basin is largely attributed to nonpoint overland sheet flow (Gentry et al., 2007). However, there is a problem of excessive nutrient loads from nonpoint pollution sources in the Illinois Basin, contributing to poor water quality. Anthropogenic sources of phosphorus and nitrogen include sewage, agricultural runoff, lawn fertilizers, pet wastes, and atmospheric pollution (Dodson, 2005). Although sewage effluent is still a large nutrient source, agriculture has been identified as the major nonpoint source of nutrients to surface waters, due largely to the use of commercial fertilizers (Gentry et al., 2007).

As described in Section 3.5 (see Table 3.5-5), there are a total of approximately 70,645 miles of intermittent streams and 24,073 miles of perennial streams in this coal region. A more detailed discussion about the general habitat features and hydrology of these different types of streams is presented in Appendix C and Section 3.5.

3.8.6.3.1.1 Energy Flow/Primary Production

Carbon compounds have a large influence on ecosystem processes in these streams. The primary energy source for aquatic systems can be based on carbon fixed by photosynthesis within the system (autochthonous), or on inputs of carbon-containing organic materials from outside of the system (allochthonous). A common source of carbon is dissolved organic carbon (DOC), typically produced from particulate organic carbon, such as leaf litter inputs, which serve as an allochthonous energy source for Illinois Basin aquatic systems. Detritivores that remobilize carbon into food webs is an important part of energy production, particularly in small streams of the Illinois Basin (Hart and Reynolds, 2002). Carbon, particularly inorganic carbon, supports the major pH buffering system in freshwater (Dodson, 2005). A primary source of inorganic carbon in these streams is carbonate found in limestone and dolomite bedrocks and soils, which are common throughout the coal region (McNab et al., 2005).

Algal biomass consisting of cyanobacteria, filamentous chlorophytes, halophilic diatoms, and other diatoms comprises the most of the primary production in streams of this region. The species and type of these organisms is influenced by water chemistry, land use, and geology (Leland and Porter, 2000). Light and nutrients are key determinants controlling algal productivity.

Though the streams in this coal region are dominated by algal production, aquatic plants are also important to these ecosystems, providing food and cover for fauna, and recycling nutrients (Illinois DNR, 1994b). Many streams provide the shallow-water habitats that facilitate the development of rich aquatic plant communities. The growth and maintenance of these communities are dependent on slope, substrate, and the stability of stream discharge (Reid, 1961). In flowing waters, rooted aquatic plants are more common than floating species. Macrophytes common in streams in the Illinois coal basin include yellow water-lily (*Nuphar lutea*), arrowleaf (*Sagittaria* spp.), water-plantains (*Alisma* spp.), and creeping water primrose (*Ludwigia* sp.) (Roegge and Evans, 2003). Common herbaceous species which occur along the banks and shores of nearly all rivers and streams are woodreed (*Cinna arundinacea*), pony grass (*Eragrostis hypnoides*), sedges, tall hempweed (*Acnida altissima*), stalkless watercress (*Rorippa sessiliflora*), *Gerardia lenuifolia*, narrowleaf paleseed (*Leucospora multifida*), and willow aster (*Aster praealtus*) (Mohlenbrock et al., 1961). In the Illinois Basin common woody species along stream banks which contribute allochthonous carbon, stabilize banks, and shade the stream include American sycamore (*Platanus occidentalis*), river birch (*Betula nigra*), sandbar willow (*Salix interior*), and swamp chestnut (*Quercus michauxii*) (Mohlenbrock et al., 1961

3.8.6.3.1.2 Invertebrates

Segmented worms (Annelida) are typically abundant in the streams of the Illinois Basin. They consume considerable quantities of organic substances and the continual working of these burrowing species turn over much of the material in the sediment, which aids in the assimilation of carbon into the aquatic system (Reid, 1961). Annelids are also integral items in the diets of larger organisms, such as fish. Common stream insects in the Illinois Basin include stoneflies (Plecoptera); damselflies and dragon flies (Odonata); mayflies (Ephemeroptera); caddisflies (Tricoptera); mosquitoes, and blackflies and craneflies (Diptera). A large number of these insects shred and scrape decaying organic material, which aids in the assimilation of allochthonous inputs to the aquatic system (Dodson, 2005). Many aquatic insects are predatory, and actively feed on smaller insects and other invertebrates.

Mussels are important species in the aquatic systems of the Illinois Basin. Unionid mussels often constitute the highest percentage of biomass relative to other benthic stream animals; therefore, they are a key link in the food chain between aquatic microorganisms, such as algae and bacteria, and large animals that prey on them, like otter, turtles, fish, and hellbenders (Badra, 2005). The Illinois Basin is very rich in freshwater mussel diversity. Of the over 300 species of freshwater mussels known to occur in North America, approximately 27 percent (80 species) are known to occur in Illinois alone (Warren, 1995), and 104 species are known to occur in Kentucky (Cicerello and Schuster, 2003).

Crayfish are relatively common freshwater crustaceans that inhabit very diverse niches that include small streams, large rivers, lakes, and even subterranean environments (Fetzner Jr., 1996). Like freshwater mussels, crayfish are abundantly diverse in the Illinois Basin coal region. Illinois is home to 23 species, while 17 species are known to occur in Indiana, and 51 species in Kentucky (Fetzner Jr., 2010). These species totals represent only moderate overlap between states, as crayfish are commonly restricted geographically. Species of crayfish that are known to occur in each state of the Illinois Basin include devil crawfish (*Cambarus diogenes*), big water crayfish (*Cambarus robustus*), digger crayfish (*Fallicambarus fodiens*), calico crayfish (*Orconectes immunis*), virile crayfish (*Orconectes virilis*), and white river crawfish (*Procambarus acutus acutus*). Crayfish have significant roles in aquatic ecosystems and are a major component of the food web. They are omnivorous and process organic matter in addition to feeding on snails, small fish, and aquatic insects; they transform energy between different levels in the food chain and are themselves eaten by more than 240 predators (Butler et al., 2003).

3.8.6.3.1.3 Vertebrates

Amphibians account for a considerable portion of energy flow; their ingested energy is efficiently transferred to other trophic levels in the food web (Pough, 1980; Regester et al., 2005). In the Illinois Basin, salamanders are an abundant and diverse group and perform multiple ecological roles in aquatic systems (Regester et al., 2005). In Illinois, 20 species of salamanders are known to occur (Illinois Natural

History Survey, 2012). There are also 23 species in Indiana (Indiana DNR, 2013a), and 19 species in western Kentucky (WKU, 2010). Though some salamanders are terrestrial for much of the year and inhabit forest burrows or are found under logs, rocks, and leaves, they breed in water. Salamander larvae and aquatic adults rely on rivers, creeks, lakes, ponds, swamps, and ditches as habitat.

Due to their permeable skin, frogs are semi-aquatic. Frogs and toads typically depend on streams, ponds, or lakes for their larvae to develop in water. There are 22 species of frogs and toads in Illinois (Illinois Natural History Survey, 2012), 17 species in Indiana (Indiana DNR, 2013a; Indiana DNR, 2013b), and 16 species in western Kentucky (WKU, 2009). Like most amphibians, frogs are ecosystem indicators; because of their skin permeability, frogs are susceptible to the absorption of many pollutants in waters of poor quality. Frogs are an important component of the vertebrate food chain and are consumed by a variety of predators, including fish, snakes, and turtles (Moler, 1994).

Turtles (both aquatic and terrestrial) inhabit a unique blend of niches from wetlands to uplands. There are 17 species of turtles in Illinois (Illinois Natural History Survey, 2012), 18 species in Indiana (Indiana DNR, 2012; Indiana DNR, 2013a), and 17 species in Kentucky (Daviess County Audubon Society, 2011a).

There are a total of 39 species of snakes that inhabit Illinois (Illinois Natural History Survey, 2012), 33 species in Indiana (Indiana DNR, 2013a), and 44 species in Kentucky (Daviess County Audubon Society, 2011b). They dwell in forests, grasslands, marshes, swamps, ponds, lakes, streams, rivers, and sloughs. Many species are semi-aquatic and are important components of the food web that transfer energy between terrestrial and aquatic environments.

Fish assemblages are variable across the basin and depend on stream type. Species overlap between stream types is significant, and the descriptions below represent common assemblages.

Shallowly entrenched, slow-flowing, meandering streams are common in most of the Illinois Basin. Fish assemblages in this stream type commonly include largemouth bass, channel catfish, crappie, bluegill, yellow perch (*Perca flavescens*), striped shiner (*Luxilus chrysocephalus*), silverjaw minnow (*Notropis buccatus*), bluntnose minnow (*Pimephales notatus*), sand shiner (*Notropis stramineus*), quillback (*Carpiodes cyprinus*), and silver redhorse (*Moxostoma anisurum*) (OSMRE, 2008; Pescitelli and Rung, 2009). Medium to large perennial streams and associated rivers are common to the rolling landscapes throughout the Illinois Basin. Fish assemblages in this stream type commonly include smallmouth bass (*Micropterus dolomieu*), channel catfish, bluegill, walleye (*Sander vitreus*), the central stoneroller (*Campostoma anomalum*), the bluntnose minnow, the sand shiner, and the horny head chub (*Nocomis biguttatus*) (Pescitelli and Rung, 2009).

Upland clear, rocky streams are typically cool-water streams that are typically found in the upper reaches of watersheds. They are present across the Illinois Basin, but are more common in the southern tip of Illinois and western Kentucky. Fish assemblages in this stream type commonly include the central stoneroller, the bluntnose minnow, the sand shiner, the horny head chub, the spotfin shiner (*Cyprinella spiloptera*), striped shiner, large-scale stoneroller (*Campostoma oligolepis*), banded darter (*Etheostoma zonale*), creek chub, and the white sucker (*Catostomus commersonii*) (Pescitelli and Rung, 2009). Other species of note are the least brook lamprey (*Lampetra aepyptera*), blackspotted topminnow (*Fundulus olivaceus*), and the spottail darter (*Etheostoma squamiceps*) (OSMRE, 2008).

Anthropogenic impacts have drastically changed the fish assemblages in the Illinois Basin; from 1900-1994, approximately one in five fish species has been extirpated or is threatened by extinction (Illinois DNR, 1994b). Selective overfishing, extensive watershed modifications, draining of wetlands, and the introduction of exotics, sea lamprey (*Petromyzon marinus*), alewife (*Alosa pseudoharengus*), and salmonids (family Salmonidae), have all contributed to the decline of fish assemblages in the Illinois Basin (Karr et al., 1985).

3.8.6.3.2 Lentic Systems

Numerous lakes and wetlands exist in the Illinois Basin due to past geologic events and the construction of reservoirs and ponds. In contrast, natural lakes are rare in the prairie sections of Illinois. However, there are prairie potholes and historic oxbows along the floodplains of meandering streams and rivers.

Lentic systems have been heavily impacted by indirect filling through the process of erosion and sedimentation from agricultural activities in the Illinois Basin (Illinois DNR, 1994a). Unlike the flow-through system of streams, lakes tend to collect sediment and most of the pollutants that are washed into them. Thus, they function, in part, as environmental sinks for pollutants such as nitrogen- and phosphorous-containing compounds. This has resulted in excessive algal and macrophyte growth in ponds and lakes in the Illinois Basin caused by nutrients from farm fields and septic fields, such as hog and cattle lagoons (Illinois DNR, 1994a).

3.8.6.3.2.1 Energy Flow/Primary Production

In the Illinois Basin, the littoral zone of ponds and lakes generally extends from the depth of rooted plant growth, usually 15 to 25 feet deep, as submersed plants generally do not grow below a depth of 30 feet due to light and pressure limitations (O'Neal and Soulliere, 2006). A large number of plants contribute to primary production in the littoral zone and the shoreline. These plants are responsible for a significant portion of the primary production for the entire lentic systems (Ozimek et al., 1990; Wetzel, 2001). Common aquatic plants in lakes and ponds in the Illinois basin are similar to those listed above for the streams in this basin.

3.8.6.3.2.2 Invertebrates

The macroinvertebrates that are common in the lentic systems of the Illinois Basin can include annelids, plecopterans, odonates, ephemeropterans, trichopterans, and a variety of dipterans.

As mentioned above in the discussion for lentic systems, freshwater mussels are abundant and diverse in the Illinois Basin coal region. Different mussel species have varying habitat preferences, some live in large rivers, some in small creeks, and some in lentic systems with standing water, such as ponds or lakes. Their role in the food web, their water filtering activities, and their habitat production are very important to the aquatic systems the mussels inhabit.

Crayfish are abundant in lentic systems in the Illinois Basin. In ponds, crayfish are generally found in shallow waters such as the littoral zone and typically inhabit waters less than a meter in depth (Pennak, 1989). Despite this limitation, lakes and ponds can attain production as high as 1,500 pounds of crayfish per acre, though averages are usually closer to 100 pounds per acre (Pennak, 1989). This abundance indicates the importance of crayfish in lentic food webs, both for processing organic matter, and as a food source for turtles, fish, and otters (*Lontra Canadensis*).

3.8.6.3.2.3 Vertebrates

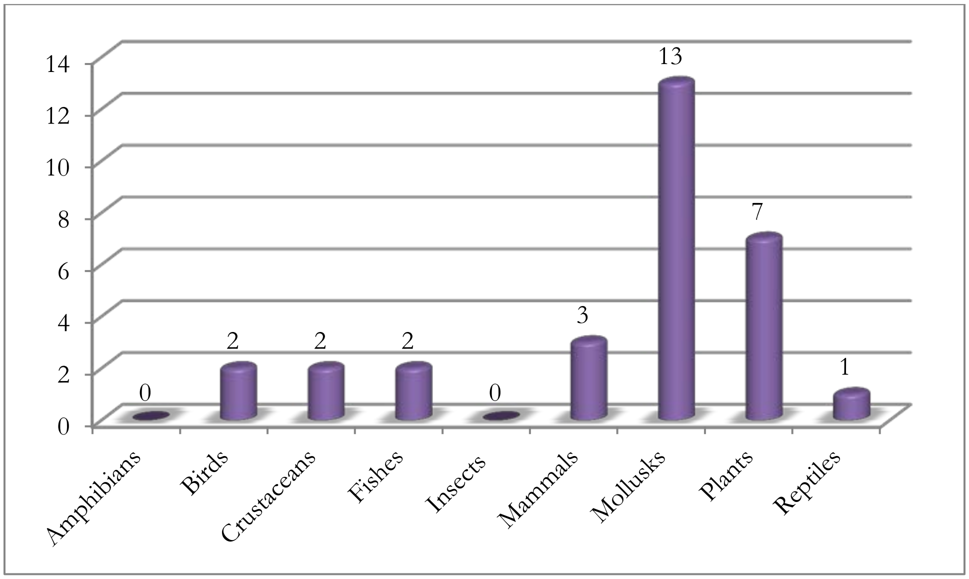
The importance of salamanders in the Illinois Basin was discussed above for lotic systems. Lentic systems are particularly important to terrestrial salamanders, which use ponds, lakes, and wetlands for reproduction and larval growth. As with lotic systems, the main threats to salamanders in lentic systems are habitat loss, fragmentation, and degradation. The draining or filling of wetlands can be a particular threat to terrestrial salamanders. Frogs and toads typically depend on streams, ponds, or lakes, for their larval development. They are an important component of the food chain in these lentic systems; they are abundant, efficiently transfer energy to other trophic levels in the food web, and are consumed by a variety of predators.

Reptiles are an important part of lentic systems in the Illinois Basin. Aquatic turtles can represent a significant portion of biomass in a lentic system. In a recent study in a southern Illinois lentic system, four of the ten turtles present were found to have a biomass greater than 55 pounds per acre (Dreslik et al., 2005). Semi-aquatic snake species are also important components of the food web because they transfer energy between terrestrial and lentic environments. In the lentic systems of Illinois, fish assemblages are usually a mix of warm water species and commonly include largemouth bass, bluegill, crappie, bullhead catfish, channel catfish, common carp, white bass, hybrid striped bass (*M. saxatilis* x *M. chrysops*), freshwater drum (*Aplodinotus grunniens*), and various sunfish species (Cruse and Wight, 1996a; Cruse and Wight, 1996b; Cruse and Wight, 1998). Other notable species in Illinois basin lentic systems include walleye, yellow bass (*Morone mississippiensis*), northern pike (*Esox lucius*), and muskellunge (*Esox masquinongy*) (Cruse and Wight, 1996a; Cruse and Wight, 1996b; Cruse and Wight, 1998). Historical selective overfishing, draining wetlands, and the introduction of exotics, especially the sea lamprey, alewife, and salmonids, have all contributed to the decline of fish assemblages in the Illinois Basin (Karr et al., 1985).

3.8.6.4 Protected Species in the Coal Mining Areas of the Illinois Basin Coal Region

In mining areas of the Illinois Basin coal region, there are a total of 30 federally listed (and proposed listed) species. Figure 3.8-8 depicts the number of listed species and relative proportion for each taxonomic group. The three mammals listed are all bats, including the recently listed Northern long-eared bat (*Myotis septentrionalis).* The Indiana bat's range stretches over 13 coal-producing states. The Indiana bat has experienced decades of decline associated with human disturbance and associated habitat loss. The fungal disease white-nose syndrome has had tremendous impact on bats in this region, including the Indiana bat. In 2009, a team comprised of representatives from OSMRE, U.S. FWS, and a representative group of state regulatory authorities developed, "Range-wide Indiana Bat Protection and Enhancement Plan (PEP) Guidelines." See Appendix F for all species names and status information.

Figure 3.8-8. Count of Federally Listed and Proposed Species in the Illinois Basin Region



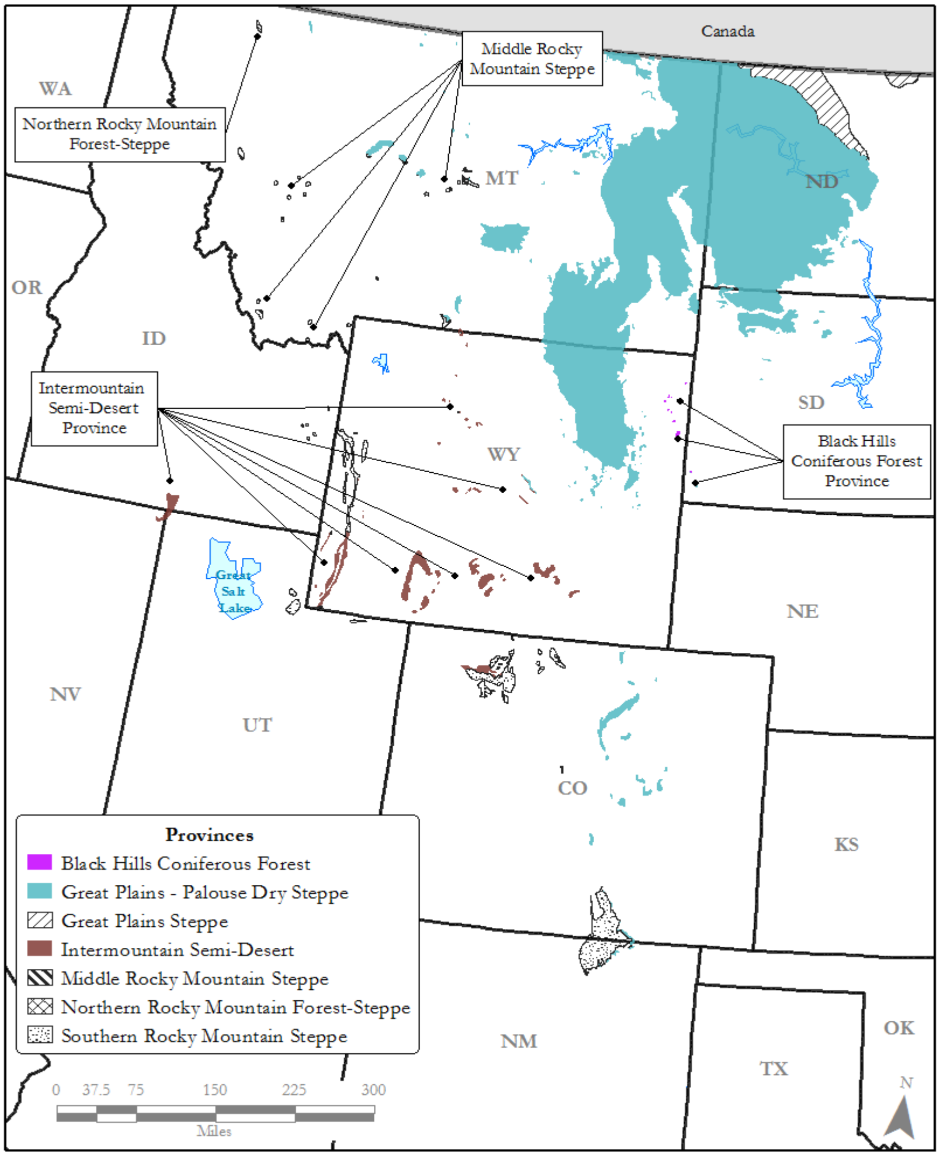
All the species listed in the Illinois Basin coal region are threatened by a variety of stressors including loss of habitat, non-point source pollution, erosion, and physical alterations to tributaries and riparian habitat. The endangered species are also at risk from a number of plant, and animal invasive species that grow and reproduce quickly, spread aggressively, and compete with native species for habitat. An example of invasive species threatening mussels is the zebra mussel (*Dreissena polymorpha*) and quagga mussel (*Dreissena bugensis*). Originally from Eastern Europe, both species were picked up in the ballast water of ocean-going ships and brought to the Great Lakes in the 1980s. By 1990 zebra mussels and quagga mussels had infested all of the Great Lakes and now both quagga mussels and zebra mussels have spread to 29 states on boats moving between the Great Lakes and Mississippi River Basins and further spread through artificial channels (NWF, 2016).

3.8.7 Northern Rocky Mountains and Great Plains Region

3.8.7.1 General Ecological Setting

The coal mining in the Northern Rocky Mountains and Great Plains region straddles the continental divide, including primary areas in Colorado, Wyoming, Montana, and North Dakota (Figure 3.8-9). A variety of physical and chemical factors affect the biological resources of this coal region. Table 3.8-6 lists the ecological provinces located within this coal region and the approximate area of each.

Figure 3.8-9. Ecological Provinces within the Northern Rocky Mountains and Great Plains



Region

USGS, 2011, Coal Fields, http://nationalatlas.gov/atlasftp.html?openChapters=chpgeol#chpgeol

Table 3.8-6. USFS Provinces Associated with the Northern Rocky Mountains and Great Plains Region

Ecological Province	Area of Coal Region in Province (square miles)
Great Plains - Palouse Dry Steppe	58,308
Great Plains Steppe	3,154
Intermountain Semi-Desert	2,046
Middle Rocky Mountain Steppe - Coniferous Forest - Alpine Meadow	306
Southern Rocky Mountain Steppe - Open Woodland - Coniferous Forest - Alpine Meadow	3,346
Northern Rocky Mountain Forest-Steppe - Coniferous Forest - Alpine Meadow	29
Black Hills Coniferous Forest	51
Total	67,242

The descriptions provided below for the ecological provinces distributed within the Northern Rocky Mountains and Great Plains coal region come from Bailey (1995), Cleland et al. (1997), McNab and Avers (1994), and McNab et al. (2007).

3.8.7.1.1 Great Plains-Palouse Dry Steppe Province

This region is characterized by rolling plains and tablelands of moderate relief. The vegetation in this province is predominantly herbaceous with lesser areas of shrubland. Major rivers in the province are large plains rivers such as the Platte, Missouri, and Arkansas.

3.8.7.1.2 Middle Rocky Mountain Steppe-Coniferous Forest-Alpine Meadow Province

The vegetation in this province is mainly evergreen, needleleaf forest that varies in composition with altitude, although lower slopes and plains are dominated by shrubland and herbaceous cover. Perennial streams have a dominant dendritic drainage pattern and are fairly widely spaced in the eastern portion of the province; however, drainage patterns are increasingly complicated in westward portions of the province due to complex geology. Larger streams such as the Salmon and Missouri Rivers also flow through the province and are often deeply incised in V-shaped canyons as they leave the mountains. Reservoir lakes, such as Holter Lake and Canyon Ferry Lake, are found in this province, while smaller natural alpine lakes produced by glacial events occur at higher elevations in the province.

3.8.7.1.3 Intermountain Semi-Desert Province

This province covers the plains and tablelands of the Columbia-Snake River Plateaus and Wyoming Basin. The plateaus include most of the Northwest’s lava fields. The vegetation in this province consists of shrubland on the plains and woodlands on steeper slopes.

Water is scarce in some areas of this province, though rivers exist. These include the Green River, the Lower Snake River, and Platte River. These rivers are moderate to deeply incised, have warm water, and are third to fifth order systems with dendritic drainage patterns. The province also supports some small and intermittent streams and cool water streams.

3.8.7.1.4 Great Plains Steppe Province

This region is characterized by flat and rolling plains. The vegetation of this province is predominantly herbaceous with woodlands along riparian areas of waterways.

Internal drainage patterns of warm water streams are complex, with many glacial pothole lakes and ponds, and some long, lineal drainages fed by a high density of dendritic drainages. In the coal region, the major river of the province is the Mouse River.

3.8.7.1.5 Southern Rocky Mountain Steppe – Open Woodland – Coniferous Forest – Alpine Meadow

A description of the Southern Rocky Mountain Steppe-Open Woodland-Coniferous Forest-Alpine Meadow province is provided above in Section 3.8.2. Rapidly flowing, cool water perennial rivers and streams occur in this province, including many short, steep tributaries with high water and sediment delivery efficiencies. Many lakes and wet meadows are associated with areas above 6,000 feet, occurring in glaciated terrain, as well as in high elevation cirques and basins. Major rivers in this province include the Platte and Canadian Rivers.

3.8.7.1.6 Northern Rocky Mountain Forest-Steppe - Coniferous Forest-Alpine Meadow Province

High-elevation, high-relief mountains are the main landforms in this province. Vegetation is mainly evergreen deciduous, needleleaf forest that varies in composition with altitude and aspect. Common cover types include lodgepole pine, fir-spruce, larch, and mountain grasslands.

3.8.7.1.7 Black Hills Coniferous Forest Province

The climate of this province is characterized by relatively long, cold winters and warm to hot summers. Annual precipitation is low and occurs mostly as snow. The ecoregion is a highly eroded, old, isolated, unglaciated large mountain dome of Precambrian origin that is surrounded by plains. The vegetation is forest, mostly of evergreen needleleaf species, although several deciduous broadleaf species common to more northern latitudes may be present. In Wyoming, this can be characterized by ponderosa pine and Great Plains grasslands cover types.

3.8.7.2 Terrestrial Resources

The Northern Rocky Mountains and Great Plains coal region includes numerous disconnected bands that extend across the north-central U.S., including portions of Montana, North Dakota, Wyoming, and Colorado. All of the ecoregion descriptions and vegetation cover type descriptions below are adapted from McNab et al. (2005 and 2007). The common vegetation and fauna in each cover type are described briefly in Appendix G.

Most of the area in this coal region is contained within four ecoregion provinces. In the less mountainous areas of Montana, North Dakota, Colorado, and Wyoming, the coal region is within the Great Plains-Palouse Dry Steppe Province. Vegetation in this province includes mountain grasslands, Great Plains grasslands, ponderosa pine, sagebrush, prairie, and pinyon-juniper cover types.

In the more mountainous regions along its northern side, the coal region is located within the Middle Rocky Mountain Steppe-Coniferous Forest-Alpine Meadow Province. Vegetation in this province includes Douglas fir, lodgepole pine, sagebrush, and mountain grasslands cover types.

In the mountainous regions south of the Middle Rocky Mountain Steppe-Coniferous Forest-Alpine Meadow Province is the Southern Rocky Mountain Steppe-Open Woodland-Coniferous Forest-Alpine Meadow Province. Vegetation in this province includes lodgepole pine, fir-spruce, sagebrush, alpine tundra, ponderosa pine, chaparral-mountain shrub, and hemlock-Sitka spruce cover types.

In southern Idaho, Wyoming, and Colorado, the coal belt is located within the Intermountain Semi-desert Province. Vegetation in this province includes sagebrush, desert shrub, chaparral-mountain shrub, Great Plains grasslands, pinyon-juniper, and Douglas-fir cover types.

Isolated areas of the coal belt are also located in Great Plains Steppe Province in northern North Dakota, characterized by Great Plains grasslands and aspen-birch cover types; the Northern Rocky Mountain Steppe-Coniferous Forest-Alpine Meadow Province in northwest Montana, characterized by lodgepole pine, fir-spruce, larch, and mountain grasslands cover types; and the Black Hills Coniferous Forest Province in east Wyoming, characterized by ponderosa pine and Great Plains grasslands cover types.

Beginning in the northern part of this coal region, the area of northeast Montana and northwest North Dakota moving through the central and southcentral portion of that state supports natural prairie vegetation characterized by western wheatgrass, needleandthread, green needlegrass, big bluestem, and blue grama. Little bluestem is an important species on the more sloping and shallower soils. Prairie cordgrass, northern reedgrass, and slim sedge are important species on wet soils. Western snowberry, stiff goldenrod, echinacea, and prairie rose are commonly interspersed throughout the area. The major wildlife species in this area are mule deer, whitetailed deer, red fox, raccoon, muskrat, mink, jackrabbit, fox squirrel, antelope, pheasant, sharp-tailed grouse, gray partridge, Hungarian partridge, sharptailed grouse, mourning dove, Canadian goose, mallard, blue-winged teal, pintail, and pelican.

The middle and southwest parts of North Dakota and northwest South Dakota support natural prairie vegetation characterized by western wheatgrass, needleandthread, green needlegrass, threadleaf sedge, and blue grama. Little bluestem, prairie sandreed, and sideoats grama are important species on shallow soils. Prairie rose, leadplant, and patches of western snowberry are interspersed throughout the area. Green ash, chokecherry, western snowberry, and buffaloberry occur in draws and narrow valleys. North-facing slopes support Rocky Mountain juniper, green ash, and chokecherry and an understory of little bluestem, porcupinegrass, and needleandthread. Some of the major wildlife species in this area are whitetailed deer, mule deer, pronghorn antelope, red fox, coyote, white-tailed jackrabbit, prairie dog, ring-necked pheasant, gray partridge, sharp-tailed grouse, hawks, turkey, ducks, and geese.

The area of central and southeast Montana supports grassland vegetation. Western wheatgrass, bluebunch wheatgrass, green needlegrass, and needleandthread are the dominant species. In the eastern part of the area, little bluestem replaces bluebunch wheatgrass as the dominant species. Some of the major wildlife species in this area are mule deer, white-tailed deer, antelope, coyote, fox, badger, beaver, raccoon, jackrabbit, cottontail, muskrat, mink, ground squirrel, pheasant, sharp-tailed grouse, Hungarian partridge, sage grouse, geese, and ducks.

Continuing south into northeast Wyoming, this area supports grassland vegetation. Rhizomatous wheatgrasses, green needlegrass, needleandthread, and blue grama are the dominant species on deep soils. Rhizomatous wheatgrasses, bluebunch wheatgrass, Indian ricegrass, and needleandthread are the major species on shallow soils on hills and ridges. Basin wildrye, green needlegrass, rhizomatous wheatgrasses, and shrubs are dominant along bottom land and streams. Big sagebrush is the dominant shrub. Some of the major wildlife species in this area are elk, deer, antelope, coyote, beaver, muskrat, jackrabbit, cottontail rabbit, sage grouse, and turkey.

Further south, through the lower half of Wyoming and the portions of Colorado and New Mexico within this coal region, the vegetation varies from one precipitation zone to another. The salt desert zone occurs in small areas receiving less than 8 inches (205 millimeters) of annual precipitation. The representative plant species are Gardner's saltbush, mat saltbush, greasewood, shadscale, bud sagebrush, winterfat, Indian ricegrass, and western wheatgrass. Wyoming big sagebrush may occur but only as a few widely spaced plants. A semi-desert grass-shrub zone, the largest in the MLRA, is characterized by a vast sagebrush steppe. This zone occurs in the areas receiving 8 to 16 inches (205 to 405 millimeters) of annual precipitation. The representative vegetation includes Wyoming big sagebrush, early sagebrush, antelope bitterbrush, bluebunch wheatgrass, western wheatgrass, prairie junegrass, needleandthread, and Indian ricegrass. Utah juniper may occur in small areas. Cottonwood and willows grow in riparian zones along the major perennial streams and rivers. A foothill-mountain zone in Wyoming is in the narrow mountain ranges that receive more than 16 inches (405 millimeters) of annual precipitation. The vegetation on these ranges includes ponderosa pine, limber pine, lodgepole pine, and Engelmann spruce and an understory of big sagebrush, Oregon-grape, Saskatoon serviceberry, antelope bitterbrush, bluebunch wheatgrass, and Idaho fescue. A lower foothill-mountain zone along the southern boundary of Wyoming and in Colorado occurs on the higher hills and mesas receiving more than 12 inches (305 millimeters) of annual precipitation. This zone is characterized by forested areas of Utah juniper with lesser amounts of pinyon pine and with an understory of Gambel oak, Wyoming big sagebrush, mountain mahogany, muttongrass, needleandthread, prairie junegrass, and Indian ricegrass. Some of the major wildlife species in this region are whitetailed prairie dog, white-tailed jackrabbit, desert cottontail rabbit, coyote, red fox, badger, pronghorn, mule deer, elk, sage grouse, golden eagle, bald eagle, screech owl, common raven, sage sparrow, Brewer's sparrow, western rattlesnake, and bull snake.

3.8.7.3 Aquatic Resources

The Northern Rocky Mountains and Great Plains coal region includes streams on both sides of the continental divide. The major rivers that drain to the Pacific include the Green, Colorado, and Snake Rivers. The major rivers that drain to the Atlantic include the Platte, Yellowstone, Missouri, Arkansas, and Canadian Rivers.

3.8.7.3.1 Lotic Systems

A variety of flowing water habitats is present in the Northern Rocky Mountains and Great Plains coal region. These include ephemeral, intermittent, low order (first through third) and higher order (fourth through sixth) streams as well as rivers. A more detailed discussion about the general habitat features of these different types of streams is presented in Appendix C.

The predominant stream type in the coal region varies with topography. In general, in the mountain and valley streams and rivers are often perennial (U.S. ACE, 2010). The lower relief topography of the plains and plateaus in this coal region, which are typically more arid, has predominantly ephemeral and intermittent streams. Although major rivers run through these areas, their headwaters are typically found outside of the semiarid regions in the Middle Rockies (U.S. ACE, 2010). These mountain headwater streams are rapidly flowing, having steep staircase-like channels with steps and plunge pools, and with pools and riffles appearing as stream slope decreases towards the plains and plateaus (U.S. EPA, 2006). Streams on the plains are typically low-sloped with riffles, runs, pools, and few rapids, and are often deeply incised as they exit mountainous areas. Many plains streams have intermittent stream flow with perennial pools that are sustained by groundwater (Peterson et al., 2009).

Many streams in this coal region have diversion dams or dams that are used for irrigation withdrawals and reservoirs, in addition to numerous small impoundments which have been built on small tributary streams (Peterson et al., 2009). The streams and rivers of the coal region have been influenced by a high level of disturbance, with riparian disturbance exceeding 38 percent in the mountains, and 62 percent in the plains (Stoddard et al., 2005). In addition, sedimentation from erosion and agricultural activities remain stream habitat stressors, with the vast majority of streams having low stream bed stability, indicating that their substrates are dominated by finer or smaller sediments than would be expected. In the plains, 40 percent of stream lengths have excessive sedimentation (Stoddard et al., 2005).

As described in Section 3.5 (see Table 3.5-5), it is estimated that there are a total of 147,003 miles of intermittent streams and 8,645 miles of perennial streams in this coal region. A more detailed discussion about the general habitat features and hydrology of these different types of streams is presented in Appendix C and Section 3.5.

3.8.7.3.1.1 Energy Flow/Primary Production

Streams in mountainous areas of the coal region drain forested catchments that provide abundant woody debris as an allochthonous energy source (U.S. EPA, 2006). At lower elevations, hardwoods in riparian corridors provide an allochthonous energy source of leaves and woody debris (Peterson et al., 2009).

Algal biomass consisting of cyanobacteria, filamentous chlorophytes, halophilic diatoms, and diatoms comprises a major unit of primary production in the stream of the Northern Rocky Mountains and Great Plains coal region. Although diatoms contribute the most to overall taxa richness, blue-green algae (cyanobacteria) and green algae account for a substantial amount of periphyton abundance in this coal region (Peterson et al., 2009). In heavily shaded mountain and canyon streams, light availability can be the overriding factor controlling the algal biomass and primary production, even in the presence of high nutrient concentrations (Mosisch et al., 2001). Although moderate algal biomass is recorded in lower elevation streams of the coal region, in mountainous areas concentrations of chlorophyll *a* (an indicator of algal biomass) have been found to be generally small, suggesting that primary production is higher in the lower elevations (Peterson et al., 2009). Non-algal macrophytes, such as bryophytes (liverworts, hornworts, and mosses), and emergent and aquatic vascular plants (e.g., sedges, rushes, grasses, and shrubs) are important primary producers. The growth and maintenance of the macrophyte communities are dependent on slope, substrate, and the stability of stream discharge (Reid, 1961).

3.8.7.3.1.2 Invertebrates

When sampling perennial and intermittent streams, the most abundant aquatic insects in the Northern Rocky Mountains and Great Plains include midges, mosquitoes, blackflies and craneflies (Diptera); mayflies (Ephemeroptera); caddisflies (Tricoptera); stoneflies (Plecoptera); beetles (Coleoptera); and damselflies and dragon flies (Odonata) (Peterson et al., 2009). A large number of these insects shred and scrape decaying organic material, which aids in the assimilation of allochthonous inputs to the aquatic system (Dodson, 2005). Many aquatic insects are predatory and actively feed on smaller insects and other invertebrates.

In areas of increased disturbance, chironomid (Chironomidae) and other groups like crustacean scuds, mites (Hydrachnidiae), and pond snails (Lymnaeoidea) increase in abundance.

3.8.7.3.1.3 Vertebrates

The fish assemblages the Northern Rocky Mountains and Great Plains coal region are diverse, as they include both cold- and warm-water species. However, these assemblages have been heavily impacted by the introduction of non-native fish species and loss of habitat due to stream alteration and damming. Rivers reaching the Pacific Ocean historically had large runs of salmon and trout, including pink salmon (*Oncorhynchus gorbuscha*), Chinook salmon (*O. tshawytscha*), Coho salmon (*O. kisutch*), and cutthroat trout (*O. clarkii*) (U.S. EPA, 2006). Non-native fishes were and are stocked as sport fish; the most common non-native species currently reported in the coal region are brown trout, brook trout, rainbow trout, common carp, smallmouth bass, green sunfish (*Lepomis cyanellus*), and largemouth bass (Stoddard et al., 2005). Other notable introduced species to the coal region include northern pike, yellow perch, rock bass (*Ambloplites rupestris*), northern plains killifish (*Fundulus kansae*), and bullhead catfishes.

Fish diversity can be high at sites in this coal region. In a recent fisheries survey in the Powder River Basin, an area that contains both cold- and warm-water habitats, 36 species were identified, but only 17 were native (Peterson et al., 2009). The most abundant species in that Powder River Basin study (in order of relative abundance) were fathead minnows (*Pimephales promelas*), smallmouth bass, sand shiners, rock bass, white suckers, common carp, green sunfish, and the shorthead redhorse (*Maxostoma macrolepidotum*). Fish assemblages in the coal region change in composition from the cooler waters in headwater and mountain streams to the warmer waters of lower sloped streams in the plains. These communities change from larger percentages of mountain sucker, white sucker, northern plains killifish, and longnose dace at sites farthest upstream, to larger percentages of channel catfish, stonecat, river carpsucker, and goldeye at the sites farthest downstream (Peterson et al., 2009).

In Wyoming, the heart of this coal region, there are 11 species of amphibians (Wyoming Game and Fish Department, 2005). Common aquatic species in the coal region’s largest coal area, the Powder River Basin, include Woodhouse’s toad (*Bufo woodhousii*), the northern leopard frog (*Rana pipiens*), the tiger salamander, and the boreal chorus frog (*Pseudacris maculata*) (Wyoming Game and Fish Department, 2005). The invasive bull frog is negatively influencing native species and has become well established throughout the coal region, competing for resources and habitat (Stoddard et al., 2005). Turtle diversity is low in this coal region; in Wyoming there are four species of turtles, three of which are aquatic, the western spiny softshell (*Apalone spinifera hartwegi*), the western painted turtle (*Chrysemys picta bellii*), and the snapping turtle (Cerovski et al., 2004).

3.8.7.3.2 Lentic Systems

In the Great Plains area there are glacial pothole lakes and ponds, along with many manmade impoundments and farm ponds. In the more mountainous areas of the coal region, reservoir lakes, such as Holter Lake and Canyon Ferry Lake are the main lentic systems, while smaller natural alpine lakes occur in glaciated terrain, as well as in high elevation cirques and basins (McNab and Avers, 1994). In the more arid areas of the coal region, some drainages lack outlets, producing temporary saline ponds and lakes (U.S. ACE, 2010).

3.8.7.3.2.1 Energy Flow/Primary Production

Allochthonous carbon sources are important to the lentic systems in this coal region. Litter fall from the surrounding forests of spruce, fir, hemlock, pine, Douglas fir, aspen, and cottonwood provides the major food supply for many invertebrate consumers. The arid climate and fluctuating precipitation throughout the year can cause variability in the shorelines of lakes and ponds, and can greatly reduce the amount of macrophytes present in some lentic systems. However, other lentic systems with perennial sources of water from streams and springs can provide habitat for the development and establishment of macrophyte communities. In the Northern Rocky Mountains and Great Plains, the littoral zone generally extends from the depth of rooted plant growth, usually 15 to 25 feet deep, as submersed plants generally do not grow below a depth of 30 feet due to light and pressure limitations (O'Neal and Soulliere, 2006). Aquatic macrophytes are responsible for a significant portion of the primary production for the lake systems (Ozimek et al., 1990; Wetzel, 2001). The macrophyte species present in lentic systems within the coal region do not generally differ from those that are known to occur in lotic systems.

3.8.7.3.2.2 Invertebrates

The macroinvertebrates that are common in the lentic systems of the Northern Rocky Mountains and Great Plains can include annelids, plecopterans, odonates, ephemeropterans, trichopterans, and dipterans.

3.8.7.3.2.3 Vertebrates

Amphibians found in natural alpine lakes are particularly impacted by introduced fish species that compete with amphibians for aquatic insects.

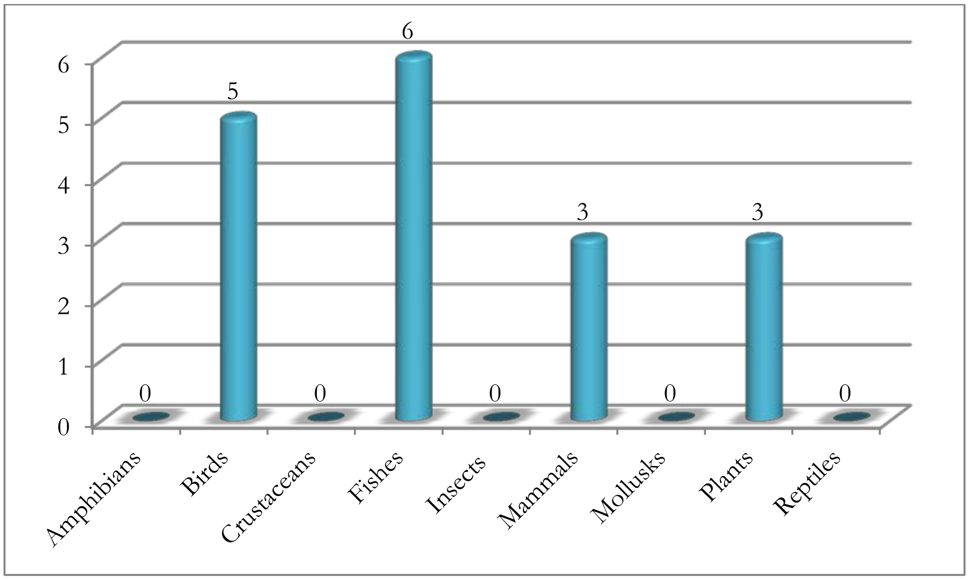
In the lentic systems of this coal region, fish assemblages generally include species similar to the lotic systems as described above. The non-native species that state agencies stock into lentic systems commonly move into lotic systems; threats to native fish assemblages remain from the introduction of exotic species, loss of habitat from sedimentation, and potential overfishing in lotic and lentic systems.

3.8.7.4 Protected Species in the Coal Mining Areas of the Northern Rocky Mountains and Great Plains

A total of 17 federally listed and proposed species occur in the active coal mining areas of the Northern Rocky Mountains and Great Plains coal region. Figure 3.8-10 depicts the number of listed species and relative proportion for each taxonomic group. See Appendix F for the species names and status information.

Primary threats to listed species in the active coal mining areas, as with other coal regions, include habitat loss and invasive species. Human population growth has resulted in the encroachment of human development into wildlife habitats. Additionally, road and pipeline construction has produced fragmented habitat and dangerous movement corridors, and collisions between wildlife and vehicles are a concern. Invasive species threaten listed species through direct habitat loss, deterioration of habitat, and displacement. (AFS, 2004)

Figure 3.8-10. Count of Federally Listed and Proposed Species in the Northern Rocky Mountains and Great Plains Region



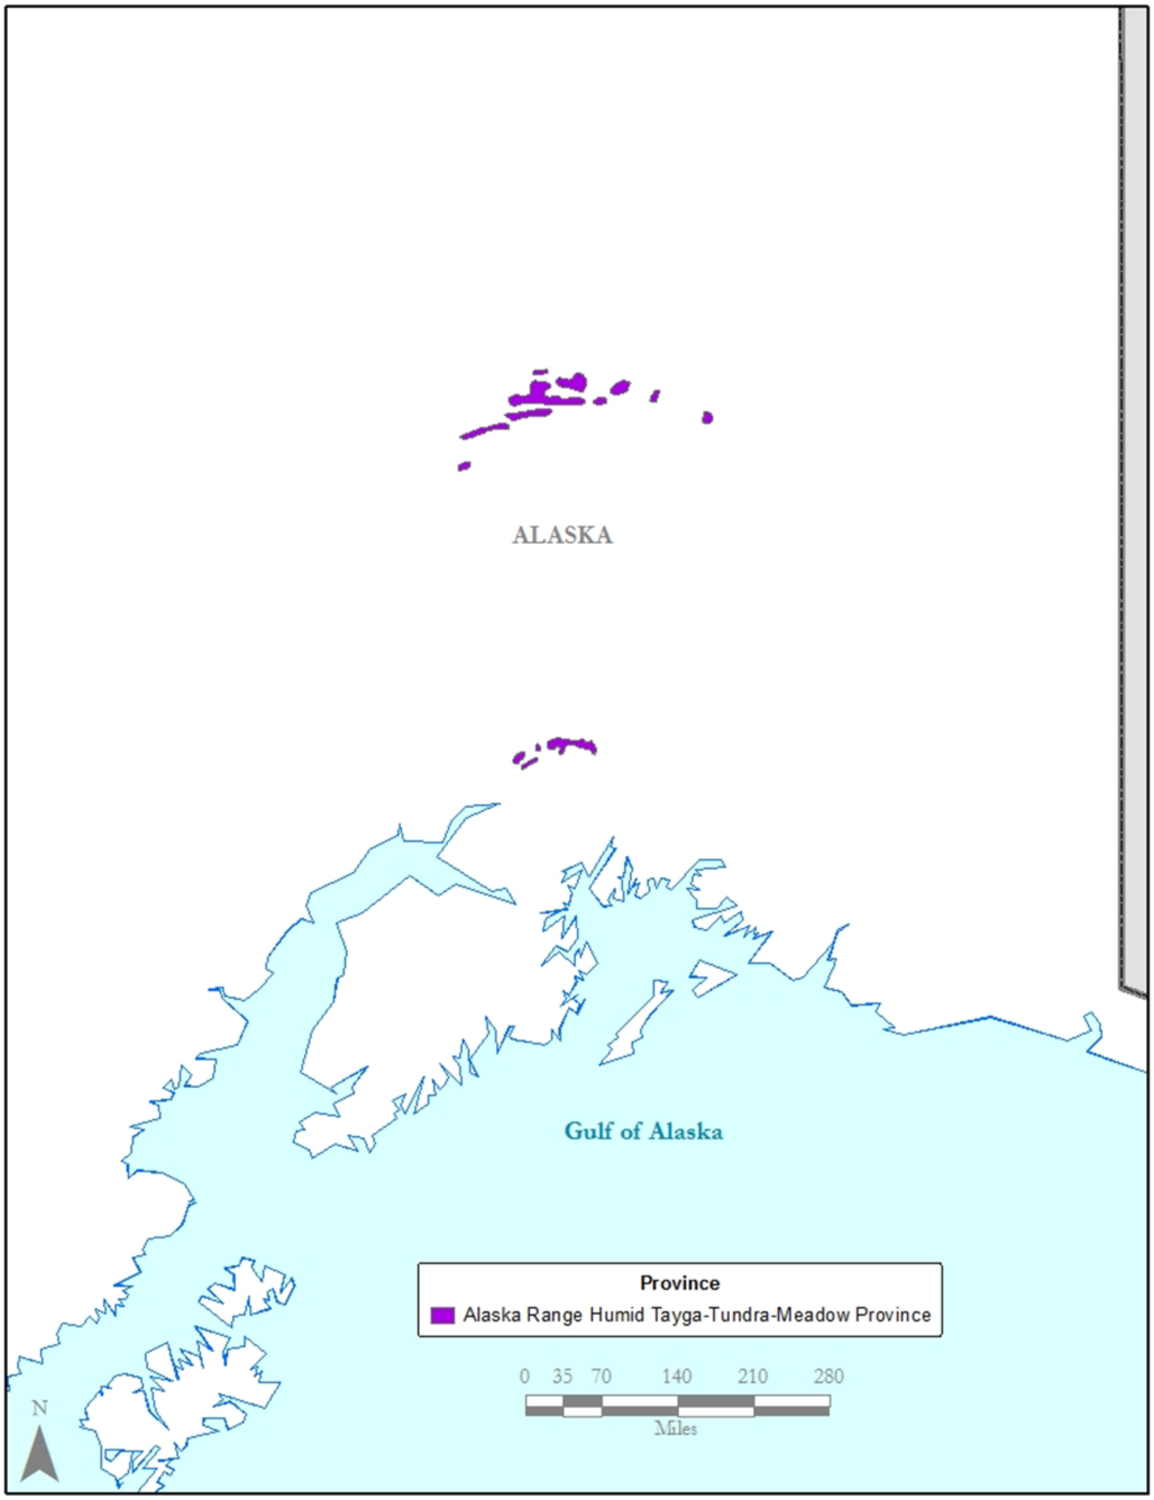
3.8.8 Northwest Region

3.8.8.1 General Ecological Setting

Presently, there is only one actively producing mine in the Northwest coal region, located near Healy, Alaska. This mine is located in Denali Borough, near the mouth of Healy Creek on the Nenana River in the Nenana coal field. Permits have been approved in the Matanuska coal field, but no active mine or mining exists here presently; however, mining could reasonably occur in the future.

Figure 3.8-11 shows the location of the two active Alaskan coal fields, which are both in the Alaska Range Humid Tayga-Tundra-Meadow ecosystem provinces in the Northwest region (Alaska). The Nenana is located in the north of the ecosystem province along the Alaska Range and the Matanuska on the southern edge of the ecosystem province. The description provided below for the Alaska Range Humid Tayga-Tundra-Meadow ecological province is from the USFS (2015) Ecosystem Map. Figure 3.8-11 presents the ecological provinces in the Northwest region, while Table 3.8-7 lists provinces derived from Gallant 1995 and their approximate area.

Figure 3.8-11. Ecological Provinces within the Northwest Region



Source: USFS, 2015, Ecological Provinces, http://data.fs.usda.gov/geodata/;

USGS, 2011, Coal Fields, http://nationalatlas.gov/atlasftp.html?openChapters=chpgeol#chpgeol

Table 3.8-7. Ecological Provinces Associated with the Northwest Region[9]

Ecological Province	Area of Coal Region in Province (square miles)
Interior Forested Lowlands and Uplands	16
Alaska Range	667
Cook Inlet	56
Total	739

The descriptions provided below for the ecological provinces distributed within the Northwest coal region come from Gallant et al. (1995).

3.8.8.1.1 Interior Forested Lowlands and Uplands Province

This ecoregion represents a patchwork of ecological characteristics. Region-wide unifying features include a lack of Pleistocene glaciations, a continental climate, a mantling of undifferentiated alluvium and slope deposits, a predominance of forests dominated by spruce and hardwood species, and a very high frequency of lightning fires. On this backdrop of characteristics is superimposed a finer-grained complex of vegetation communities resulting from the interplay of permafrost, surface water, fire, local relief, and hill slope aspect.

3.8.8.1.2 Alaska Range Province

The mountains of south-central Alaska, the Alaska Range, are very high and steep. This ecoregion is covered by rocky slopes, ice fields, and glaciers. Much of the area is barren of vegetation. Dwarf scrub communities are common at higher elevations and on windswept sites where vegetation does exist. The Alaska Range has a continental climatic regime but because of the extreme height of many of the ridges and peaks, annual precipitation at higher elevations is similar to that measured in some ecoregions as having a maritime climate.

3.8.8.1.3 Cook Inlet Province

Located in the south central part of Alaska adjacent to the Cook Inlet, the ecoregion has one of the mildest climates in the State. The climate, the level to rolling topography, and the coastal proximity have attracted most of the modern human settlement and development in Alaska. The region has a variety of vegetation communities but is dominated by stands of spruce and hardwood species. The area is generally free from permafrost. Unlike many of the other non-montaine ecoregions, the Cook Inlet Ecoregion was intensely glaciated during the Pleistocene epoch.

3.8.8.2 Terrestrial Resources

The Northwest coal region study area includes small coal areas in Alaska. Vegetation occurs in zones based on moisture and altitude. Dense stands of white spruce (*Picea glauca*) and cottonwood occur on the floodplains and low terraces of the Copper and Susitna Rivers within Alaska Range and Wrangell

[9] From Gallant et al. 1995

Mountains. Black spruce (*Picea mariana*) predominates in poorly drained areas above 1000 feet of elevation. Spruce-hardwood forests with components of white spruce, birch (*Betula* spp.), aspen (*Populus* spp.), and poplar (*Populus* spp.), and an understory dominated by moss, fern, grass, and berries are typical in areas up to the elevation of timberline (2,500 to 3,500 feet).

Coal resources occur in the area of the Cook Inlet and in the vicinity of the Copper River. Lowland spruce-hardwood forests are abundant in the Cook Inlet, with wet tundra communities along the coastline. Black spruce forests interspersed with tundra. The Copper River lowland is characterized by black spruce forest interspersed with large areas of brushy tundra. White spruce forests occur on south-facing gravelly moraines, and cottonwood-tall bush communities are common on large floodplains.

Upland sites within the region's lower elevation forest and subalpine zones are vegetated in white spruce, paper birch, and quaking aspen. On the southern Kenai Peninsula the vegetation changes and Lutz spruce becomes dominant. Cottonwoods and mixed cottonwood forests are common the flood plains and seepage areas of the mountain slopes. In the lowlands and peatlands white and black spruce woodlands occur, as do low scrub communities comprised of willows and ericaceous shrubs, with a variety of sedges and grasses in the meadows. The Cook Inlet coast is dominated by halophytic sedges and sedge-grass meadows. With the higher elevations of the subalpine zone the vegetation is again different with forest gradually giving way to grasslands of bluejoint reedgrass, tall alder scrub and low willow scrub. Dwarf scrub and herbaceous communities are characteristic in the alpine zone at and above 1800 to 2500 feet in elevation. Spruce bark beetle infestations have greatly impacted the white spruce, Lutz spruce and mixed spruce forests of the region, some of which occur in the coal-bearing areas. In some areas, the dominant forest canopy has been entirely killed off by bark beetles.

Within the true alpine zone, the primary species include a variety of dwarf scrub and herbs. Low willow scrub is common in drainages. Lichens and scattered herbs and dwarf shrubs dominate areas with exposed bedrock and very shallow soils. In general, there is little or no plant growth above about 7,500 feet (2,287 meters) elevation. Along the boundary with the Cook Inlet lowlands, there are stringers and inclusions of tall alder scrub and bluejoint reedgrass grassland, characteristic of the subalpine zone.

Common large mammals include caribou (*Rangifer tarandus*), introduced bison (McNab and Avers, 1994, Bailey, 1995, and McNab et al., 2005), moose (*Alces alces*), brown bear (*Ursus arctos*), and black bear (*Ursus americanus*). Dall sheep (*Ovis dalli*) are found in the high mountains. Typical small mammals include furbearers, such as marten (*Martes americana*), mink, shorttail (*Mustela ermine*), and least weasels (*Mustela nivalis*), as well as Hoary marmots (*Marmota caligata*) woodchucks (*Marmota monax)*, arctic ground squirrels (*Spermophilus parryii*) and northern flying squirrels (*Glaucomys sabrinus*), and longtail (*Microtus longicaudus*) and yellow-cheeked (*M. xanthognathus*).

In the true alpine zone, some of the major mammal species of the area include brown bear, Dall sheep, mountain goat, caribou, moose, wolf, coyote, fox, snowshoe hare, arctic ground squirrel, and hoary marmot. Ptarmigan, American golden plovers, golden eagles, and a wide variety of other birds are common in many places.

3.8.8.3 Aquatic Resources

In the Northwest coal region, each province has unique climatic, physiographic, and geologic properties that influence the types of aquatic systems and biota that occur within them.

3.8.8.3.1 Lotic Systems

A variety of flowing water habitats are present in the Northwest coal region. These include ephemeral, intermittent, low order (first through third) and higher order (fourth through sixth) streams as well as rivers. A more detailed discussion about the general habitat features of these different types of streams is presented in Appendix C.

Streams of Alaska vary both in both physical and hydrological aspects (Craig and McCart, 1975; Huryn et al., 2005), which results in a wide range of disturbance regimes. Differences in disturbance regime between mountain streams and perennial spring streams have been shown to result in large differences in biological communities (Parker and Huryn, 2006). Some species cope with these disturbances while some will develop in winter to avoid disturbance related to flood events (Danks, 2007). Streams with outlets to lakes have different temperature regimes and fauna (Hieber et al., 2002). Also, a study comparing food web structure and function of a mountain stream and a spring stream by Parker and Huryn (2006) indicated that macroinvertebrate taxa richness was greater in the spring stream than in the mountain stream. Further, the mean macroinvertebrate biomass was greater in the spring stream than in mountain stream, indicating significant differences between these two stream types in the volume of material and energy flow between food-web nodes.

Streams draining permafrost-dominated watersheds have a hydrologic regime characterized by low base flows, but high storm flows with the onset of snowmelt or rainfall (Smidt and Oswood, 2002). This differs from streams draining permafrost-free watersheds as the absence of permafrost allows deeper infiltration of precipitation, allowing greater and more sustained base flows and reduced storm flows (Woo and Winter, 1993). A study by MacLean et al. (1999) showed that stream chemistry (dissolved organic carbon, dissolved organic nitrogen, and dissolved inorganic nitrogen) in permafrost-dominated watersheds was more closely associated with the chemistry of organic horizons in the upper soil as compared to the chemistry of streams draining permafrost-free watersheds. The water chemistry of runoff from permafrost-free soils is controlled by contact between water and mineral soils. This study showed that streams in permafrost-dominated watersheds are likely to be more sensitive to nutrient inputs than those in permafrost-free watersheds. Material transport of dissolved materials into streams from surrounding terrestrial landscapes can have a significant influence on the ecology of stream organisms (MacLean et al., 1999).

As described in Section 3.5 (see Table 3.5-5), it is estimated that there are a total of 3,554 miles of intermittent streams and 2,912 miles of perennial streams in this coal region. A more detailed discussion about the general habitat features and hydrology of these different types of streams is presented in Appendix C and Section 3.5.

3.8.8.3.1.1 Energy Sources and Primary Production

Food webs in arctic Alaska are functionally seasonal and essentially no dependence on riparian vegetation exists; therefore, food webs are driven by primary production during the short summer and by old carbon from peat bogs during the long winter (Oswood et al., 2000). A study conducted by Peterson et al. (1993) on a tundra river on the north slope of Alaska found that the rocky cobble bottom of the river was colonized by filamentous algae, diatoms, and bacteria. Large amounts of organic matter were found to enter the river from peat eroding from the river banks and from dissolved organic matter leaching from the tundra landscape. Allochthonous organic matter inputs far outweighed autochthonous production of epilithic algae (Peterson et al., 1986). While allochthonous peat and dissolved organic matter strongly dominated the carbon cycle (Peterson et al., 1986), all trophic levels of the riverine food web were found to be highly responsive to fertilization by phosphorus and nitrogen, which primarily stimulated epilithic diatoms and filamentous algae.

A study by Huryn et al. (2005) identified 120 periphyton taxa from 24 streams on the northern slope of Alaska. Diatoms were found to be widespread; filamentous cyanobacteria were also observed.

3.8.8.3.1.2 Invertebrates

Typical freshwater invertebrates found in or associated with Alaskan lotic systems include Tricorythidae (mayflies), Amphipoda (malacostracan crustaceans), Rhyacophilidae and Systellognatha (stoneflies), Elmidae (riffle beetles), Hydroptilidae (micro-caddisflies), Brachycentridae (caddisflies), Oligochaeta (worms) (Corkum, 1989), and Chironomidae (Smidt and Oswood, 2002; King et al., 2012). According to Alaska's Comprehensive Wildlife Strategy (Alaska Department of Fish and Game, 2006) invertebrate species associated with clearwater river/streams include, but are not limited to, stoneflies (Plecoptera), mayflies (Ephemeroptera), caddisflies (Trichoptera), freshwater clams (Pelecypoda), and the Yukon floater mussel (*Anodontata beringiana*).

Diversity and abundance of benthic invertebrates in Alaska's tundra streams are higher than in mountain streams but less than in spring streams (Craig and McCart, 1975). Spring streams contain the greatest diversity of benthic invertebrates, and high densities of benthic invertebrates (10,000 organisms/square meter) occur in these streams (Craig and McCart, 1975). A study conducted by Huryn et al. (2005) found that macroinvertebrate community structure was distinct among stream categories. For instance, tundra streams had significantly greater filter feeder biomass than the other stream types, and filter feeders were absent from glacial streams. In mountain streams, predator biomass was greater than any other stream types where Perlodid stoneflies (e.g., *Arcynopteryx compacta* and *Isoperla sobria*) contributed an average of 87 percent to predator biomass.

In a recent small scale study in this region, first order streams, regardless of topographic or geomorphic setting, support relatively high numbers of macroinvertebrate taxa and at least one life history stage of salmonids (King et al., 2012). The majority of these invertebrates are consumers of grass litter, which is positively correlated with supporting juvenile stages of salmonids. This study also found that pH, water temperature, substrate composition, and channel morphology were significant variables in fish and macroinvertebrate composition.

3.8.8.3.1.3 Vertebrates

Reptiles and amphibians are of minimal importance in the freshwater aquatic systems in Alaska.

The fishes with perhaps the greatest biologic and economic importance in the Northwest coal region are the salmonid species, which include salmon, trout, char, grayling, and whitefish. Salmonids require relatively cold freshwater habitats with high water quality and diverse habitat to complete all stages of their life cycle. Salmon typically use large stream and river systems but can also be found in smaller coastal streams (U.S. BLM, 2008; King et al., 2012). The vast majority of salmonids are anadromous; their life cycle includes spawning and early development in freshwater systems, followed by foraging activities in the ocean during juvenile stages, and finally returning to freshwater systems to spawn.

According to studies reviewed by Oswood et al. (2000), fish faunas vary from the Arctic region to the panhandle of southeast Alaska due to ecological differences over the latitudinal and marine-continental gradients of Alaska. Combined high latitude and high elevation attributes of the high mountains of Alaska create barriers to fish exchanges across headwater divides, which may result in the greater differences in fish faunas compared to regions separated by low mountains and lowlands. During the winter, the headwater streams of the Brooks Range and Alaska Range mountains can be either partially or completely dewatered and covered with ice, forcing fish to migrate to suitable overwintering areas downstream. Loss of winter habitat from substratum freezing requires that most fish migrate out to sea or move to suitable overwintering locations, which are primarily perennially flowing springs.

Based on a study conducted by Craig and McCart (1975), mountain streams have low biological productivity during the summer compared to tundra streams and spring-fed streams. In mountain and spring streams, arctic char (*Salvelinus alpinus*) are commonly found, and grayling (*Thymallus arcticus*) also occur. Tundra streams are used as spawning and rearing grounds by grayling. Other fish species found in arctic streams included round whitefish (*Prosopium cylindraceum*), slimy sculpin, and ninespine stickleback (*Pungitius pungitius*).

According to Alaska's Comprehensive Wildlife Strategy (Alaska Department of Fish and Game, 2006), fish species associated with glacial river/streams include rainbow smelt (*Osmerus mordax*), eulachon (*Thaleichthys pacificus*), longfin smelt (*Spirinchus thaleichthys*), and pygmy whitefish (*Prosopium coulteri*). Species associated with clearwater river/stream include, but are not limited to, Alaska blackfish (*Dallia pectoralis*), arctic lamprey (*Lampetra camtschatica*), broad whitefish (*Coregonus nasus*), and ninespine stickleback. The trout-perch (*Percopsis omiscomaycus*) is an endemic species found in the Yukon River.

A study conducted by Adams et al. (1993) at two refuges on the Alaska Peninsula (Bering Tundra Province) found that length, weight, and age characteristics of chum (*Oncorhynchus keta*), coho salmon (*Oncorhynchus kisutch*), sockeye salmon, and Arctic char from the study area generally exhibit similar characteristics to other Alaska populations. This study also found that tundra streams exhibited greater fish species diversity than upland streams, and that the mean lengths of juvenile coho salmon captured from tundra streams were greater than those captured from upland streams.

3.8.8.3.2 Lentic Systems

According to Alaska's Comprehensive Wildlife Strategy (Alaska Department of Fish and Game, 2006), Alaska has more than three million lakes greater than five acres in size, many of which are distributed in the coal region. Lakes are differentiated by the Alaska Department of Fish and Game (2006) as either glacier influenced or clearwater lakes. Lakes can also form as a result of glaciers flowing across tributary valleys and trapping runoff. Most of the state's lakes are glacially formed, particularly those in the southwest and south-central portions of the state. Glacial lakes are important to both resident and anadromous fishes for overwintering. Clearwater lakes can have surface or groundwater sources, or both, and water levels, thermal regimes, and chemical composition are determined by flow regime, groundwater source, and connectivity. Alaska has many isolated lakes with no surface water connection; examples include lakes/ponds of thermokarst, fluvial, and volcanic origin. Subsurface flows may still exist with isolated lakes/ponds such as through underlying permafrost. Isolated lakes/ponds tend to have unique biological assemblages; however, most isolated lakes/ponds provide the same functions as non-isolated systems.

3.8.8.3.2.1 Energy Sources and Primary Production

A study conducted by Goldman (1960) produced the following results and observations. Photosynthetic carbon fixation by phytoplankton and bacteria demonstrated to represent the major part of the organic production in Alaskan lakes; chemosynthetic productivity is of secondary importance. Changes and differences in productivity may influence the rate of accumulation of organic matter in successive trophic levels. Results in Naknek Lake, Brooks Lake, and Lake Becharof on the Alaska Peninsula found that primary productivity per unit volume at comparable depths consistently increased towards the tributary end of the lake and that magnesium was a limiting factor for phytoplankton production throughout the summer. Seasonal changes in the total phytoplankton at Brooks Lake supported the relationship between standing crop and rate of production estimates for major changes in productivity during a season, although it was noted in this study that standing crop measurements would give very unreliable values for the rate of production if nutrient or other factors are limiting. Diatoms were the dominant algal phylum followed by green algae.

According to studies reviewed by Pfauth and Sytsma (2005), native aquatic plants found in lentic systems in Alaska include 15 species of pondweed (*Potamogeton* spp.), two species of water milfoil (*Myriophyllum* spp.) as well as duckweeds, and bladderworts. This survey also reported that in southern (Kenai Peninsula) and central (near Telin National Wildlife Refuge) portions of Alaska 33 submersed and floating-leaved aquatic plant species were found and included two aquatic mosses, one macro-alga, and one liverwort. Non-native aquatic plant species were not discovered during this survey.

3.8.8.3.2.2 Invertebrates

Small invertebrates associated with lakes and ponds differ from those found in streams and rivers. Lake/pond dwelling insects or benthic invertebrates live in the bottom sediments on aquatic plants and are an important food source for fish. Invertebrate species commonly associated with lakes/ponds in Alaska include, but are not limited to, dragonflies (suborder Anisoptera), damselflies (Suborder Zygoptera), mayflies, water fleas (*Daphnia* spp.), and bivalve mollusks such as the Yukon floater. Water fleas are the dominant plankton found in freshwater habitats and are an important food source for fish and predatory insects. The invertebrates of the Northwest Coal region do not greatly differ between lotic and lentic aquatic systems. Common aquatic invertebrates in the region include mayfly, stonefly nymphs, caddisfly larvae, Riffle beetles, fly larvae, aquatic worms, roundworms, freshwater earthworms, amphipods, and mollusks (U.S. EPA, 2009b). However, invertebrates more common in lentic systems than lotic include benthic organisms such as dragonfly and damselfly larvae, mayfly nymphs, water fleas (*Daphnia* spp.), and some bivalve mollusks.

3.8.8.3.2.3 Vertebrates

There are only six native species of amphibians in Alaska that have an association with lotic systems; these species are also found in lentic systems. Of these six species, only two, the wood frog and the western toad (*Bufo boreas)* are thought to possibly occur in the Nenana and/or Matanuska coal fields. The wood frog is widely distributed throughout Alaska and is the only amphibian found above the Arctic Circle (MacDonald, 2010). The western toad, Alaska’s only toad species, has a recorded distribution from southeast Alaska along the mainland coast to Prince William Sound (Alaska Department of Fish and Game, 2006). Non-native species associated with aquatic environments (both lotic and lentic) that are known to occur in Alaska include the Pacific chorus frog (*Pseudacris regilla*) that breeds in slow-moving streams as well as marshes, lakes, ponds; and the red-legged frog (*Rana aurora*) whose habitat includes quiet permanent waters of streams, marshes, or ponds (McClory and Gotthardt, 2008; Alaska Department of Fish and Game, 2006; MacDonald, 2010).

3.8.8.4 Protected Species in the Coal Mining Areas of the Northwest

Upon review of the U.S. FWS species list OSMRE determined that there were no federally listed or proposed species within the area of direct or indirect effects from coal mining. Therefore no listed species are identified here for this region.

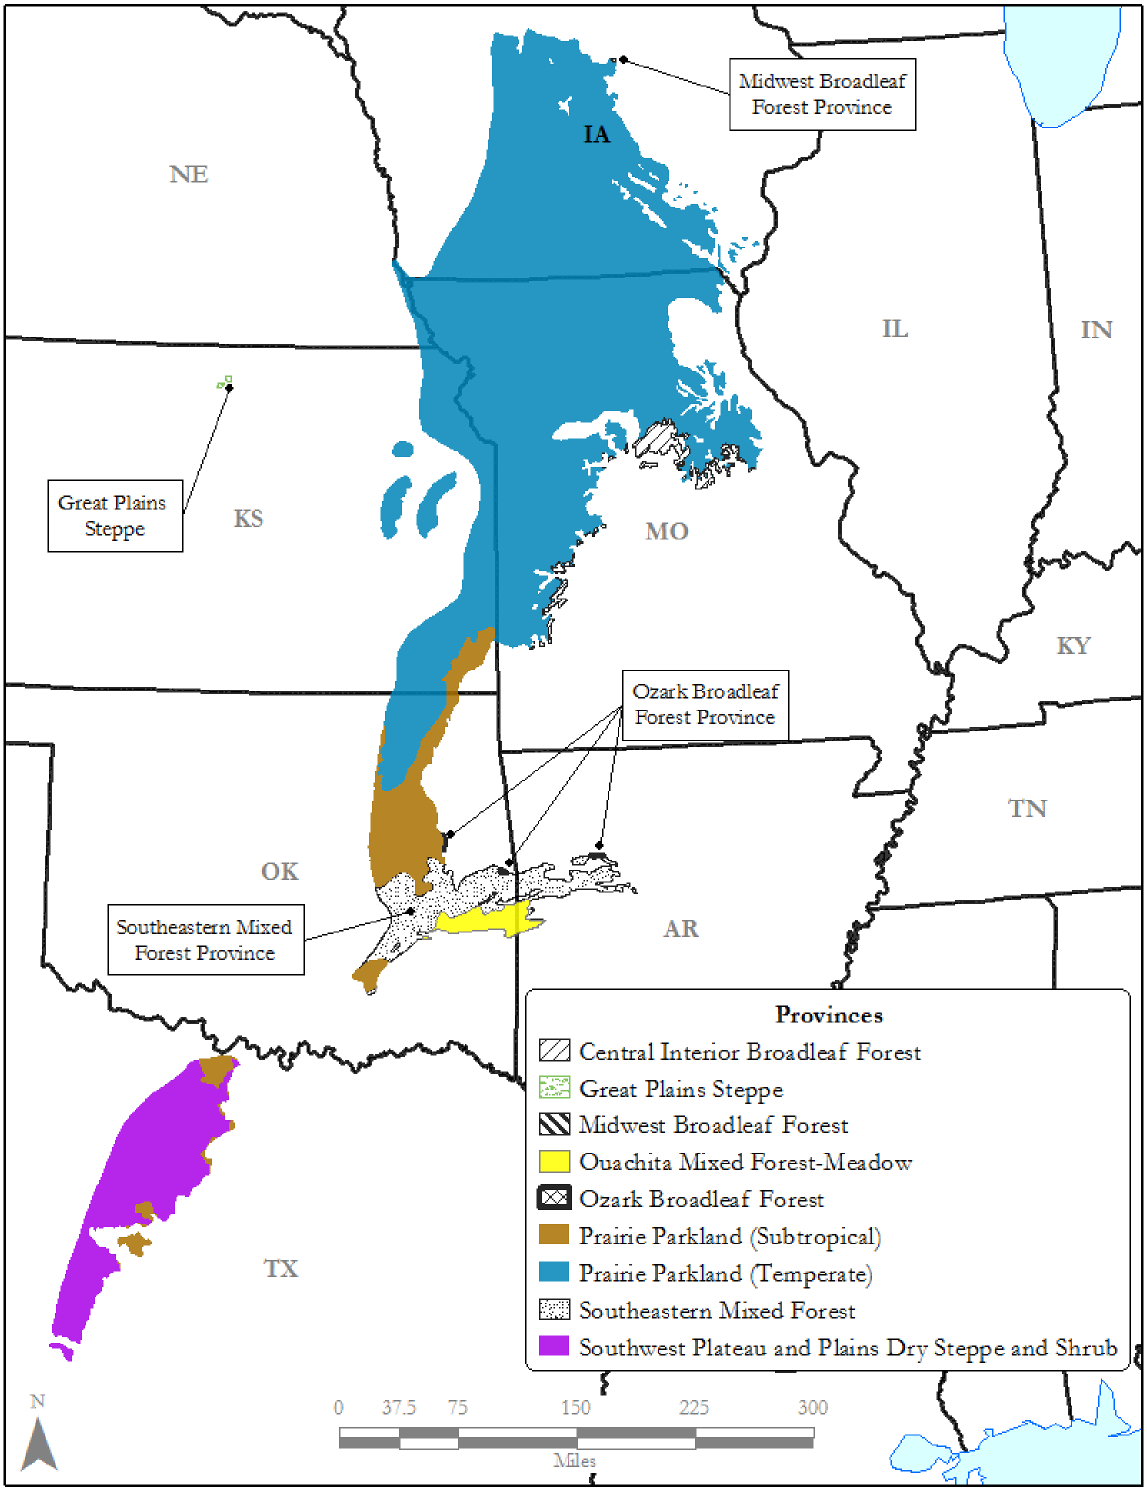
3.8.9 Western Interior Coal-Producing Region

The Western Interior coal region is described by three coal basins, the Arkoma, the Cherokee and the Forest City Basins (U.S. EPA, 2004a). The counties with active mines in these three coal basins are distributed in four states including Arkansas, Oklahoma, Kansas, and Missouri (Figure 3.8-12).

3.8.9.1 General Ecological Setting

A wide variety of habitat types are distributed in this coal region because of the geographic extent and climatic extremes represented over this area. The Western Interior coal region is largely located in the climate of the Humid Temperate Domain, an area governed by both tropical and polar air masses, with strong annual cycles of temperature and precipitation, causing seasonal fluctuation of energy and temperature greater than the diurnal fluctuation (Bailey, 1995). Table 3.8-8 lists the ecological provinces located in this coal region and the area of each province.

Figure 3.8-12. Ecological Provinces within the Western Interior Region



Source: USFS, 2015, Ecological Provinces, http://data.fs.usda.gov/geodata/;

USGS, 2011, Coal Fields, http://nationalatlas.gov/atlasftp.html?openChapters=chpgeol#chpgeol

Table 3.8-8. USFS Provinces Associated with the Western Interior Region

Ecological Province	Area of Coal Region in Province (square miles)
Central Interior Broadleaf Forest	915
Ouachita Mixed Forest-Meadow	871
Prairie Parkland (Subtropical)	4,612
Prairie Parkland (Temperate)	48,606
Southeastern Mixed Forest	3,603
Midwest Broadleaf Forest	5
Great Plains steppe	21
Ozark Broadleaf Forest	14
Southwest Plateau and Plains Dry Steppe and Shrub	6,971
Total	65,619

The descriptions provided below for the ecological provinces distributed within the Western Interior coal region come from Bailey (1995), McNab and Avers (1994), Cleland et al. (1997), and McNab et al. (2007). The common vegetation and fauna in each cover type are described briefly in Appendix G.

3.8.9.1.1 Central Interior Broadleaf Forest

A description of the Central Interior Broadleaf Forest Province is presented in the discussion of the Appalachian Basin.

3.8.9.1.2 Prairie Parkland (Subtropical)

A description of the Prairie Parkland (Subtropical) province is presented in the discussion of the Gulf Coast.

3.8.9.1.3 Prairie Parkland (Temperate)

A description of the Prairie Parkland (Temperate) province is presented in the discussion of the Illinois Basin.

3.8.9.1.4 Ouachita Mixed Forest – Meadow

This province is found in west Arkansas and southeast Oklahoma, consisting of oak-hickory-pine forest with a conifer understory and hardwood overstory. Generally shortleaf pine-dominated communities occur on poor upland soils and loblolly pine-dominated communities are distributed on richer valley soils. Hillsides have a mix of shortleaf oak on southerly slopes and oak-hickory on northerly slopes.

There is a high density of small-to-medium size perennial streams and associated rivers in this province; those in intermountain basins have moderate rates of flow, and some on mountainsides are characterized by high rates of flow and velocity. A trellis drainage pattern has developed largely with bedrock structural control; major rivers include the Fourche and Dutch Creek, which flow into the Arkansas River.

3.8.9.1.5 Southeastern Mixed Forest

A description of the Southeastern Mixed Forest province is presented in the discussion of the Appalachian Basin.

3.8.9.1.6 Midwest Broadleaf Forest

A description of the Midwest Broadleaf Forest province is provided in Section 3.8.1. Streams in the Michigan portion of this province drain to the Great Lakes, while streams in the Indiana portion of this province are in the Ohio River watershed. Lakes in this province are generally small-t- medium in size. Wetlands are formed in extensive low-lying areas in former glacial lakebeds in the province. There is moderate to high density of streams in this province; low gradient streams and rivers predominate and typically have substrates composed of sand, gravel, bedrock, and boulders.

3.8.9.1.7 Southwest Plateau and Plains Dry Steppe and Shrub Province

A description of the Southwest Plateau and Plains Dry Steppe and Shrub province is provided in the discussion of the Colorado Plateau.

3.8.9.1.8 Great Plains Steppe Province

A description of the Great Plains Steppe province is provided in the discussion of the Northern Rocky Mountains and Great Plains.

3.8.9.2 Terrestrial Resources

The Western Interior coal region study area includes several different terrestrial habits within the central U.S., within the states of Kansas, Missouri, Oklahoma, and Arkansas. Except as noted, all of the ecoregion descriptions and vegetation cover type descriptions below are taken from McNab et al. (2007). Many provinces and cover types are represented in this region, and as a result, the list of representative species is long. As with the other regions, detailed descriptions of the cover types are included in Appendix G.

In general this coal region is dominated by agricultural land interspersed with oak-hickory and prairie cover types, and elm-ash-cottonwood cover types. Near its southern limits, the coal region crosses several different provinces. The Prairie Parkland (Subtropical) Province is located in Oklahoma and is characterized by oak-hickory and Great Plains grasslands cover types. The Central Interior Broadleaf Forest Province is located in Missouri and Oklahoma and consists of oak-hickory and oak-pine cover types. The Ozark Broadleaf Forest-Meadow Province is located in Oklahoma and consists of oak-hickory and oak-pine cover types. The Southeastern Mixed Forest Province is located in Oklahoma and Arkansas and consists of oak-hickory, oak-pine, and loblolly-shortleaf pine cover types. The Ouachita Mixed Forest-Meadow Province is located within Oklahoma and Arkansas and consists of loblolly-shortleaf pine, oak-pine, and oak-hickory cover types.

Representative fauna for this region include many of the same species discussed for other regions due to the overlap of cover types. Typical representatives of the oak-hickory cover type are similar to that of other eastern hardwood and hardwood-conifer areas and vary somewhat from north to south. Important species include the white-tailed deer, black bear, bobcat, gray fox, raccoon, gray squirrel, fox squirrel, eastern chipmunk, white-footed mouse, pine vole, northern short-tailed shrew, and cotton mouse.

Birds such as turkey, ruffed grouse, bobwhite, and mourning dove are game birds in forested parts of the region, including those covered in the oak-hickory cover type. Abundant breeding birds include the cardinal, tufted titmouse, wood thrush, summer tanager, red-eyed vireo, blue-gray gnatcatcher, hooded warbler, and Carolina wren. The box turtle, common garter snake, and timber rattlesnake are characteristic reptiles. Other important wildlife species in the wooded areas include the Indiana bat, spotted skunk, blue grosbeak, great crested flycatcher, western meadowlark, western fox snake, smooth green snake, speckled king snake, western worm snake, brown snake, smallmouth salamander, and Woodhouse's toad.

Within the grassland and prairie cover types the predominant species change to include jackrabbits as common residents of the prairie, and cottontail rabbits in areas with abundant streams and cover. Typical burrowing rodents include ground squirrels, prairie dogs (*Cynomys* spp.), pocket gophers (family Geomyidae), and many smaller rodents. Burrowing predators include the badger and the black-footed ferret (*Mustela nigripes*). The coyote is still common. Other important wildlife species in the prairies include barn and longeared owls, broad-winged hawk, Henslow's sparrow, northern harrier, Leonard's skipper, Pawnee skipper, Ottoe skipper, dusted skipper, wild indigo dusky wing, sleepy dusky wing, zebra swallowtail, Great Plains toad, plains leopard frog, plains spadefoot, massasauga rattlesnake, prairie skink, ornate box turtle, six lined racerunner, bobcat, black-tailed jackrabbit, plains pocket mouse, whitetailed deer, raccoon, skunk, opossum, muskrat, cottontail, mink, squirrel, and least shrew.

Migratory waterfowl rely on areas of the region within the prairie cover type for breeding and overwintering. Mourning doves are abundant, as are sharp-tailed grouse (*Tympanuchus phasianellus*), greater prairie chicken (*Tympanuchus cupido*), and bobwhite.

3.8.9.3 Aquatic Resources

The Western Interior coal region is very ecologically diverse. Major rivers such as the Missouri River, Mississippi River, Arkansas River, Canadian River, Red River, Brazos River, and the Pecos River drain portions of the coal region.

3.8.9.3.1 Lotic Systems

A variety of flowing water habitats are present in the Western Interior coal region. These include ephemeral, intermittent, low order (first through third) and higher order (fourth through sixth) streams as well as rivers. A more detailed discussion of the general habitat features of these different types of streams is presented in Appendix C.

Lotic systems in the Western Interior coal region are diverse, ranging from perennial spring-fed mountain streams to ephemeral desert streams. Rivers that exist in the plains prairies, which exist sporadically throughout the Prairie Parkland provinces and constitute a majority of the areas that are used for coal mining, start from prairie potholes and springs. Agricultural runoff also contributes to river flow. These prairie rivers carry large volumes of fine sediments and tend to be turbid, wide, and shallow. Major rivers in the coal region include the Arkansas, Missouri, and Red Rivers. The large rivers within the coal region historically experienced spikes in flows during the spring and early summer, which enabled sediment to be transported and deposited, and enabled channels to meander and migrate. Anthropogenic manipulations of these river systems have reduced natural flows and affected the system processes.

Rivers in this area have been heavily affected by channelization and flow controls, such as dikes and levees that restrict natural channels. Rivers are also affected by the construction of dams that have altered many natural riverine processes, such as sediment transportation and annual flooding. Agricultural activities have also caused impacts on streams, such as sedimentation and eutrophication. The leading stress indicators in lotic systems of the coal region include total nitrogen, riparian disturbance, and the reduction of in-stream fish habitat and riparian vegetative cover (U.S. EPA, 2006). The rivers and streams of the Western Interior coal region are affected by the surrounding land uses. Nutrient loading in this coal basin has become a major concern of the state environmental agencies due to the rapid growth of agricultural activities (Haggard et al., 2001). Anthropogenic sources of phosphorus and nitrogen include sewage, agricultural runoff, lawn fertilizers, pet wastes, and atmospheric pollution (Dodson, 2005).

As described in Section 3.5 (see Table 3.5-5), it is estimated that there are a total of 91,932 miles of intermittent streams and 65,673 miles of perennial streams in this coal region. A more detailed discussion about the general habitat features and hydrology of these different types of streams is presented in Appendix C and Section 3.5.

3.8.9.3.1.1 Energy Flow/Primary Production

A major unit of primary production in the Western Interior coal region is algal biomass, consisting of cyanobacteria, filamentous chlorophytes, halophilic diatoms, and diatoms. Common algal species include attached and floating filamentous species; however, phytoplankton is typically sparse (Power and Stewart, 1987). In heavily shaded mountain and canyon streams, light availability can be the overriding factor controlling the algal biomass and primary production, even in the presence of high nutrient concentrations (Mosisch et al., 2001). In mountainous areas, concentrations of chlorophyll *a* have been found to be generally small, indicating a relatively small amount of algal biomass in riffles (Peterson et al., 2009). In these areas, there can be an increased reliance on non-algal macrophytes and allochthonous sources for energy input within lotic systems.

In mountainous areas, non-algal macrophytes, such as bryophytes (liverworts, hornworts, and mosses), and emergent and aquatic vascular plants (e.g., sedges, rushes, grasses, and shrubs) are important to the primary production of the aquatic system for habitat and autochthonous energy input. Trees are typically the main source of woody debris and leaf pack material, except in the plains, where herbaceous plants and shrubs are a major component. Broadleaf cover types are typical of the coal region, consisting of common species of oak, hickory, hackberry (*Celtis* sp.), rough-leafed dogwood (*Cornis drummondi*) and sycamore (*Platanus* spp.), which line the stream banks in the region (Power and Stewart, 1987). Federally listed aquatic noxious weeds are also present in this region (Appendix E).

3.8.9.3.1.2 Invertebrates

Common insect orders found in streams in the Western Interior coal region include midges, mosquitoes, blackflies, and craneflies (Diptera); mayflies (Ephemeroptera); caddisflies (Tricoptera); stoneflies (Plecoptera); beetles (Coleoptera); damselflies and dragon flies (Odonata); springtails (Collembolan); water boatmen, water scorpions, pondskaters, and water striders (Hemiptera); and alderflies, dobsonflies and fishflies (Megaloptera). A large number of these insects shred and scrape decaying organic material, which aid in the assimilation of allochthonous inputs to the aquatic system (Dodson, 2005). Many aquatic insects are predatory and actively feed on smaller insects and other invertebrates. Non-insect invertebrates also common to lotic systems in the coal region include megadrile and microdrile worms

(Oligochaeta); haplotaxid worms (Haplotaxida); water fleas (Cladocera); copepods (Copepoda); isopods (Isopoda); amphipods (Amphipoda); crayfish (Decapoda); arachnids (Acari); and snails (Basommatophora).

Another invertebrate group important to the region is freshwater mussels. Although not as rich as in the Appalachian Basin region, the Western Interior coal region has a relatively sizeable mussel fauna. Common species include the three-ridge (*Amblema plicata*), the pistolgrip (*Tritogonia verrucosa*), the plain pocketbook (*Lampsilis cardium*), and the pigtoe (*Fusconaia flava*) (Spooner and Vaughn, 2007). Unionid mussels often constitute the highest percentage of biomass relative to other benthic stream animals and are a key link in the food chain between aquatic microorganisms, such as algae and bacteria, and large animals like otter, turtles, fish, and hellbenders that eat unionids (Badra, 2005). Mussel populations have declined in recent decades to become the most imperiled group in North America because of siltation, pollution, and competition from exotic mollusks like the zebra mussel (Warren, 1995).

Crayfish are another relatively common freshwater invertebrate that inhabit very diverse niches, including small streams, large rivers, lakes, and even subterranean environments (Fetzner, 1996). Like freshwater mussels, crayfish are abundantly diverse in the Western Interior region. Arkansas is home to 61 species, while 32 species are known to occur in Missouri, 28 species in Oklahoma, and 11 species in Kansas (Fetzner, 2010). These species represent one of the largest aquatic faunal groups in North America north of Mexico but are so poorly known that over half of them do not have common names (Butler et al., 2003). However, crayfish have significant roles in aquatic ecosystems and are a major component of the food web. They are omnivorous and process organic matter in addition to feeding on snails, small fish, and aquatic insects; they transform energy between different levels in the food chain, and are themselves eaten by more than 240 predators (Butler et al., 2003).

3.8.9.3.1.3 Vertebrates

Amphibians, (frogs, toads, and salamanders) account for a considerable portion of energy flow in this region. Some of the more common amphibian species in the areas of concentrated mining include the bullfrog, the southern leopard frog (*Rana sphenocephala*), the green frog (*Lithobates clamitans*), the pickerel frog (*Lithobates palustris*), the Red River mudpuppy (*Necturus maculosus louisianensis*), the central newt (*Notophthalmus viridescens louisianensis*), and the western slimy salamander (*Plethodon albagula*) (Arkansas Herpetological Society, 2013).

The reptile species associated with lotic systems vary greatly across this coal region. Reptiles common to aquatic ecosystems in areas of the coal region where mining is currently conducted include the western cottonmouth (*Agkistrodon piscivorus leucostoma*), the plain-bellied watersnake (*Nerodia erythrogaster*), the midland watersnake (*Nerodia sipedon pleuralis*), the snapping turtle, the Ouachita map turtle (*Graptemys ouachitensis ouachitensis*), the eastern river cooter (*Pseudemys concinna concinna*), the red-eared slider (*Trachemys scripta elegans*), and the spiny softshell (*Apalone spinifera*) (Arkansas Herpetological Society, 2013). Reptiles' ingested energy is efficiently transferred to other trophic levels in the food web (Pough, 1980; Regester et al., 2005).

Due to the wide variation of environments in the Western Interior coal region, there is a high diversity of fishes. The lotic systems of the coal region range from spring-fed headwater streams to the main stem of the Missouri River. Most of the coal region is characterized by fish assemblages, including two common orders; Siluriformes, the catfishes, and Perciformes, which contains the fish families of Centrarchidae and Percidae. Common Siluriformes include black and yellow bullhead catfish (*Ictalurus melas* and *I. natalis*), and the channel catfish. Common Centrarchids in the region include largemouth bass, orange-spotted sunfish (*Lepomis humilis*), bluegill, longear sunfish (*L. megalotis*), green sunfish (*L. cyanellus*), and crappie (Stevenson et al., 1974). Common Percids include the orangethroat darters (*Etheostoma spectabile*), logperch (*Percina caprodes*), and slenderhead darters (*Percina phoxocephala*) (Stevenson et al., 1974). Fish assemblages are variable across the basin depending on stream type and climate; however, there is significant species overlap between stream types with similar ecoregions, and the assemblage descriptions below represent common groupings from areas currently targeted for coal production.

In most of the coal region, such as the prairie and plains provinces, shallowly entrenched, slow-flowing, meandering streams are the most common stream type. Fish assemblages in this stream type are commonly minnow dominated, including species such as the golden shiner, redfin shiner (*Lythrurus umbratilis*), suckermouth minnow (*Phenacobius mirabilis*), sand shiner, and fathead minnow (Pflieger, 1975). Other species of nongame fish common to the slow flowing, meandering stream type are gizzard shad (*Dorosoma cepedianum*), common carp, stonecat (*Noturus flavus*), black bullhead catfish, channel catfish, and flathead catfish (*Pylodictis olivaris*) (Pflieger, 1975). In addition to largemouth bass, other game fish such as smallmouth bass, white bass, and freshwater drum are also common. In addition to the meandering stream species, the main stems of the major rivers in the coal region include additional species indicative of larger lentic systems. These big river species include the chestnut lamprey (*Ichthyomyzon castaneus*), shovelnose sturgeon (*Scaphirhynchus platorynchus*), pallid sturgeon (*Scaphirhynchus albus*), paddlefish, skipjack herring (*Alosa chrysochloris*), goldeye (*Hiodon alosoides*), blue sucker (*Cycleptus elongatus*), and blue catfish (*Ictalurus furcatus*) (Pflieger, 1975).

Spring-fed or upland clear, rocky streams are typically cool-water streams that are typically found in the upper reaches of watersheds. They are present across this coal region but are more commonly found in the Ouachita Mixed Forest-Meadow province. Like meandering streams, these cool streams are typically dominated by minnows such as the southern redbelly dace, horny head chub, rosyface shiner (*Notropis rubellus*), bleeding shiner (*Luxilus zonatus*), and striped shiner (Pflieger, 1975). In addition to minnows, darters are very common in these streams; widespread species include the orangethroat darter, the banded darter, the greenside darter, the rainbow darter (*E. caeruleum*), and the fantail darter. Other species common to these stream types include brook lampreys (*Lampetra* spp.), suckers such as the northern hog sucker (*Hypentelium nigricans*), black redhorse (*Moxostoma duquesni*), and golden redhorse (*Moxostoma erythrurum*), and other large species such as smallmouth bass, rock bass, longear sunfish, and in larger cool streams, walleye (Pflieger, 1975).

3.8.9.3.2 Lentic Systems

There are a relatively low number of warm water lakes and wetlands in the western portion of the Western Interior coal region due to the climate and topography. In the more arid areas of this coal region, some drainages lack outlets, producing temporary saline ponds and saline lakes (U.S. ACE, 2010). However, lakes produced by prior glacial action are common in the northern portion, and oxbow lakes and wetlands are abundant along the larger river systems. A large number of farm ponds are distributed throughout the agricultural areas. Water reservoirs have also been constructed throughout the coal region

(McNab and Avers, 1994). In arid areas, playas are important because they store water in areas commonly subjected to drought conditions and where there are no permanent rivers or streams. Consequently, playas create an oasis-like area that provides habitat for a variety of species, especially in the more arid areas of this coal region.

3.8.9.3.2.1 Energy Flow/Primary Production

As mentioned previously in aquatic systems, primary production is accomplished by phytoplankton, macro algae, and vascular aquatic plants. The algae associated with lentic systems make a significant contribution to the primary productivity of the aquatic ecosystems in the Western Interior coal region (O'Neal et al., 1985). In general, productive lakes average approximately one gram of carbon fixed per day per square meter (Dodson, 2005).

The littoral zone generally extends from the depth of rooted plant growth, usually 15 to 25 feet deep, as submersed plants generally do not grow below a depth of 30 feet due to light and pressure limitations (O'Neal and Soulliere, 2006). These plants are essential in promoting the biodiversity of an aquatic system and are responsible for a significant portion of the primary production for entire lentic systems (Ozimek et al., 1990; Wetzel, 2001). The aquatic plant species present in lentic systems within this coal region do not generally differ from those that are known to occur in lotic systems; however, some plants are more common to lentic systems, such as coontail (*Ceratophyllum demersum*), pondweeds (*Potamogeton* spp.), water lily (*Nuphar advena*), water willow, and cattail. Though woody debris and leaf litter input are not as important to lentic systems as they are to lotic systems, they remain important as an allochthonous energy component from the surrounding forests of oak-hickory and mixed forest cover types. Arid climates with fluctuating precipitation cause variability in the shorelines of lakes and ponds, and can greatly reduce the amount of macrophytes present in the lentic system. However, lentic systems with perennial source water from streams and springs can provide habitat for the development and establishment of macrophyte communities.

3.8.9.3.2.2 Invertebrates

The invertebrate orders common in the lotic systems of the Western Interior coal region are generally the same as those found in the lentic systems of the region. These insects, worms, crayfish, and mussels form the base of the food web in lentic systems, and serve as a food source for other predators, including fish and mammals. Common pond macroinvertebrate species include mosquitoes, blackflies, and craneflies; amphipods; damselflies and dragonflies; and beetles (Bass and Potts, 2001).

3.8.9.3.2.3 Vertebrates

Reptile and amphibian species do not greatly differ between the lotic and lentic systems in this coal region. However, lentic areas are particularly important to terrestrial salamanders, which use ponds, lakes, and wetlands for reproduction and for their larval stages of life. Salamanders are abundant and efficiently transfer energy to other trophic levels in the food web.

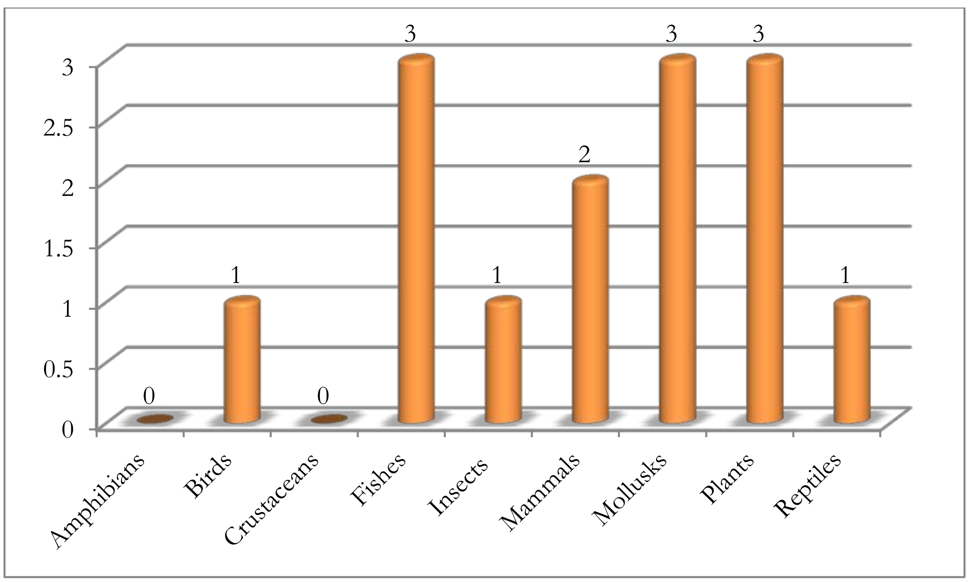
Reptiles fill important roles in the lentic ecosystems of the Western Interior coal region. Aquatic turtles are known to survive for extended lengths of time, remaining an important part of the wetland, pond, and lake systems. They can represent a significant portion of biomass in a lentic system. Semi-aquatic snake species are also important components of the food web. They transfer energy between terrestrial and lentic environments. These snakes feed on fish, frogs, tadpoles, salamander, crayfish, and insects in wetlands, lakes, and ponds.

Common lentic system species include largemouth bass, bluegill, crappie, bullhead catfish, channel catfish, carp, white bass, freshwater drum, and various sunfish species. In larger reservoirs and lakes, game fish are stocked or have been introduced; these species include northern pike, walleye, hybrid striped bass, and wiper (*Morone chrysops* x *M. saxatilis*). The non-native species that state agencies stock in lentic systems commonly move into lotic systems. Exotic species continue to threaten native fish sustainability as does loss of habitat from sedimentation, and potential overfishing in lotic and lentic systems.

3.8.9.4 Protected Species in the Coal Mining Areas of the Western Interior Region

As shown in Figure 3.8-13there are 14 federally listed and proposed listed species in the Western Interior region; two birds, three fish, three mussels, two plants, two mammals, and one insect. See Appendix F for species names and specific status.

Figure 3.8-13. Count of Federally listed species in the Western Interior Coal-Producing Region



Current threats to the listed species in the Western Interior coal region include losses of prairies, forests, and other terrestrial and aquatic resources from agricultural use and industrial and residential development. Fragmentation and ecosystem loss have increased the vulnerability of plant populations, particularly through reduced seed loss of ecosystems make plant populations vulnerable from poor seed production and decrease the health of the habitats (Wilcove et.al., 1998). In addition, invasive species can spread, change, and overtake listed species habitats.

3.9 Wetlands

3.9.1 Introduction

Wetlands can be described as “the halfway world between terrestrial and aquatic ecosystems, exhibiting some of the characteristics of each system” (Mitsch and Gosselink, 2007). The Clean Water Act (CWA) defines a wetland as “those areas that are inundated or saturated by surface or groundwater at a frequency and duration sufficient to support, and that under normal circumstances do support, a prevalence of vegetation typically adapted for life in saturated soil conditions” (33 CFR Part 328). Commonly used terms for wetlands include swamp, marsh, bog, wet meadow, fen, pocosin, pothole, and vernal pool.

Wetlands provide a number of ecosystem services that benefit humans. Wetlands help to control floods and erosion, trap sediments, remove excess nutrients, recharge and discharge groundwater, purify water, process chemical and organic waste, and a variety of other functions (Mitsch and Gosselink, 2007). Wetlands serve as important conduits for the movement of material, energy, flora and fauna across landscapes. They provide habitat for nearly 5,000 species of plants, one-third of all species of birds (including all species of ducks and geese), and 190 species of amphibians in the U.S. (NRCS, 1996). Riparian and wetland habitats are limited throughout the arid and semi-arid areas of the western U.S. The wildlife inhabiting wetlands in the semi-arid and arid west depend on wetlands for one or more critical stages in their life cycle; habitat abundance and quality is often the limiting factor to these wildlife populations. Wetlands also support a large number of rare species of plants and animals. Approximately a third of threatened and endangered plant species in the U.S. inhabit wetlands, and half of the threatened and endangered animal species are wetland dependent (Niering, 1988).

3.9.2 Wetlands Status and Trends

Estimates of the total wetland acres that existed within the coal-producing regions pre-settlement, compared to the acres in existence today, vary by source. Estimates of the original extent of wetlands in the U.S. range between 211 to 221 million acres (Dahl, 1990). Nevertheless, the number and acreage of wetlands has historically been on the decline over the last 200 years as a result of human activities. A large portion of that decline began with the passage of the Swamp Lands Act of 1850. Approximately 45 million acres of wetland loss is attributed to this legislation (National Research Council, 1995). The Swamp Lands Act enabled states to take possession of wetlands and begin draining them so they could be farmed. The trend of wetland loss continued unhampered until the 1970s with the passage of the 1972 Federal Water Pollution Control Amendments, which was then amended with the passage of the CWA in 1977. The CWA includes Section 404, designed to regulate the discharge of dredged and fill material into waters of the U.S., including wetlands. In 1986, Congress enacted the Emergency Wetlands Resources Act, recognizing that wetlands are nationally important resources and requiring the U.S. FWS to update wetland status of the U.S. every ten years. In 1988, under the administration of President George H.W. Bush, the wetland “No Net Loss Policy” was established, further slowing the rate of wetland loss. This policy continued under the administration of Presidents William Clinton, George W. Bush, and Barack Obama. As of 2009, the lower 48 states contained an estimated 110.1 million acres of wetlands (Dahl, 2011). The U.S. EPA is scheduled to release its initial National Wetland Condition Assessment, which is designed to provide regional and national estimates of wetland ecological integrity and rank the stressors most commonly associated with poor wetland conditions. At least 22 states have lost at least 50 percent of their original wetlands, mainly located in the East and Midwest (Mitsch and Gosselink, 2007; Dahl, 2006).

Despite regulations and a positive trend of wetland protection, wetlands are lost in the U.S. at an estimated rate of 290,000 acres per year (Dahl, 2006). Human activity is considered to be a major cause of wetland loss; other causes include natural threats and indirect causes such as erosion, subsidence, sea level rise, climate change, droughts, hurricanes, and other large storms (Dahl, 2011; North Carolina State University, 2006). The majority of the wetland loss occurring today is the loss of marine and estuarine wetlands, which is caused by coastal erosion. Freshwater wetlands loss is mainly caused by urban and rural development (Dahl, 2006). The acreage of wetlands loss due specifically to coal mining impacts was not available, although peat mining (where occurring) is a cause of freshwater wetlands loss and is restricted to a few areas of the country.

3.9.3 Location of Wetlands

Wetlands are found in nearly every county in the United States (U.S. EPA, 2004b) and are found within all of the coal-producing regions. Wetlands can be created (and have been created) both intentionally and unintentionally by ground disturbance, including during surface and underground coal mining. Wetlands can also be created at the surface over underground mines (mainly longwall mines) due to planned subsidence, and during reclamation of surface activities. Wetlands are typically located at the interface of a body of water (such as an ocean, a lake, pond, or a stream) and land but are also found in other portions of the landscape remote from waterbodies. These isolated wetlands do not contain outlets; they are the result of groundwater at or near the soil surface or in topographically low areas where enough water collects to create saturated (hydric) soils and support a wetland plant community (Mitsch and Gosselink, 2007; Leibowitz, 2003; Whigham and Jordan, 2003).

The U.S. FWS maintains maps of the nation's wetlands. The National Wetland Inventory (NWI) Program (U.S. FWS, 2013a) produces maps and a digital database of the location, size, and status of wetlands. In addition the NWI provides the wetland cover type according to "Classification of Wetlands and Deepwater Habitats of the United States" (Cowardin et al., 1979). This classification system often is referred to as the "Cowardin Classification System," and is based on vegetation, soils, and frequency of flooding. Open water areas such as ponds and streams are also classified as wetlands under this system and are included on NWI maps.

Wetlands are mapped and classified for the NWI through aerial interpretation and limited field verification. Attempts are made to update and increase the accuracy of the mapping at a rate of one to two percent of the U.S. per year. Throughout its history, most of the NWI mapping was performed through a multi-stage process, starting from aerial photography. As GIS and mapping technology advanced, the process of data collection and map production became a single step done on-screen by the image analysts. These analysts delineated wetlands; other data were then simultaneously entered into a digital data layer that could be used to generate maps at various scales using GIS technology. Today, all of the NWI data are created through this on-screen process (Tiner, 2009). The reliance placed on the NWI and its resulting effort has provided a valid, consistent source of the location and size of wetlands within all of the coal regions. The tables within Appendix H summarize the general wetland cover types and percent acreage of each cover type, organized by coal-producing regions covered in this discussion. Data from U.S. FWS were used to calculate these estimations; however, due to incomplete data sets, some regions in Appendix H are also incomplete. These data were last updated on October 29, 2013. In the creation of these regional tables, the wetlands were sized by state based on the area that resides within the basin boundary. These sized state areas were merged together to define wetlands for the entire coal basin boundary. These areas were calculated in square meters, and then converted to acres in ArcMap for each wetland polygon within the boundary. The data was then converted to tabular form and consolidated by class, and statistics were generated for area calculations.

3.9.3.1 Appalachian Basin Region

The Appalachian Basin is characterized by mountains with steep slopes that contain high gradient streams. Wide river valleys wind around the base of the mountains, and the majority of the wetlands in this region are located in these river valleys. Large wetlands are commonly found on floodplains along rivers and perennial streams (i.e., riparian wetlands). Large wetland complexes consisting of a variety of habitats can be found in the floodplains within large river systems such as the Ohio River. Headwater streams found on the steep slopes are high-gradient with a small floodplain, typically located with a scoured channel; wetlands are typically absent next to these streams. Instead of being associated with a stream channel in these upper headwater regions, wetlands are found in depressional areas at the top of mountains and along the slopes (U.S. EPA, 2005). These wetlands are often isolated and therefore are not afforded protection under the CWA.

NWI data indicates there are approximately 727,000 acres of wetlands within the coal-producing areas of the Appalachian Basin (see Appendix H). In total, only two percent of the land area of the Basin is identified as wetland. This region has experienced wetland loss due to rural development.

3.9.3.2 Colorado Plateau Region

The Colorado Plateau coal-bearing region is located in the arid western U.S. The dry climate limits wetland development. As a result, wetlands comprise less than two percent of the region (USGS, 1996). The wetlands that do exist in this region are mainly found in association with streams, ponds, lakes, and rivers. The majority of the wetlands within this region, not including open water areas, are emergent riparian wetlands, oxbow lakes, marshes, cienegas, and bosques (USGS, 1996). The hydrology supporting these wetland communities is based on yearly snowmelt and late summer thunderstorms. They are typically found in higher elevations and have a richer diversity of plant species than the adjacent uplands. Studies in Colorado have found that more than 70 percent of Colorado's wildlife species (including fish, crustaceans, spiders and insects, and 27 percent of the state's breeding birds) use wetlands (Rocchio, 2005a). Big game species such as deer, moose, and elk seek out wetlands for lush and nutritious grasses.

Other wetlands are seasonal and can be dry for more than one year at a time. Often these wetlands are playas (USGS, 1996). Playas are typically shallow depressions within the desert basins or abandoned stream channels that are occasionally wet due to stream flow or shallow ground water. These are wetlands heavily influenced by snowmelt and heavy precipitation events. This, along with the salinity of the soil, has a strong influence on the plant community and plant coverage (Rocchio, 2005b). These wetlands are known to support threatened and endangered species, including many endemic species (USGS, 1996).

There are only 70,000 acres of wetlands within this 11.3 million-acre coal region, constituting less than 1 percent of the land area (see Appendix H). Of these wetland acres, over 80 percent (or 57,000 acres) would qualify as open water habitat.

3.9.3.3 Gulf Coast Region

The majority of the wetlands located within the Gulf Coast lignite and bituminous coal-bearing region are in the Mississippi River basin. Wetlands occupy more than 13 percent of Mississippi, and freshwater forested wetlands comprise the majority of wetlands within the state of Louisiana. Bottom-land forests, swamps, and freshwater marshes within floodplain areas of rivers account for most of Mississippi's wetland acreage (USGS, 1996). In addition, the majority of all the wetlands found in the state of Texas are located in the eastern, coal-bearing portion of the state. These wetlands are also forested wetlands, occurring within the floodplains and bottomlands of rivers (USGS, 1996).

Forested wetlands account for over 2.3 million acres within the coal-bearing portions of this region and comprise over 66 percent of all wetlands. Open water habitat such as lakes, ponds and rivers compose about 29 percent of the regions wetlands (see Appendix H). The wetlands in this region are important to wildlife, especially migrating and overwintering birds. They are also vital to the local economies.

3.9.3.4 Illinois Basin Region

The major land use in the Illinois Basin is agriculture. This portion of the country converted a large percentage of its wetland to farmland in the late 1800s and early 1900s (Dahl, 2006; USGS, 1996). Illinois has lost an estimated 90 percent of its wetlands (USGS, 1996). NWI data estimates 1,322,542 acres remain. More than 57 percent of the natural wetlands in Illinois are found within the larger river basins in the southern portion of the state (Illinois Department of Natural Resources, 2013). The southwestern portion of Indiana and western Kentucky experienced similar wetlands losses and contain similar wetlands habitat. In total, only 4 percent of the coal-producing land area is identified as wetland. Despite these losses wetlands continue to be important habitats for many species here as in other regions. The Illinois Department of Natural Resources for example recognized that 49 of the 59 mammal species in Illinois use wetlands to some extent during their life cycle, that 37 of the 41 amphibian species in Illinois depend upon wetlands at last part of the year, and that approximately 105 bird species depend upon, or are strongly associated with, Illinois wetlands (Illinois DNR, 2015).

3.9.3.5 Northern Rocky Mountains and Great Plains Region

According to the NWI database (with incomplete datasets from CO, MT, and UT) wetlands comprise 2.89 percent of the Northern Rocky Mountains and Great Plains region’s 43,069,200 potential coal-producing acres. However, the prairie pothole region within the Great Plains portion of the region (including northeastern Montana and much of North Dakota) was once the greatest expanse of grasslands and small wetlands on earth (U.S. FWS, 2009). Formed by glaciers, prairie potholes are characterized by shallow depressions, generally round in shape, which support emergent vegetation. In fact, according to the NWI dataset there are more than 542,000 acres of emergent wetland within this coal region (see Appendix H). Many of these wetlands do not have inlets or outlets and are fed by runoff from the surrounding area or have a limited connection with groundwater (Savage, 2004). Sometimes the water in the potholes will evaporate in the summer. The wet-and-dry cycles are characteristic of the hydrology of the potholes and are essential to maintaining the wetland plant communities (Mitsch and Gosselink, 2007). In addition, evaporation can concentrate salts in the water, making some potholes as salty as the sea (Savage, 2004).

The prairie pothole region located throughout the central portion of North America serves as the primary breeding grounds for waterfowl (Mitsch and Gosselink, 2007). In 2010, the U.S. FWS reported an estimated 1.9 million breeding pairs of waterfowl in Montana and the Dakotas. Their annual waterfowl breeding and habitat survey noted a decline in habitat conditions due to a number of years of low precipitation (Zimpfer et al., 2010). During dry years, water impoundments used for coal mining, livestock, and bentonite clay production in this region have served as alternative breeding habitat for waterfowl and as habitat for shorebirds (Uresk and Severson, 1988).

Wetlands located in the portions of Wyoming and Colorado that are a part of this coal-producing region are similar in characteristics to the prairie potholes of the Dakotas and Montana. The lower elevations contain short grass prairies, and northeastern Wyoming contains the highest density of breeding waterfowl. There are areas containing sage brush steppe and coniferous forested wetlands, depending on the elevation (Copeland et al., 2010). The climate is more arid and many of the emergent wetlands are considered playas.

NWI data indicates there are approximately 1,244,000 acres of wetlands within the coal-producing areas of this coal-producing region (see Appendix H). In total, only three percent of the land area of the Basin is identified as wetland.

3.9.3.6 Northwest Region

The Northwest coal-bearing region includes Alaska, the state of Washington and small areas within Oregon. For the purposes of this FEIS, only mining in the state of Alaska is being considered (see Section 3.0 for rationale). Wetlands are created by permafrost, glacial melt water, snow melt, beavers, springs, and tides. Permafrost is a frozen layer of soil substrate that is present throughout the year. The frozen layer traps water near the soil surface. The tundra wetlands located in northern Alaska are the breeding grounds for many species of shorebirds, ducks, geese, and swans. The majority of the wetland habitat present in this area is freshwater scrub/shrub. Coastal estuarine wetlands are also common (Hall et al., 1994).

Extensive lowlands and peatlands support stunted white and black spruce woodland, low scrub of ericaceous shrubs and willow, and a variety of sedge and grass meadows. Some of the major mammal species of the area that use wetlands are moose, brown bear, black bear, wolf, coyote, fox, beaver, and lynx. Tundra swans, Canada geese, sandhill cranes, and a wide variety of ducks use area wetlands and lakes for nesting and as stop over sites during migration.

While 43 percent of the entire state of Alaska is wetland, the coal-bearing parts of the state are only about 13 percent (or approximately 159,000 acres) wetland according to the incomplete NWI dataset.

3.9.3.7 Western Interior Region

The Western Interior coal-bearing region is located in the heart of the Midwest and has a diversity of wetland habitats. These include prairie potholes, bottomland hardwood forested wetlands, shrub/scrub wetlands, emergent marshes, wet meadows, fens, and riparian wetlands. These wetlands provide habitat for migrating waterfowl and passerine birds along the central flyway. According to NWI data, there are 1,663,272 acres of wetlands, constituting about four percent of the land area. Of these wetland acres, about 50 percent (or 825,648 acres) are open water habitat (see Appendix H).

Agriculture is the primary land use in this region and has been for the last 200 years. As a result, more than five million acres of wetland were authorized to be drained in the states comprising the Western Interior coal-bearing region. The dramatic loss of wetland in the Midwest has made it a focal area for restoration programs, such as the USDA NRCS Wetland Reserve Program (WRP).

3.10 Recreation

3.10.1 Introduction

This section provides an overview of the type, capacity, demand, and quality of experience associated with existing and proposed recreational facilities in the coal-producing regions. A limited amount of information is also included on economic contributions of recreational facility usage. For further discussion of socioeconomic conditions in the coal-producing regions, refer to Section 3.14.

Resident and non-resident tourists travel to various outdoor recreational sites throughout the coal-producing regions for outdoor recreation. Tourists are drawn to the many visual, cultural, and natural amenities found throughout the coal-producing regions. A variety of both public and private sector facilities are available to meet the Nation's recreational demand. For purposes of this document, information provided is focused on public sector recreational facilities but does not include specific information on: (1) public recreational facilities provided by the county or municipal levels of government; or (2) private sector recreational facilities. While local government and private facilities provide significant recreational opportunities to the public, few systematic data sources exist to characterize these resources. In accordance with 40 CFR 1502.22, this FEIS notes that such information is not included, and that the absence of quantified information on these types of recreational facilities is not essential to making a reasoned choice among the Alternatives being considered.

Recreation in active coal mining areas is largely precluded during mining and for a period of time after mine closure due to sensitivity of reclamation. For instance hunting is precluded on active mines due to safety, and may be altered elsewhere in the vicinity of mining due to human activity and noise. However, approved postmining lakes may specify water-based recreation opportunities. Designation of individual compatible recreational uses is often left up to the state land management agencies.

For the Nation at large, public lands managed by federal and state agencies are perhaps the most extensive resource available for recreational amenities. Federal lands managed by the National Park Service (NPS), USFS, and BLM provide the opportunity for visitors to participate in a variety of outdoor recreational activities such as auto touring, biking, boating, camping, climbing, fishing, hiking, horseback riding, hunting, snow skiing, swimming, and wildlife viewing.

The NPS manages some 84 million acres of land comprising 393 national parks, 2,461 national historic landmarks, 582 national natural landmarks, and 40 national heritage areas (NPS, 2013a). During 2010, the NPS recorded slightly over 281.3 million recreational visits to NPS-managed facilities (NPS, 2011). Visitation data specific to each of the coal-producing states is provided in Appendix I, Table I-1. In FY 2010, the USFS managed 17,906 recreational sites at 155 national forests and 20 national grasslands.

Total area under management was slightly less than 193 million acres. In FY 2007, the USFS properties had approximately 192 million visitors (USFS, 2011). In 2009, the BLM managed slightly less than 250 million acres of land and recorded approximately 57.4 million recreational use visits (U.S. BLM, 2010b).

State agencies also provide significant recreational opportunities. Visitors to state park and recreation areas participate in many of the same activities provided at federal parks and recreational areas. In 2007, over 7.2 million acres of state park land was under management in the 25 coal-producing states, while 2007 state park visitations for the coal states varied from a low of 0.9 million in North Dakota to high of 49.7 million in Ohio. During that same period, revenue generated as a result of these park visits varied from a low of $1.4 million in Wyoming to a high of $55 million in Kentucky (U.S. Census Bureau, 2007). Visitation, acreage, and revenue data for each of the states in the study area is available in Appendix I, Table I-3.

Tourism revenue information was not available by county or as a subset of any state; therefore, the monetary value of tourism to a specific study area is not available. The economic importance of recreation tourism specific to each individual coal mining state is presented in Appendix I, Table I-2.

The text below in the remainder of Section 3.10 provides a discussion of the extents of public land areas broken down by region. The acreage figures provided in this text are derived from ESRI data, most recently downloaded in September 2016. These are not the official acreages from the federal or state land owner and may therefore vary from other sources, but are intended only to provide a relative comparison on the extent of public land areas within each region.

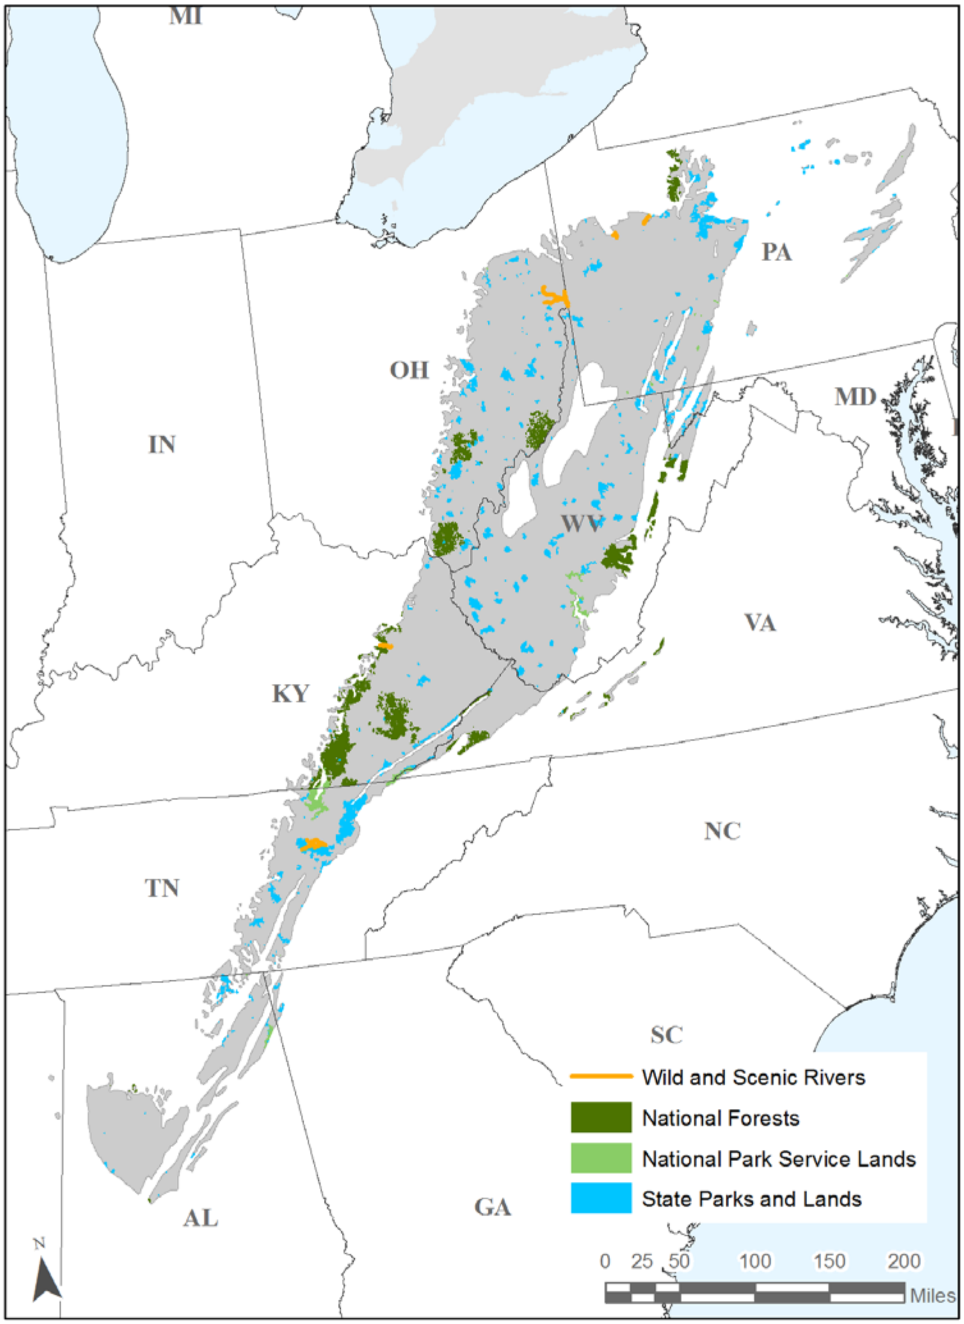
3.10.2 Appalachian Basin Region

The Appalachian Basin coal-producing region includes portions of the states of Pennsylvania, Ohio, West Virginia, Virginia, Kentucky, Maryland, Tennessee and Alabama. Within these populous eastern states, there are numerous recreational opportunities for both residents and visitors to the area. Table I-2 in Appendix I lists the economic contribution of the tourism and recreation industry as well as food service and accommodation-related jobs, payroll, and per capita expenditures for each of these states. Table I-3 in Appendix I lists 2007 data for visitation, acreage, and revenue for state parks in the coal mining states.

Approximately 1.1 million acres of national forest lands fall within the boundaries (see Figure 3.1-1) of the Appalachian Basin coal-producing region, of the approximately 4.7 million total acres within these forests. Table I-4 in Appendix I provides information on the national forests in this region, including total acreages for each forest. Seventeen NPS-managed facilities occur partially or entirely within the region with a total of approximately 168,623 acres within the region of the 297,902 acres these areas encompass in total. Park-specific information is displayed in Table I-5 of Appendix I.

A review of Table I-6 in Appendix I shows that 325 state-managed recreational facilities occur partially or entirely within this coal-producing region, totaling approximately 1.3 million acres inside the boundaries out of their total 2.5 million acre area. Figure 3.10-1 locates the designated wild and scenic rivers in this region and shows where areas of the region overlap national and state parks and forests. Table I-7 in Appendix I provides information on each of the identified wild and scenic rivers located within the Appalachian Basin coal-producing region.

Figure 3.10-1. Appalachian Basin Region National and State Recreation Areas



Coordinate system used: North America Albers Equal Area Conic

Source: U.S. Geological Survey, Gap Analysis Program (GAP). May 2016. Protected Areas Database of the United States (PAD-US), version 1.4 Combined Feature Class.

U.S. FWS conducts a survey every five years to evaluate the popularity of hunting, fishing, and wildlife watching in each state (U.S. FWS, 2011c). The 2011 survey reported fishing expenditures totaling 41.8 billion nationwide, and hunting expenditures totaling $another 33.7 billion. As illustrated by the 2011 data, the Appalachian Basin region provides ample opportunity for fishing, hunting, and wildlife-watching activities. In almost every state of the Appalachian Basin, wildlife-watching is the preferred activity of the three, followed by fishing, then hunting. Data for these three activities in the Appalachian Basin states, in addition to national totals, is provided in Table I-8 of Appendix I.

The following subsections provide state-specific information on recreational resources in the Appalachian Basin.

3.10.2.1 Alabama Tourism and Recreation

The Alabama portion of the Appalachian Basin coal-producing region is located in the tourism region that the Official Alabama Vacation Guide (Alabama Tourism Department, 2013) designates as the Alabama Mountains Region, located in the northern third of the state. The Tennessee River winds through the Appalachian Mountain foothills in this region creating a prime destination for outdoor recreation. Major tourism and recreational opportunities in the region include the Little River Canyon National Preserve and Russell Cave National Monument, along with plentiful boating, fishing, hiking, and golfing opportunities. The region is home to the William B. Bankhead National Forest, the state's largest national forest and wilderness area, with 181,000 acres of deep canyons, towering cliffs, and hidden waterfalls. The region includes six state parks including Buck's Pocket, Rickwood Caverns, DeSoto, Lake Guntersville, Lake Lurleen and Oak Mountain. Alabama is one of the premier states in the nation for hunting white-tailed deer and eastern wild turkey.

3.10.2.2 Kentucky Tourism and Recreation

The Kentucky portion of the Appalachian Basin coal-producing region is located in the tourism region designated by the Kentucky Official Visitor's Guide (Kentucky Department of Travel (DT), 2011) as the Eastern Region; the Eastern Region includes the Kentucky Appalachians and Daniel Boone sub-regions. Tourism and recreational activities in this area relate to the natural scenic beauty of the Appalachian Mountains. A significant attraction is the Daniel Boone National Forest, which includes the Red River Gorge.

The Red River Gorge is a unique landscape containing unusual flora and surrounded by more than 80 natural arches sculpted by wind and water over 70 million years. The Red River is Kentucky's only National Wild and Scenic River. Another significant attraction in the Eastern Region is the Cumberland Gap National Historic Park. This 24,000-acre area of wilderness is the largest National Historic Park in the country. The region also boasts fourteen state recreational and resort parks including Cumberland Falls, Pine Mountain, Greenbo Lake, Grayson Lake, and Jenny Wiley, among others. Elk herds were reintroduced into the mountains of eastern Kentucky on reclaimed mine sites in the late 1990s, and have since grown to nearly 10,000 animals. There are now more elk in Kentucky than anywhere else east of the Rocky Mountains. Recreational activities in this region of Kentucky include biking, hiking, camping, golfing, skiing, boating, hunting, fishing, horseback riding, rock climbing, and wildlife watching (e.g., bald eagles and elk).

3.10.2.3 Maryland Tourism and Recreation

The Maryland portion of the Appalachian Basin coal-producing region lies in the Western Maryland tourism region as designated by the Destination Maryland (Maryland Office of Tourism, 2013) travel guide. Western Maryland represents the mountainous side of Maryland and offers rapidly flowing rivers with white-water rafting opportunities and rugged mountain trails for year-round adventure. Deep Creek Lake is Maryland's largest body of fresh water, providing fishing, swimming, and boating activities. Rock-climbing, kayaking, rafting, hiking, and cross country skiing are other popular outdoor activities. State parks in the Maryland coal fields include Swallow Falls, Savage River, Dans Mountain, and Deep Creek Lake.

3.10.2.4 Ohio Tourism and Recreation

The Ohio portion of the Appalachian Basin coal-producing region is located in the tourism regions designated by the Ohio Official State Travel Planner (Ohio Division of Tourism, 2011) as the Southeast and Northeast Regions. The Northeast Region includes the 33,000-acre Cuyahoga Valley National Park and First Ladies National Historic Site, along with at least ten state parks and four state forests. The Southeast Region is recognized for outdoor adventures in places like Hocking Hills State Park, which features towering cliffs, waterfalls, and deep gorges. The Southeast Region offers at least 21 state parks and 12 state forests. Wayne National Forest, Ohio's only national forest, has more than 300 miles of trails available for recreational usage. The Southeast Region is also home to the 34,000-acre reclamation project known as Recreation Land. This area was constructed by American Electric Power on former strip mined land, and involved the planting of more than 63 million trees and the establishment of more than 350 lakes and ponds, thus returning the former mine lands into a public recreation area.

3.10.2.5 Pennsylvania Tourism and Recreation

The Pennsylvania portion of the Appalachian Basin coal-producing region is located in the tourism regions designated by VisitPA.com website as the Laurel Highlands; Pittsburgh and Its Countryside; and the Pennsylvania Wilds (Pennsylvania Department of Community and Economic Development (PA DCED), 2013). Recreational opportunities include biking, boating, camping, caving, ATV trails, fishing, golfing, hiking, hunting, snow skiing, whitewater rafting, wildlife viewing, and state park and state forest visitation. The Laurel Highlands Region includes nine state parks and/or forests. The 68-mile Laurel Highlands Scenic Byway leads to the 90-mile Historic National Road that passes by the Fort Necessity National Battlefield and other points of interest. The Pittsburgh Countryside Region is home to five state parks including Moraine State Park with over 16,000 acres of public lands. The western part of the Pennsylvania Wilds is situated within the coal fields and offers forests and mountains that are well suited for fishing, hiking, kayaking, and other outdoor activities. The Pennsylvania Wilds includes several state parks along with the Allegheny National Forest.

3.10.2.6 Tennessee Tourism and Recreation

The Tennessee portion of the Appalachian Basin coal-producing region falls mostly within the tourism regions designated by the tnvacation.com website as the Knoxville and Middle East; and the Chattanooga and Southeast (Tennessee Department of Tourist Development (DTD), 2013). Recreational opportunities include biking, boating, camping, ATV trails, fishing, golfing, hiking, hunting, wildlife viewing, and state park visitation. Several state parks lie within this region including Fall Creek Falls, Cumberland

Mountain, Frozen Head, Cove Lake, Indian Mountain, South Cumberland, and Pickett State Park. Fall Creek Falls State Resort Park "is one of the most scenic and spectacular outdoor recreation areas in America" (Tennessee Department of Environment and Conservation (DEC), 2013).

3.10.2.7 Virginia Tourism and Recreation

The Virginia portion of the Appalachian Basin coal-producing region falls within the tourism region designated by the Virginia Travel Guide (Virginia Tourism Corporation, 2013) as the Heart of Appalachia Region. Natural wonders abound throughout the region and include the deep gorges at Breaks Interstate Park and Cumberland Gap National Historic Park. Cumberland Gap National Historic Park, located along the borders of Kentucky, Virginia and Tennessee, stretches for 26 miles along the Cumberland Mountain and contains over 24,000 acres of wilderness and recreational area. The area's past coal mining history plays a significant role in the tourism opportunities in the region, evidenced by the Southwest Virginia Museum Historical State Park and Virginia's Coal Heritage Trail.

3.10.2.8 West Virginia Tourism and Recreation

The West Virginia portion of the Appalachian Basin coal-producing region includes the tourism regions designated by the West Virginia Official State Travel Guide (West Virginia Department of Commerce, 2013) as the New River-Greenbrier Valley, Mountaineer Country, Northern Panhandle, Mountain Lakes, Metro Valley, Mid-Ohio Valley, and a portion of the Potomac Highlands. Most of West Virginia falls within the Appalachian Basin coal-producing region, with the exception of the Eastern Panhandle and part of the Potomac Highlands. West Virginia offers some of the Nation's best whitewater rafting, extensive trail systems, snow skiing, hunting, fishing, boating, camping, and other recreational opportunities. Major tourism and recreational attractions in the area include over 180,000 acres in state parks and state forests; the Hatfield-McCoy Trail System; the 300-mile Appalachian Trail; Monongahela National Forest; and Gauley River National Recreation Area and New River Gorge National River. Coal heritage also plays a prominent role in tourism in the state with attractions such as the National Coal Heritage Trail.

3.10.3 Colorado Plateau Region

The Colorado Plateau coal-producing region includes portions of the states of Colorado, New Mexico, Arizona, and Utah. Table I-2 in Appendix I lists the economic contribution of the tourism and recreation industry; food service and accommodations-related jobs, payroll, and per capita expenditures for each of these states. Table I-3 in Appendix I lists the 2007 data for visitation, acreage, and revenue generated by state parks for Colorado Plateau coal mining states.

Approximately 1.2 million acres of national forest lands fall within the boundaries of the Colorado Plateau coal-producing region. Table I-9 in Appendix I provides information on the national forests in this region including their total acreage of approximately 23 million. The USFS-managed Pecos Wild and Scenic River, the only designated wild and scenic river in this region, is located in New Mexico's Santa Fe National Forest (USFS, 2013). Six NPS-managed facilities, occur partially or entirely within the region with a total of approximately 117,000 acres inside the region boundaries, out the 1.5 acres total that these areas encompass. Park-specific information is displayed in Table I-10 of Appendix I. A review of Table I-11 in Appendix I shows that 56 state recreation areas are located within this coal-producing region, totaling approximately 11 million acres of which 0.5 million fall within the region boundaries.

Figure 3.10-2 locates the only designated wild and scenic river in this region and depicts where the region overlaps national and state parks and forests. Table I-12 provides information on the wild and scenic rivers located within the Colorado Plateau region.

Relevant data from the U.S. FWS 2011 National Survey of Fishing, Hunting, and Wildlife-Associated Recreation (U.S. FWS, 2011c) is provided in Table I-13 of Appendix I. The table includes total expenditure data by state. The survey identifies Colorado as an especially popular destination for outdoor recreation, with the highest numbers of hunters, anglers, and wildlife-watchers among the states in the Colorado Plateau region.

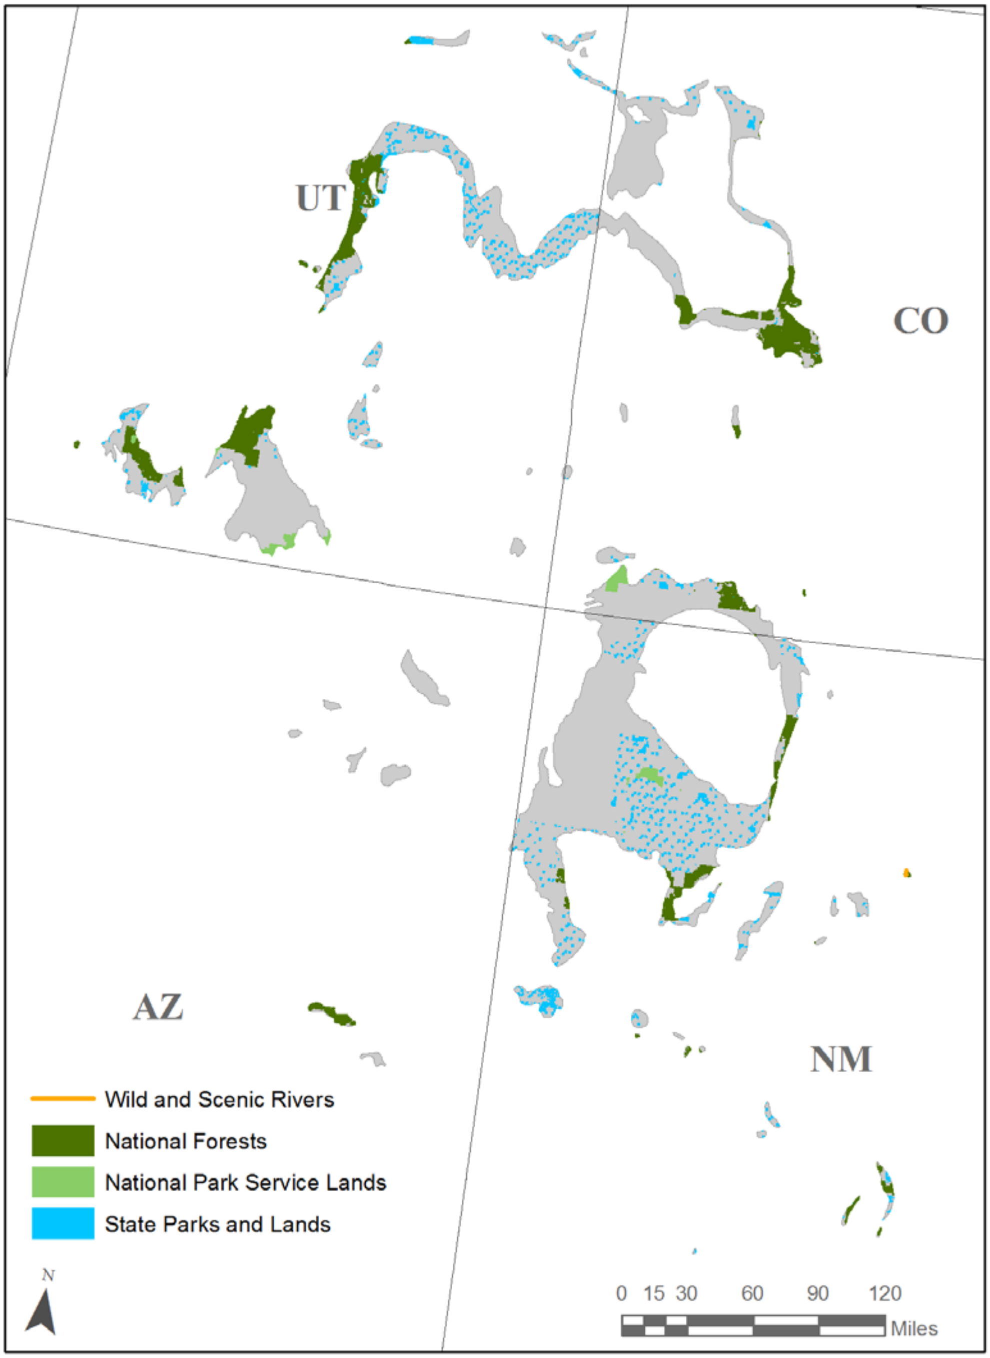
3.10.3.1 Arizona Tourism and Recreation

The area of Arizona that includes the coal-producing region lies in the northern third of the state. This area includes the Navajo Tribal Area near Lake Powell and the surrounding Glen Canyon National Recreation Area. Seven national parks, seven national monuments, and many state parks, historical sites, ghost towns, prehistoric native ruins and sculpted mesa, buttes and geologic wonders surround Lake Powell.

3.10.3.2 Colorado Tourism and Recreation

The portion of Colorado that lies in the Colorado Plateau coal-producing region is designated by the Colorado Official State Travel Guide (Colorado Tourism Office, 2013) as the Northwest and Southwest tourism regions. The Colorado River passes through the Northwest region, creating epic gorges and defining the landscape of the region. The region is best known for legendary ski resorts such as Aspen, Steamboat Springs, and Vail. The Southwest Region boasts colorful terrain, including the San Juan Mountains, Crested Butte, and Mesa Verde National Park. In addition to skiing, these regions offer whitewater rafting, hiking, mountain biking, fly fishing, hunting, wildlife viewing, and various other recreational activities.

Figure 3.10-2. Colorado Plateau Region National and State Recreation Areas



Coordinate system used: North America Albers Equal Area Conic

Source: U.S. Geological Survey, Gap Analysis Program (GAP). May 2016. Protected Areas Database of the United States (PAD-US), version 1.4 Combined Feature Class.

3.10.3.3 New Mexico Tourism and Recreation

The coal-producing region in New Mexico lies in the areas designated by the New Mexico Vacation Guide (New Mexico TD, 2013) as the Central, North Central, and Northwest Regions. In the Central region, the Sandia Mountains rise to over 10,000 feet. Popular attractions in the Central Region include Petroglyph National Monument, Jemez State Monument, and the Turquoise Trail. The Northwest region is rich in "Indian Country" culture, history, and geologic wonders. Popular attractions in the region include Aztec Ruins National Monument, Bisti/De-Na-Zin wilderness Areas, El Malpais National Monument, and El Morro National Monument. The North Central region also includes abundant cultural and historical sites. The Sangre de Cristo Mountains offer rugged adventures, and the Enchanted Circle's alpine terrain provides golfing, fishing, horseback riding, and whitewater rafting on the Rio Grande. The Turquoise Trail National Scenic Byway provides 15,000 square miles of old mining towns and natural wonders.

3.10.3.4 Utah Tourism and Recreation

A majority of the coal-producing region in Utah lies in the south central and southeastern portions of the state, including the Wasatch Plateau, Kaiparowits Plateau, and Book Cliffs areas (Utah Geological Survey, 2013; Utah Office of Tourism, 2013). This area is known for high adventure, offering spectacular outdoor activities, including boating, fishing, camping, biking, and hiking. The Green River flows through the Book Cliffs region, providing blue ribbon trout fishing and exciting whitewater rafting. The Sevier River flows through the Wasatch and Kaiparowits Plateau areas. Major recreation attractions include Bryce Canyon National Recreation Area, Fishlake National Forest, Scofield State Park, Green River State Park, San Rafael Swell, and Escalante State Park.

3.10.4 Gulf Coast Region

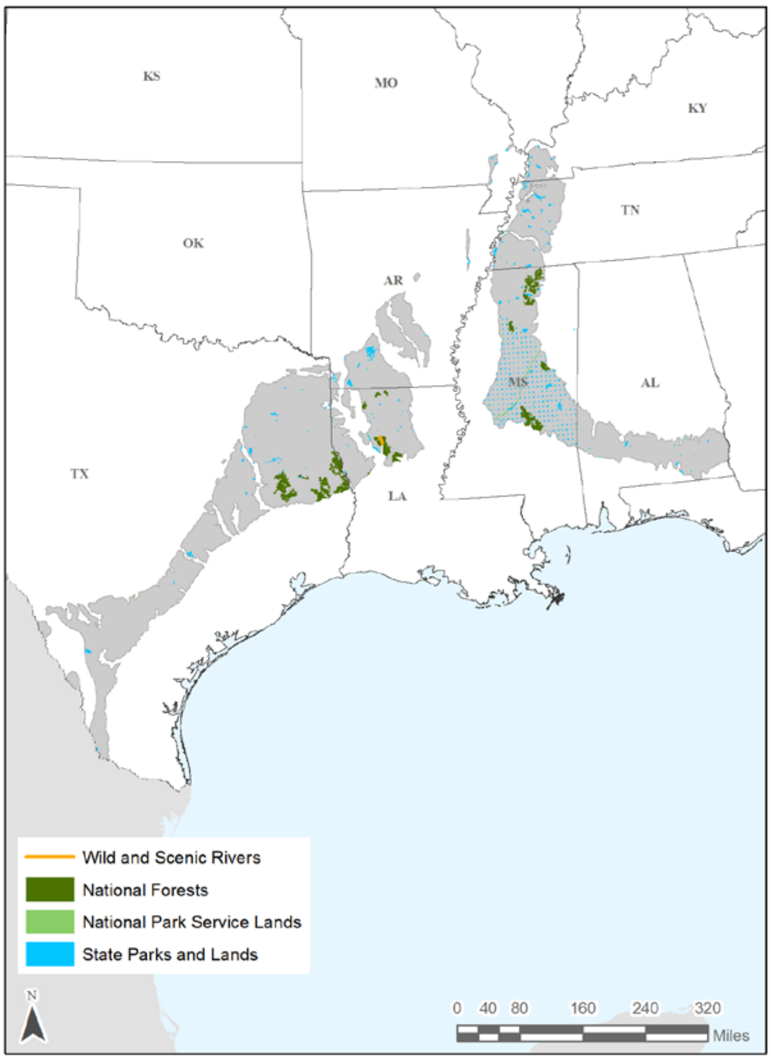
The Gulf Coast coal-producing region includes portions of the states of Alabama, Arkansas, Georgia, Illinois, Kentucky, Louisiana, Mississippi, Missouri, Tennessee, and Texas. As discussed in Section 3.1, the vast majority of current coal (lignite) production, in the region occurs in Texas, with the remainder in Mississippi and Louisiana. Table I-2 in Appendix I lists the economic contribution of the tourism and recreation industry as well as food service and accommodations-related jobs, payroll, and per capita expenditures for each of these states. Table I-3 in Appendix I lists the 2007 data for visitation, acreage, and revenue generated by state parks in the coal-mining states.

Approximately 0.9 million acres of national forest lands fall within the boundaries of the Gulf Coast coal-producing region, out of the 3.1 million acres total within these national forests. See Table I-14 in Appendix I for the listing by forest. The USFS-managed Saline Bayou Wild and Scenic River, the only designated wild and scenic river in this region, is located in Louisiana's Kisatchie National Forest. The Natchez Trace Parkway and National Scenic Trail, and the San Antonio Missions, are the only NPS-managed facilities that intersect the coal resource study area within the boundaries of the Gulf Coast coal-producing region. They encompass 11,204 acres within the region and 31,847 in total. Approximately nine miles of the Saline Bayou National Wild and Scenic River also occurs within the boundaries of the region. Park specific information is displayed in Table I-15 of Appendix I. A review of Table I-16 in Appendix I shows that 175 state-managed recreational facilities are located within this coal-producing region, with nearly half of their 1.1 million acres occurring within the region boundaries. Figure 3.10-3 locates the only designated wild and scenic river in this region and depicts where the coal-producing areas of the region overlap national and state parks and forests.

Relevant data from the U.S. FWS 2011 National Survey of Fishing, Hunting, and Wildlife-Associated Recreation (U.S. FWS, 2011c) is provided in Table I-17 of Appendix I. The table also includes total expenditure data by state. For the activities included in the 2006 survey, Texas had the most participants (7.9 million) while Mississippi had the least (1.6 million).

Although coal is present in all ten states in the Gulf Coast region, it is only mined in Gulf Coast areas of Texas, Louisiana, and Mississippi. For this reason, the following subsections focus on these three states.

Figure 3.10-3. Gulf Coast Region National and State Recreation Areas



Coordinate system used: North America Albers Equal Area Conic

Source: U.S. Geological Survey, Gap Analysis Program (GAP). May 2016. Protected Areas Database of the United States (PAD-US), version 1.4 Combined Feature Class.

3.10.4.1 Louisiana Tourism and Recreation

The Louisiana portion of the Gulf Coast coal-producing region is located in the tourism regions designated by the Louisiana Official Tour Guide (Louisiana DCRT, 2013) as the Sportsman's Paradise and Crossroads regions. The Sportsman's Paradise region covers the northern part of the state and offers a diversity of wildlife in the longleaf pine forests, sprawling meadows, marshes, and lakes. This region includes attractions such as Poverty Point National Monument, Kisatchie National Forest, and state parks such as Chicot, Lake Claiborne, Chemin-A-Haut, and South Toledo Bend. The Crossroads region encompasses the central part of Louisiana and is a haven for water sports, fishing, hunting, birding, and horseback riding. The Toledo Bend Reservoir is noted for its bass fishing, boating, and water sports.

3.10.4.2 Mississippi Tourism and Recreation

The Mississippi portion of the Gulf Coast coal-producing region intersects all five of the tourism regions defined in the Mississippi Official Tour Guide (Mississippi Development Authority, 2013) and covers most of the state except for the southern portion of the Coastal Region and the eastern portion of the Hills Region. Mississippi offers superb fishing (saltwater and freshwater), hunting, golfing, camping, horseback riding, and wildlife viewing. Major recreational attractions include the Mississippi River bordering the western edge of the state; Leroy Percy, Wall Doxey, Clarkco, Hugh White, and Roosevelt State Parks; and the Pearl River State Wildlife Management Area and Pearl River State Waterfowl Refuge. The Natchez Trace Parkway follows the frontier route from Natchez to Nashville offering natural trails, recreation areas, and historic sites along the way.

3.10.4.3 Texas Tourism and Recreation

The Gulf Coast coal-producing region in Texas stretches from the Mexico border northeasterly to the Arkansas border in the tourism regions designated as the South Texas Plains, Prairie and Lakes, and Piney Woods in the Texas Travel Guide (Texas OEDT, 2013). This region covers much of the eastern portion of Texas except for the coastal region. Recreational areas in this region include the Sabine National Forest, Angelina National Forest, Davy Crockett National Forest, and Sam Houston National Forest. Recreational opportunities abound through the 60 state parks located within the South Texas Plains, Prairie and Lakes, and Piney Woods tourism regions.

3.10.5 Illinois Basin Region

The Illinois Basin coal-producing region includes portions of the states of Illinois, Indiana, and western Kentucky. Table I-2 in Appendix I lists the economic contribution of the tourism and recreation industry as well as food service and accommodations-related jobs, payroll, and per capita expenditures for each of these states. Table I-3 in Appendix I lists the 2007 data for visitation, acreage and revenue generated by state parks in coal mining states.

Approximately 71,944 acres of national forest lands fall within the boundaries of the Illinois Basin coal-producing region, out of the 508,141 acres they encompass in total. Table I-18 in Appendix I provides information on the national forests in this region. The Middle Fork Vermilion Wild and Scenic River, the only designated wild and scenic river in this coal-producing region, is located in Illinois. Six NPS-managed facilities, encompassing 415,071 acres in total and 157,900 acres within the boundaries, occur partially or entirely in the Illinois Basin coal-producing region. Park-specific information is displayed in

Table I-19 of Appendix I. A review of Table I-20 in Appendix I shows that 435 state-managed recreational facilities are located within this coal-producing region, with approximately 426,000 out of 489,000 acres occurring within the region boundaries. Figure 3.10-4 locates the only designated wild and scenic river in this region and depicts where the coal-producing region overlaps national and state parks and forests.

Relevant data from the FWS 2011 National Survey of Fishing, Hunting, and Wildlife-Associated Recreation (U.S. FWS, 2011c) is provided in Table I-22 of Appendix I. The table also includes total expenditure data by state. For the activities included in the 2011 survey, Illinois had the most participants (4.6 million) and Kentucky had the least (2.2 million).

3.10.5.1 Illinois Tourism and Recreation

The Illinois Basin coal-producing region covers much of the state with the exception of the northern quarter. The tourism areas within the coal-producing region, as designated by the Illinois Travel Guide (Illinois Office of Tourism, 2013), are Land of Lincoln (central-east), Great Rivers Country (west and southwest), and Trails to Adventure (southeast). The Southern region contains the expansive Shawnee National Forest, Ferne Clyffe State Park, and Giant City State Park, among other attractions. The Shawnee National Forest offers over 300 miles of hiking, biking, and equestrian trails. The Southwest region offers Jefferson National Expansion Memorial, Kaskaskia River Wildlife Area, and Pyramid State Park and Recreation Area at nearly 20,000 acres, the largest in Illinois, is made up almost entirely of formerly surface coal mined lands, as recreational opportunities. The Central region is home to Hazlet State Park, Ramsey Lake State Park, Stephen A. Forbes State Park, and Wayne Fitzgerrell State Park among several other recreation areas. The Western region is bounded on the west by the Mississippi River and on the east by the Illinois River. This region contains the Beaver Dam State Park and the Chautauqua National Wildlife Refuge.

Figure 3.10-4. Illinois Basin Region National and State Recreation Areas

Source: U.S. Geological Survey, Gap Analysis Program (GAP). May 2016. Protected Areas Database of the United States (PAD-US), version 1.4 Combined Feature Class.

3.10.5.2 Indiana Tourism and Recreation

The Indiana portion of the Illinois Basin coal-producing region includes the South and West tourism regions as designated by the Indiana Travel Guide (Indiana Office of Tourism Development (OTD), 2013). The South region offers boating, biking, camping, canoeing, caving, hiking, horseback riding, golfing, and water sports. The South region is bounded on the south by the Ohio River and includes Harmonie State Park, Angel Mounds State Memorial, Lincoln State Park, and the Hoosier National Forest among its recreational opportunities. The West region is home to Richard Lieber, Shades, Turkey Run, and Shakamak State Parks.

3.10.5.3 Kentucky Tourism and Recreation

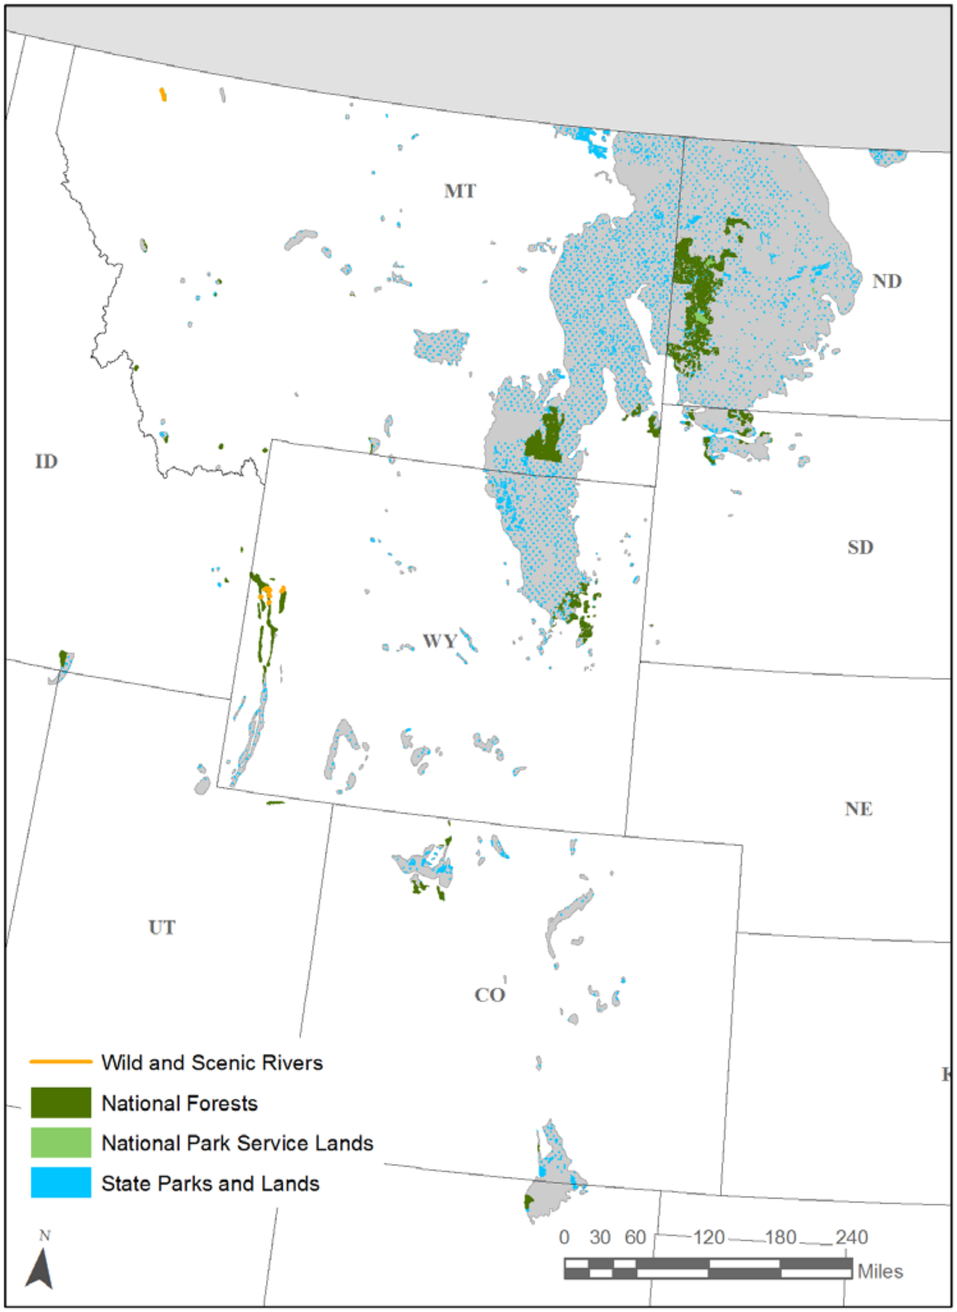
The Kentucky portion of the Illinois Basin coal-producing region is located in the tourism region designated by the Kentucky Official Visitor’s Guide as the “Bluegrass Blues & BBQ Region” (Kentucky Department of Travel (DT), 2011). The area is bounded on the north by the Ohio River; the Green River splits the area, providing a source of recreational activities. Other outdoor recreational opportunities are available at Mammoth Cave National Park; several state parks (Pennyrile, John J. Audubon, Lake Malone, and Ben Hawes); and Sloughs Wildlife Management Area.

3.10.6 Northern Rocky Mountains and Great Plains Region

The Northern Rocky Mountains and Great Plains coal-producing region includes portions of the states of Colorado, Montana, North Dakota, Utah, and Wyoming. As discussed in Section 3.1, the vast majority of current coal production in the region occurs in Wyoming, with the remainder in Montana and North Dakota. Table I-2 in Appendix I lists the economic contribution of the tourism and recreation industry as well as food service and accommodations-related jobs, payroll, and per capita expenditures for each of these states. Table I-3 in Appendix I lists the 2007 data for visitation, acreage, and revenue generated by state parks in coal mining states.

Approximately two million acres of national forest lands fall within the boundaries of the Northern Rocky Mountains and Great Plains coal-producing region. Table I-23 in Appendix I provides information on the national forests in this region, including their total acreage of approximately 38.6 million. Four national park managed facilities occur partially or entirely within the region, with 81,465 acres of their 1.1 million acre total falling within the region boundaries. Park-specific information is displayed in Table I-24 of Appendix I. A review of Table I-25 in Appendix I shows that 167 state-managed recreational facilities are located within this coal-producing region, totaling approximately 2 million acres within the region boundaries out of 21 million acres total. Figure 3.10-5 locates the designated wild and scenic rivers in this region and depicts where the coal-producing region overlaps national and state parks and forests. Table I-26 in Appendix I provides information on each of the identified wild and scenic rivers located within the Northern Rocky Mountains and Great Plains coal-producing region.

Figure 3.10-5. Northern Rocky Mountains and Great Plains Region National and State Recreation Areas



Coordinate system used: North America Albers Equal Area Conic

Source: U.S. Geological Survey, Gap Analysis Program (GAP). May 2016. Protected Areas Database of the United States (PAD-US), version 1.4 Combined Feature Class.

Data from the U.S. FWS 2011 National Survey of Fishing, Hunting, and Wildlife-Associated Recreation (U.S. FWS, 2011c) is provided in Table I-25 of Appendix I. The table also includes total expenditure data by state. For the activities included in the 2011 survey, North Dakota had the most participants (5.4 million) within this region and Wyoming had the least (0.95 million).

Although coal is present in all five states included in the Northern Rocky Mountains and Great Plains coal-producing region, it is only mined in the states of Montana, North Dakota, and Wyoming. For this reason, the following discussions focus on these three states.

3.10.6.1 Montana Tourism and Recreation

The coal-producing region in Montana intersects the tourism regions designated by the 2011 Montana Travel Planner (Montana Office of Tourism (OT), 2013) as Southeast Montana, Missouri River Country (in the northeast), and Central Montana. Central Montana features many streams and lakes, and Lake Elwell offers excellent year-round fishing for walleye, northern pike, native trout, and more. Central Montana is also home to the Upper Missouri National Wild and Scenic River, Nez Perce National Historical Site, Ackley State Park, and Sluice Boxes State Park (Montana OT, 2013). Missouri River Country boasts Fort Peck Lake with over 1,500 miles of shoreline and excellent walleye, smallmouth bass, and Chinook salmon fishing. The surrounding Charles M. Russell National Wildlife Refuge is popular with anglers as well. Missouri River Country offers world class dinosaur fossil finds and is home to the Fort Belknap and Fort Peck Indian Reservations. Southeast Montana contains the Crow Indian and Northern Cheyenne Indian Reservations, Medicine Rocks, Pirogue Island, and Rosebud Battlefield State Parks, and the Custer National Forest. The Yellowstone River is the longest free-flowing river outside of Alaska.

3.10.6.2 North Dakota Tourism and Recreation

The Northern Rocky Mountains and Great Plains coal-producing region in North Dakota is located in the western third of the state. This region is home to the North Dakota Badlands, Theodore Roosevelt National Park, Little Missouri, Lake Sakakawea, and Sully Creek State Parks (NPS, 2013b; North Dakota Parks and Recreation Department (PRD), 2013). The west region offers hiking, biking, snowshoeing, cross country skiing, and horseback riding opportunities on its many trails. Fishing is available year-round, on both water and ice.

3.10.6.3 Wyoming Tourism and Recreation

The coal-producing region in Wyoming is spread throughout the state, although few reserves are located in the Southeast Wyoming. Northwest Wyoming is home to Yellowstone and Grand Teton National Parks. Northeast Wyoming is home to the Black Hills National Forest, Devil's Tower National Monument, and the Thunder Basin National Grassland. A major tourist attraction in the Southwest Wyoming is Flaming Gorge Reservoir and Flaming Gorge National Recreation Area (Wyoming OT, 2013).

3.10.7 Northwest Region

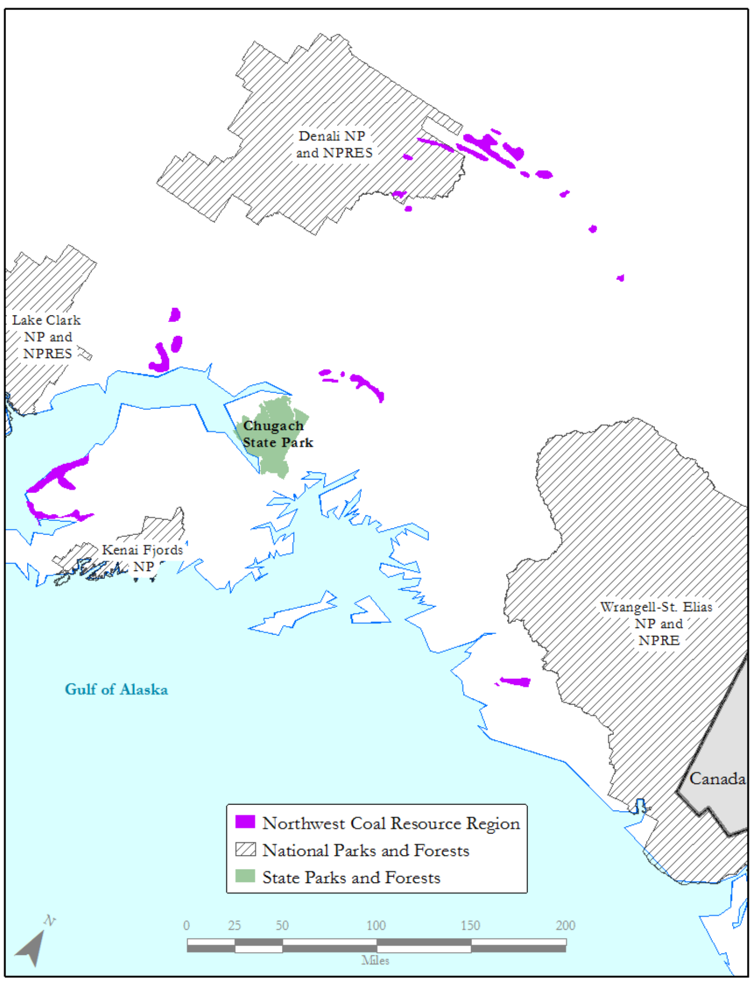
The Northwest coal-producing region includes portions of the states of Alaska, Washington, and Oregon. Although coal is present in each of these states, the only reasonably foreseeable coal mining in the region is in the state of Alaska. For this reason, the following discussions focus only on Alaska. Table I-2 in

Appendix I lists the economic contribution of the tourism and recreation industry as well as food service and accommodations-related jobs, payroll, and per capita expenditures for Alaska. Table I-3 in Appendix I lists the 2007 data for visitation, acreage, and revenue generated by Alaska state parks.

The Charley Wild and Scenic River is located in this region. The Denali National Park intersects the study area with approximately 33,000 of its 4.7 million acres occurring actually within the boundaries of the region as defined. Park-specific information is displayed in Table I-28 of Appendix I. A review of Table I-30 in Appendix I shows that two state-managed recreational properties intersect the boundaries of the region, of which 37,553 acres occur within the defined region (out of 2,433,203 in total). See Figure 3.10.10-6.

Relevant data from the U.S. FWS 2011 National Survey of Fishing, Hunting, and Wildlife-Associated Recreation (U.S. FWS, 2011c) is provided in Table I-29 of Appendix I. The table also includes total expenditure data for Alaska. For the activities included in the 2006 survey, Alaska had 0.9 million participants.

Figure 3.10-6. Northwest Region National and State Recreation Areas



Source: ESRI, 2015

3.10.7.1 Alaska Tourism and Recreation

The Alaska coal-producing region occurs in the tourism regions designated by the TravelAlaska.com (State of Alaska, 2013) as the Southcentral, Interior, and Far North. The coal fields in the Southcentral region fall mostly on the Kenai Peninsula and nearby areas, just south of Anchorage, but are not currently active. The Kenai Peninsula is known as "Alaska's Playground" and offers wildlife, cultural attractions, and fishing. The peninsula spans the Chugach National Forest and is home to Kachemak State Park, Kenai Fjords National Park, Kenai National Wildlife Refuge, and the Exit Glacier. There are 433 miles of trails and 150 miles of canoe trails available for recreational use. The Interior region is home to the only active coal mining in Alaska. The Interior region features the Yukon-Charley Rivers National Preserve and Denali National Park and Preserve. Recreational opportunities include hiking, rock climbing, ice climbing, photography, wildlife viewing, nature walks, horseback riding, river excursions, hunting, and fishing. The North Slope coal fields, immense in size and located within the Far North Region, are also inactive. The Far North region offers backpacking and river excursions in the Kobuk Valley National Park, Noatak National Preserve, Selawik National Wildlife Refuge, Gates of the Arctic National Park and Preserve, and the Arctic National Wildlife Refuge.

3.10.8 Western Interior Region

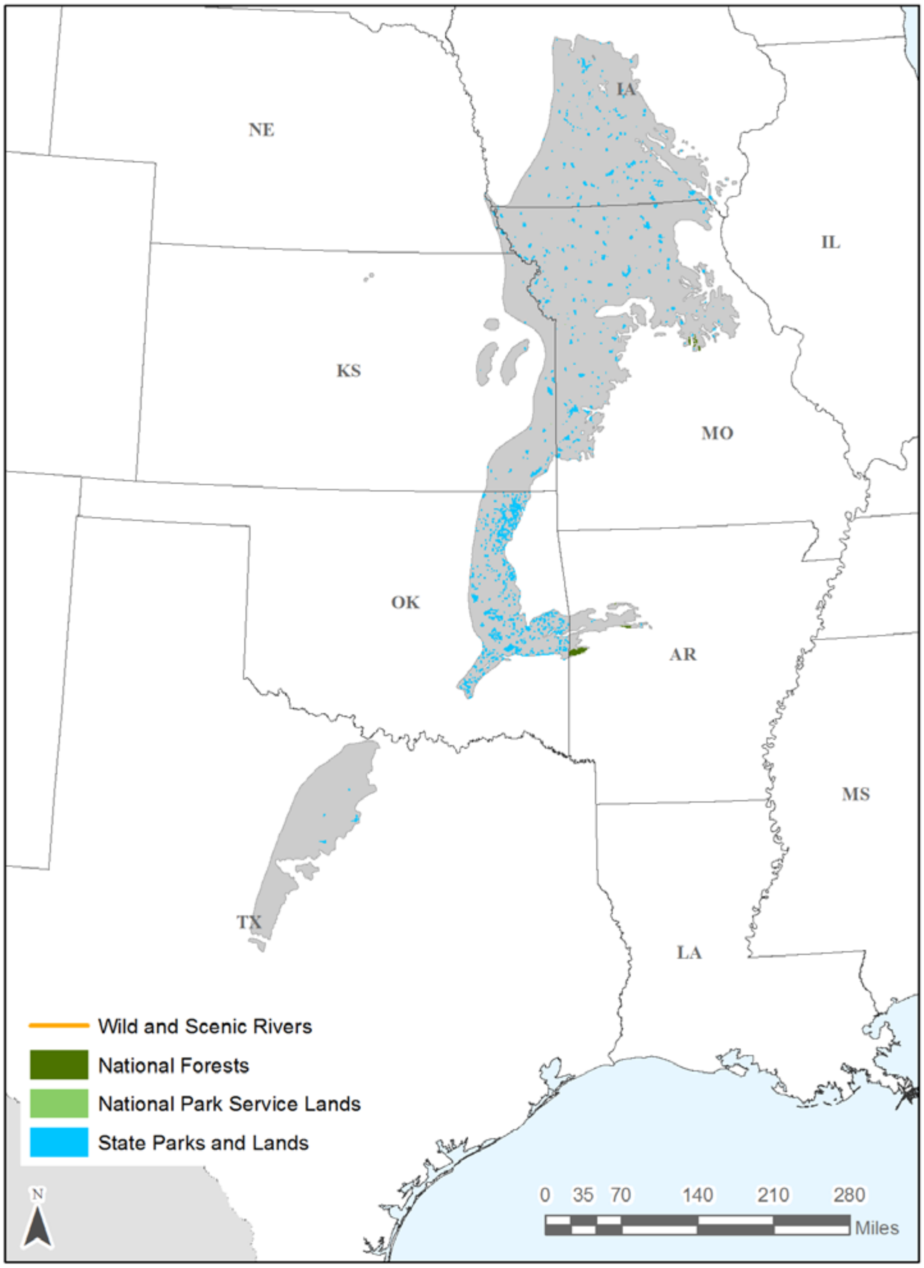
The Western Interior coal-producing region includes portions of the states of Arkansas, Iowa, Kansas, Missouri, Nebraska, Oklahoma, and Texas. As discussed in Section 3.1, the vast majority of current coal production in the region occurs in Oklahoma, with the remainder in Arkansas, Kansas, and Missouri. Table I-2 in Appendix I lists the economic contribution of the tourism and recreation industry as well as food service and accommodations-related jobs, payroll, and per capita expenditures for each of these states. Table I-3 in Appendix I lists the 2007 data for visitation, acreage, and revenue generated by state parks in coal mining states.

Approximately 48,535 acres of national forest lands fall within the boundaries of the Western Interior coal-producing region, with these areas occupying over 4 million acres in total. Table I-31 in Appendix I provides information on the national forests in this region. The USFS manages the two designated wild and scenic rivers in this region, both of which are located in Arkansas. Three National Park Service managed historic sites, for a total of 61 acres; occur within the defined area of the Western Interior coal-producing region. Park-specific information is displayed in Table I-32 of Appendix I. A review of Table I-33 in Appendix I shows that 507 state-managed recreational and conservation facilities are located within this coal-producing region, with approximately 0.8 million of the 3.8 million acres occurring within the boundaries of the region as defined for this EIS. Figure 3.10-7 locates the designated wild and scenic rivers in this region and depicts where the coal-producing region overlaps national and state parks and forests.

Relevant data from the U.S. FWS 2011 National Survey of Fishing, Hunting, and Wildlife-Associated Recreation (U.S. FWS, 2011c) is provided in Table I-35 of Appendix I. The table also includes total expenditure data by state. For the activities included in the 2006 survey, Missouri had the most participants (3.9 million) and Kansas had the fewest (1.5 million).

Although coal is present in all seven states included in the Western Interior coal-producing region, it is only mined in four of these states: Arkansas, Kansas, Missouri, and Oklahoma. For this reason, the following discussion focuses on these four states.

Figure 3.10-7. Western Interior Region National and State Recreation Areas



Coordinate system used: North America Albers Equal Area Conic

Source: U.S. Geological Survey, Gap Analysis Program (GAP). May 2016. Protected Areas Database of the United States (PAD-US), version 1.4 Combined Feature Class.

3.10.8.1 Arkansas Tourism and Recreation

The Arkansas portion of the Western Interior coal-producing region lies within two recreational regions, the River Valley Region and the Ouachita Region, as designated by the Arkansas Tour guide (Arkansas Department of Parks and Tourism (DPT), 2013). The River Valley Region offers a number of recreational opportunities. This area is known as Arkansas's wine country. The Fort Smith National Historic Site offers a glimpse into the colorful history of the Old West. The Ouachita Region is a popular destination known for its beautiful scenery. Visitors to these regions of Arkansas can enjoy many outdoor recreational activities such as rafting, kayaking, boating, fishing, swimming, camping, and hiking.

3.10.8.2 Kansas Tourism and Recreation

The Kansas portion of the Western Interior coal-producing region covers most of the eastern quarter of the state, but represents a very low amount of production. This portion of Kansas lies in the recreational regions designated by the Kansas Official Travel Guide 2013 (Kansas Department of Wildlife, Parks & Tourism (DWPT), 2013) as the Eastern Wooded Hills and Flint Hills Regions. The Santa Fe and Oregon Trails traverse these regions. Recreational opportunities include fishing, hunting, golfing, and boating. Recreational areas located near Bourbon and Linn Counties include the Fort Scott National Historical Site, Crawford, and Massacre Memorial State Parks.

3.10.8.3 Missouri Tourism and Recreation

The Missouri portion of the Western Interior coal-producing region includes most of the northwestern portion of the state; however, coal production is very minimal. This area lies mostly within the recreational region designated by the Missouri Official Travel Guide (Missouri Department of Economic Development (DED), 2013) as the Northwest region. This area of the state offers superb hunting, with deer, turkey, quail, pheasant, and waterfowl in abundance. The Missouri River traverses the area, providing water-related recreational activities. Recreational areas in the coal-producing region include the Harry S. Truman National Historical Site and the Knob Noster State Park.

3.10.8.4 Oklahoma Tourism and Recreation

The Oklahoma portion of the Western Interior coal-producing region is located in the east/northeastern part of the state, mostly within the recreational region designated by TravelOK.com (Oklahoma Tourism and Recreation Department (TRD), 2013) as Green Country (northeast). It also extends into the regions designated as Frontier Country (central) and Kiamichi Country (southeast). Green Country represents 18 counties in northeastern Oklahoma and includes 16 major lakes, along with green rolling hills and tall grass prairie. The Cimarron and Arkansas Rivers join west of Tulsa to form a large, man-made lake. Recreation opportunities in Oklahoma are focused in state parks. Many man-made lakes support boating, swimming, fishing, camping, and picnicking. Rafting, kayaking, hiking, backpacking, and mountain biking are popular activities enjoyed on the rivers and in the natural areas of the state. Recreation areas in the coal-producing region include the Fort Smith National Historical Site and Robbers Cave, Greenleaf Lake, and Fountainhead State Parks.

3.11 Visual Resources and Noise

3.11.1 Visual Resources

NEPA requires that measures be taken to "assure for all Americans … aesthetically pleasing surroundings" (42 U.S.C. § 4331). Aesthetic or visual values are a matter of personal preference and are different for different observers. Visual resources include the physical characteristics that make up the visible and aesthetic landscape, including land, water, vegetation, and manmade features. Visual resources contribute to the feeling of community value and pride and can help to define the historic and cultural identity of a region. The natural and manmade visual resources of a region are often vital to tourism, and the aesthetic quality of a region can leave a lasting impression on visitors as well as residents.

In many of the coal-producing regions mining has resulted in altered visual landscapes. Substantial areas now have non-native or fragmented vegetation with modified landforms; exposed acidic soils and spoil piles are visible and are distinct from natural land contours; and mining related infrastructure such as buildings, rail spurs, and road systems are present in areas that otherwise are remote and have few structures. Coal mines dominate foreground and middle ground views in the affected viewsheds; background views generally depend on the status of reclamation activities and the perspective from a particular observation point.

Federal and state guidelines for visual resources concentrate on the quality of the physical landscape, public concern for scenic quality, and determining whether the affected land is visible from travel routes or observation points (U.S. BLM, 2012). These guidelines typically describe the affected visual environment by identifying key views, analyzing the resources and community responses. This then allows for characterization of visual impacts and development of mitigation measures.

While SMCRA does not explicitly require analysis of visual resources during the permitting process, there are provisions within SMCRA that identify specific circumstances in which visual resources are provided varying levels of protection and visual impacts must be considered. Under Section 522(e) unless a permit applicant demonstrates that they meet one of the specific exceptions, the applicant will not be permitted to conduct surface coal mining operations in any area designated by Congress as unsuitable for surface coal mining operations (30 U.S.C. § 1272(e)). Many of the designated areas are recognized as the Nation's preeminent visual resources. For example, subject to limited exceptions, surface coal mining operations are not permitted within the boundaries of units of the National Park System, the National Wildlife Refuge Systems, the National System of Trails, the National Wilderness Preservation System, the Wild and Scenic Rivers System (including study rivers designated under Section 5(a) of the Wild and Scenic Rivers Act), and National Recreation Areas designated by Act of Congress (30 U.S.C. § 1272(e)(1)). Likewise, SMCRA allows mining within national forests only under limited circumstances and prohibits mining that would adversely affect any publicly owned park or place on the National Register of Historic Places or within 300 feet of a public park (30 U.S.C. § 1272(e)(2), (3), and (5)). See also 30 CFR Part 761.

30 CFR 761.11(c) specifies that if a proposed surface coal mining operation would have an adverse impact on a publicly owned park or place in the National Register of Historic Places, the proposed operation cannot be authorized unless both the SMCRA regulatory authority and the agency with

jurisdiction over the park or place jointly approve the operation. In essence, if adverse impacts are identified, under 30 CFR 780.31(a) or 784.17(a) the applicant must prepare a plan to prevent adverse impact, or (if approved by both agencies) to minimize adverse impacts.

Section 522 of SMCRA also establishes a process for the designation of areas as unsuitable for surface coal mining operations (30 U.S.C. § 1272). For example, areas may be designated unsuitable if the operations would "affect fragile or historic lands in which such operations could result in significant damage to important historic, cultural, scientific, and esthetic values and natural systems" (30 U.S.C. § 1272(a)(3)(B)). Such "fragile or historic lands" might include recreational resources (see also 30 CFR Part 762). Under Section 522(b) of SMCRA, all federal lands must be evaluated using the unsuitability criteria listed in that section (30 U.S.C. § 1272(b)). Finally, SMCRA allows anyone with an interest that is or may be adversely affected to petition the appropriate SMCRA regulatory authority to have certain lands, including fragile or historic lands, designated unsuitable for mining under the unsuitability criteria (30 U.S.C. § 1272(c); see also 30 CFR Parts 764 and 769).

Substantial BLM landholdings exist within some of the coal-producing regions. These BLM managed lands include lands subject to mineral leasing for coal, natural gas, or other minerals. The affected visual environment within these lands includes evidence of these activities interspersed with natural landscapes. However, BLM ensures that scenic values of these public lands are considered during the planning process through its visual resource management (VRM) system. The VRM system involves inventorying scenic values and establishing management objectives for those values through the resource management planning process, and then evaluating proposed activities to determine whether they conform to the management objectives (U.S. BLM, 2012).

3.11.2 Visual Resources by Region

3.11.2.1 Appalachian Basin Region

The Appalachian Basin coal-producing region includes parts of Pennsylvania, Ohio, Maryland, West Virginia, Virginia, eastern Kentucky, eastern Tennessee, and northern Alabama. The rugged terrain of the region is generally characterized by steep mountain slopes, confined river valleys, and narrow ridge tops. Mixed hardwood forests are prevalent throughout the region. Settlement patterns in the Appalachian Basin region were constrained by the dominant topographic features of the area such as rivers, streams, mountains, and valleys. Communities settled along rivers and within valleys primarily for transportation and agricultural purposes, and current road and rail transportation networks generally follow the network of streams. The natural environment is the key defining feature of the region (U.S. EPA et al., 2003). As described in Section 3.10 (Recreation), the tourism and recreation industries are highly dependent on the region's natural resources and scenic beauty.

Coal mining has had a pronounced influence on the visual resources within the region. Substantial areas now have non-native or fragmented vegetation with modified landforms; exposed acidic soils, and spoil piles are visible and are distinct from natural land contours. Both surface and underground mining have occurred in various locations throughout the region. Surface mining in the region has had temporary and permanent impacts on visual resources.

3.11.2.2 Colorado Plateau Region

The Colorado Plateau coal-producing region is located in the states of Arizona, Utah, Colorado, and New Mexico, encompassing approximately 150,000 square miles (388,500 square kilometers). The region is characterized by broad plateaus, volcanic intrusions and mountains at elevations of approximately 5,000 to 13,000 feet (1,520 to 3,960 meters), and deeply dissected canyons lined with sedimentary and volcanic rocks that provide striking visual vistas, including the Grand Canyon of the Colorado River (The Columbia Encyclopedia, 2013).

As discussed in Section 3.10, the region is popular with residents and tourists for its natural and historic recreational resources. Among the resources located within this region are numerous National Parks and monuments, and many ski resorts and destination resorts such as Aspen and Vail in Colorado and Park City in Utah. Resident and non-resident tourists are drawn to the many visual, cultural, and natural amenities found throughout the region.

Agricultural activity is a primary land use on the plains in the region, with agricultural lands consisting of croplands and grazing lands for livestock. In addition to coal, other diverse materials ranging from salt and gypsum to copper and gold are mined (USGS, 2013c). Communities within and around this coal-producing region were founded to support agriculture, mining, and transportation. These industries have become a part of the visual landscape of the region. The region also includes lands and resources owned and/or valued by Native American tribes.

Approximately 56.9 million acres of public lands in Colorado, Utah, New Mexico, and Arizona are managed under many different BLM offices and resource management plans (U.S. BLM, 2013d). Land is also managed by the U.S. Bureau of Reclamation (BOR) and the Bureau of Indian Affairs (BIA).

3.11.2.3 Gulf Coast Region

The Gulf Coast coal-producing region consists of lignite coal areas that spread from southern Texas eastward, primarily through the coal-producing areas of Louisiana and Mississippi. Extending into southern Alabama, the coal-producing region significantly diminishes in central Georgia and the Florida panhandle. This coal-producing region also extends northward up the Mississippi River embayment area to include much of eastern Arkansas into southeastern Missouri, extreme southern Illinois, and parts of far western Kentucky and Tennessee. While the southern edge of the coal region generally follows the arc of the coast, none of the region’s operating mines are near the Gulf of Mexico or within visual distance of the coast. Although lignite is present in all 11 states included in this region, it is only mined in Texas, Louisiana, and Mississippi.

Visual resources within the region are varied. The landscape throughout Texas includes plains and prairies as well as oak and pine forests. Low, rolling hills exist within the coastal plains and are typical of the lignite mining areas of all three Gulf Coast mining states, with the mine areas of Louisiana and Mississippi being heavily forested.

3.11.2.4 Illinois Basin Region

The Illinois Basin coal-producing region includes 68 percent of Illinois as well as a portion of southwest Indiana and the bituminous coal area of western Kentucky. This region is a part of the Interior Plains of North America and is primarily flat, with expansive open crop and pastureland areas. In various parts of the basin, forest land is a significant part of the visual landscape, particularly in the southern portions of both Illinois and western Indiana, where areas of greater topographic relief are present. The region is traversed by the Kaskaskia, Wabash, and Ohio rivers. There are a few small national park properties in the region, including the Lincoln Boyhood Memorial in Indiana, Mammoth Cave in Kentucky, and the Lincoln Home Historical Site in Illinois. This region has a higher population density than other coal regions, though most of the population centers of Illinois are not within the coal region of the Illinois Basin.

3.11.2.5 Northern Rocky Mountains and Great Plains Region

This region includes coal-producing areas in the states of Montana, Wyoming, North Dakota, and parts of Colorado and Utah. The topography generally is of low to moderate relief, with occasional buttes and mesas. The underlying bedrock in some areas is very erodible, which may result in heavily dissected topography. The general topographic gradient slopes down gently (generally southwest to northeast) with elevations ranging from 5,000 to 6,000 feet above mean sea level (AMSL) on the southern and western portions of the basin, to less than 4,000 feet AMSL on the north and northeast along the Montana state line. The Wyoming portion of the basin is bounded on the west by the Big Horn Mountains and the Casper Arch, on the south by the Laramie Mountains, on the southeast by the Hartville Uplift, and on the east by the Black Hills (U.S. BLM, 2005).

The Powder River Basin landscape is characterized by prairie grasslands, shrublands, forested areas, and riparian areas. Prairie grassland accounts a major component of the region, while sagebrush shrubland vegetation is widely distributed and also occupies a large proportion of the region. The primary vegetation communities impacted as a result of coal mine development have included mixed-grass and short-grass prairie and sagebrush shrublands. The species composition on the reclaimed land is different than surrounding undisturbed lands, particularly in regard to the percent of woody shrub species present during the years immediately following reclamation (U.S. BLM, 2005).

The BLM's Montana/Dakotas State Office manages 8.3 million acres of land and 47 million acres of mineral estate in Montana, North Dakota, and South Dakota (U.S. BLM, 2013a).

Because most of the coal in this region is managed by the BLM and subject to VRM requirements, visual resource assessment is included in environmental analysis in this region.

3.11.2.6 Northwest Region

While there is currently little mining activity ongoing in the region, the coal bedsare located in areas with high scenic value. Within the state of Washington coal beds exist in the Columbia Plateau, between the Cascade Range to the west and the Rocky Mountains in Idaho, to the east. There are also coal resources on the western and eastern flanks of the Cascade Range from Canada into northern Oregon. Oregon's coal resources are primarily located in the west-central part of Coos County, a coastal area with an economy currently driven by forest products, tourism, fishing, and agriculture.

One mine is currently extracting coal in the state of Alaska. The mine is north of Denali National Park and Preserve (DNPP) in an area of remote, mountainous foothills near Healy, Alaska (Alaska DMLW, 2004; Alaska DMLW, 2013). The mine operation is approximately ten miles north of the DNPP entrance and the closest park borders and is not visible except from the highest elevations of DNPP. The topography in the area is ranges from lowland interior plains 2,000 feet in elevation to Mount McKinley's southern peak at 20,320 feet, representing the highest point in North America. The coal operation is in the Nenana River valley, which is a sculpted U-shaped glacial valley with a broad floodplain. Scenic resources in the area are visible from multiple viewpoints including the George Parks Highway, the Alaska Railroad, and the Nenana River, all of which share the corridor through the Alaska Range. Transportation outside these established corridors is limited due to topographic constraints. Healy, Alaska is the largest town in the region, supporting a population of approximately 1,000 residents. Most residents are employed by activities connected to Usibelli coal mine, DNPP, and other recreation activities such as hiking, camping, fishing and hunting.

3.11.2.7 Western Interior Region

As a part of the Interior Plains of North America, this region includes the bituminous coal reserves of west-central Arkansas, central and southern Iowa, eastern Kansas, northwestern and central Missouri, southeastern Nebraska, eastern Oklahoma, and north-central Texas. Although coal is present in all seven states included in this region, it is not mined in Iowa and Nebraska. For this reason, further discussions focus on the Western Interior portions of the five coal-producing states.

Somewhat similar to the Illinois Basin coal-producing region, this region has a landscape that is primarily flat, with open crop and grass lands. The Oklahoma and Arkansas portions of this region have somewhat greater topographic relief, more extensive forest land cover, and may include greater visual resources. While historically this area was a large coal producer, coal mining has decreased significantly in the region. Most coal mining activities subject to SMCRA involve reclamation activities at inactive coal mining properties and the few scattered active mines remaining in this region.

3.11.2.8 Noise Environment

The ambient, or background, noise of a particular area is part of the human environment. Both natural and human produced sounds contribute to the ambient noise level. Ambient noise is discussed in this document as a resource because the proposed action has the potential to cause localized effects on ambient noise levels (as discussed later in Chapter 4). In some circumstances noise can dictate land use; extremely noisy areas are not conducive to residential development or placement of noise sensitive facilities such as schools and hospitals. In other circumstances relatively low levels of introduced noise are potentially of concern, for example on public lands where the natural quiet is a part of the context of the park and unwanted or unexpected sounds detract from the experience. In addition to the effects on humans, noise may be an issue of concern related to wildlife and domesticated animals due to the potential for disturbance.

Noise is a unique topic in that the boundaries of the affected area would change continuously (from an identical noise source at a fixed location the area affected would vary due to weather related variables). In this FEIS, the extent of the affected environment is defined by the boundaries of the area that would potentially be affected by noise associated with mining activities, including transportation routes associated with the mining. Noise has a limited travel distance; the affected environment for this resource would not likely include large areas beyond the immediate area of the activity.

In general, existing land uses can provide an expectation of ambient noise conditions. In rural settings ambient noise levels are typically lower. Rural areas are more likely to have a soundscape dominated by natural sounds such as wind or surf with less frequent additions of human noise. Intermittent noise from vehicles is a component of the affected environment in most areas, from roadway traffic to farm equipment use. However, in these settings with relatively low ambient noise levels the addition of a human produced sound may be more noticeable than in an urban environment. In relatively urbanized areas the soundscape would be dominated by human produced sounds; the additional noise associated with coal mining activities may not produce a new affected area if the additional noise is masked by those already present.

As discussed in more detail in Section 3.11.2, SMCRA prohibits surface coal mining operations within the boundaries of many types of public lands, any publically owned park or place on the National Register of Historic Places, or within 300 feet of a public park. While these lands might be part of the affected environment for other resources, for example visual resources because mining activities might be visible from a long distance, these areas are unlikely to be part of the affected environment for noise from coal mining activity due to the characteristics of sound travel and the protections within SMCRA.

3.12 Utilities and Infrastructure

This section describes two key aspects of infrastructure that are important to coal mining operations: transportation and electrical utilities. The discussion first provides an overview of these infrastructure elements and reviews relevant regulations. The remaining subsections examine the transportation infrastructure of each coal-producing region in greater detail.

3.12.1 Overview

3.12.1.1 Transportation Infrastructure Overview

Both suppliers and users rely on a variety of freight transportation modes to move coal. Coal is traditionally transported by more than one mode of freight transportation because of cost considerations, the location of the mine site, and/or the location of the customer. Rail, truck, and/or barge are the most common modes of coal transport in the U.S. Customers located at or near coal mines may also use conveyor belts to transport the coal, but this method of transportation accounts for less than seven percent of coal transport (National Energy Technology Laboratory (NETL), 2010). In multimodal coal transportation, the initial transportation mode from the mine site is not always the primary mode of coal transportation. For example, coal shipments arriving by rail to a customer are normally hauled to or away from a railroad site by truck. Similarly, coal hauled by barge is transported to or away from river terminals by truck, rail, or conveyor. Approximately 70 percent of U.S. coal is transported to market by train for at least part of its trip; waterborne (river barge) deliveries account for 12 percent of shipments, and truck deliveries account for 11 percent of shipments (2012 estimates) (U.S. Energy Information Administration (EIA) *Domestic Distribution of U. S. Coal By Origin State, Consumer, Destination, and Method of Transport Quarterly Reports, 2012*) (U.S. EIA, 2012d).[10]

[10] We have not updated the data presented in the DEIS for the sections to follow because as of February 24, 2016 the percentages of transportation by method had changed only slightly. See the U.S. EIA article "Rail continues to dominate coal shipments to the power sector," accessed September 2016,

http://www.eia.gov/todayinenergy/detail.cfm?id=25092#

3.12.1.1.1 Rail

As shown in Figure 3.12-1, four principal coal hauling railroads currently operate in the U.S: Burlington Northern Santa Fe (BNSF), Union Pacific (UP), CSX, and Norfolk Southern (NS). BNSF and UP primarily operate west of the Mississippi River, while CSX and NS primarily provide service east of the Mississippi River (NETL, 2010). Growth in the volume and tonnage of rail traffic is expected to be considerable; the U.S. Department of Transportation (U.S. DOT) estimates that demand for rail freight transportation will increase by 88 percent over current tonnage by 2035. The *National Rail Freight Infrastructure Capacity and Investment Study* (Cambridge Systematics, 2007) projects rail volumes both with and without infrastructure improvements and investments required for the railroads to carry the freight tonnage forecast by the U.S. DOT. Projected rail volumes from this study are discussed in this section.

Figure 3.12-1. National Rail Freight Network with Coal-Fired Power Plants

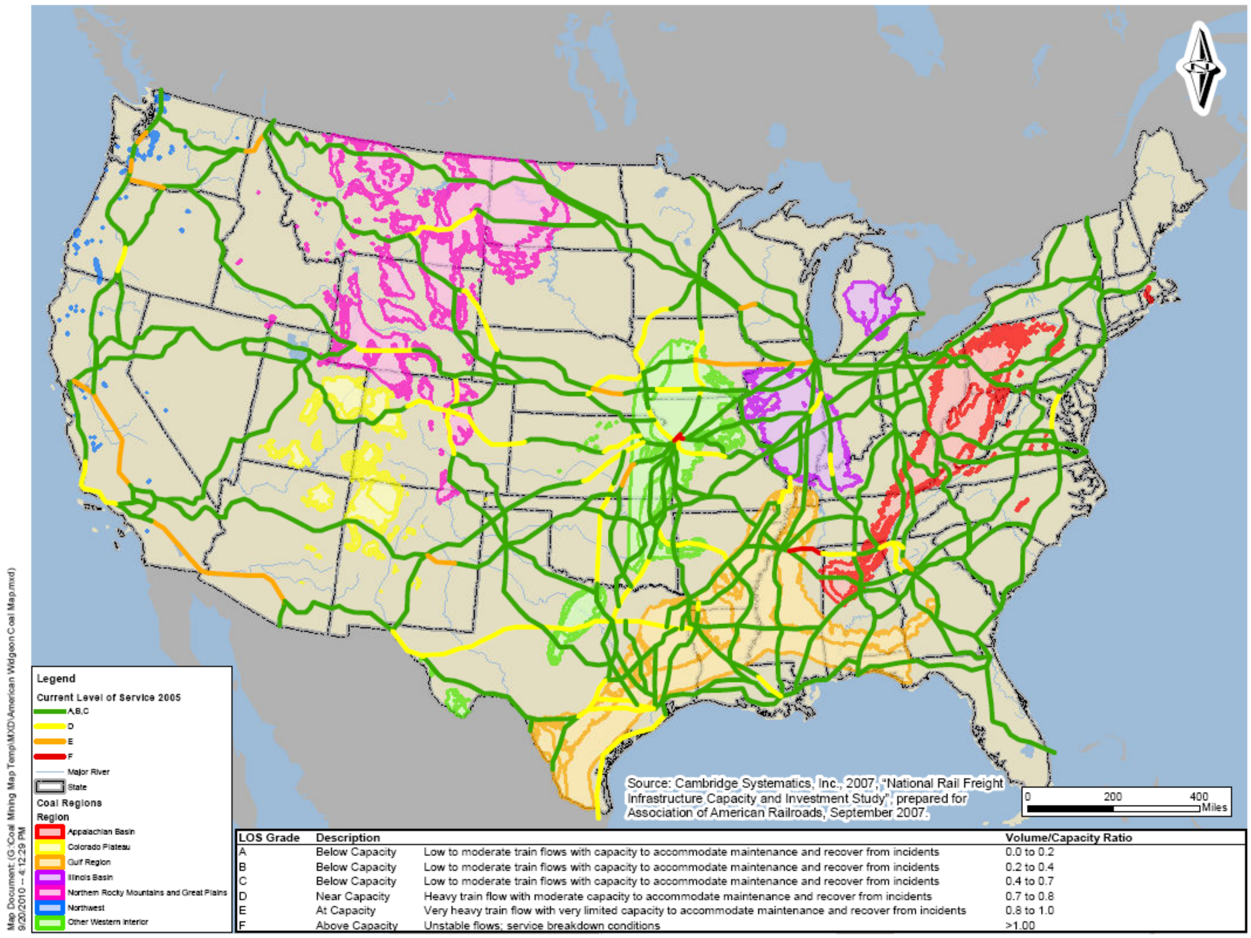
USGS, 2011a, *Coal Fields*, U.S. DOI, http://nationalatlas.gov/atlasftp.html?openChapters=chpgeol#chpgeol

CSX is the largest coal hauling railroad in the eastern U.S., serving more than 130 mines in nine states at the time the 2007 report was prepared. Primary markets for CSX coal shipments are power plants in the Northeast and Southeast (NETL, 2010).

Figures 3.12-2 and 3.12-3 depict the regional areas of constraint within the current and future freight rail system. If railroads cannot meet transportation needs in 2035, then freight will be shed to trucks and an already heavily congested highway system. Conversely, if trucks cannot carry their share in 2035, then freight would be shifted to rail.

Figure 3.12-2. Current Level of Rail Service, 2005



LOS Grade	Description		Volume/Capacity Ratio
A	Below Capacity	Low to moderate train flows with capacity to accommodate maintenance and recover from incidents	0.0 to 0.2
B	Below Capacity	Low to moderate train flows with capacity to accommodate maintenance and recover from incidents	0.2 to 0.4
C	Below Capacity	Low to moderate train flows with capacity to accommodate maintenance and recover from incidents	0.4 to 0.7
D	Near Capacity	Heavy train flow with moderate capacity to accommodate maintenance and recover from incidents	0.7 to 0.8
E	At Capacity	Very heavy train flow with very limited capacity to accommodate maintenance and recover from incidents	0.8 to 1.0
F	Above Capacity	Unstable flows; service breakdown conditions	>1.00

3.12.1.1.2 Barge

According to the 2010 National Energy Technology Laboratory report (NETL, 2010), approximately 70 electric power plants are located along the U.S. inland water system. These locations are accessible by barge, which can be an efficient and inexpensive method of transportation. Most of these plants are located along the Ohio River and its tributaries, or the Mississippi River, while a few plants are located along the Gulf or Atlantic coasts. Figure 3.12-4 shows the location of coal-fired power plants with barge access.

Figure 3.12-4. Coal-Fired Power Plants with Barge Access

USGS, 2011a, *Coal Fields*, U.S. DOI, http://nationalatlas.gov/atlasftp.html?openChapters=chpgeol#chpgeol

3.12.1.1.3 Roadways

Public highways and roads are frequently used to transport coal for a portion of the trip. Figure 3.12-5 depicts the major interstate highway system. The distance travelled by coal haul trucks varies based upon overall transport distance and the ultimate destination. Longer distances are frequently combined with other transport modes to minimize costs. Bridges and pavement in the Interstate Highway System are typically designed to allow 80,000 pounds gross vehicle weight (GVW) to travel long distances without reconfiguring. State and local authorities frequently monitor the weight of the freight vehicles, particularly with respect to the equivalent single axle load (ESAL). Kentucky and West Virginia have designated coal haul routes for which the weight of permitted vehicles is greater, typically 120,000 pounds GVW (West Virginia DOH, 2012).

Figure 3.12-5. Map of U.S. Interstate Highway System

USGS, 2011a, *Coal Fields*, U.S. DOI, http://nationalatlas.gov/atlasftp.html?openChapters=chpgeol#chpgeol

3.12.1.1.4 Other Modes

Less predominant means of coal transport also are used, including, but not limited to, the Great Lakes, Tidewater Piers, and Tramway/Conveyor/Slurry Pipelines. These other modes of transport are typically limited to a specific site or region but accounted for approximately seven percent of coal transport during 2012 (U.S. EIA, 2012d).

3.12.1.2 Electric Utilities Overview

Electricity in the U.S. is produced from a number of sources. The EIA's Electric Power Monthly 2013 (U.S. EIA, 2013f) data identifies fifteen different sources for production of electricity. Electricity produced from coal is the largest single production source in the country. In July, 2013, 38.9 percent (153,330 thousand megawatt hours) of the Nation's electricity was produced from coal. A total of 83,466,000 tons of coal were used to produce this electricity (U.S. EIA, 2013f). According to the EIA, in

July 2013, the national average retail price across all sectors of the economy for electricity was 10.71 cents per kilowatt hour. In June of 2011, an estimated 93 percent of the coal mined in this country was used to produce electricity (U.S. EIA, 013f).

The EIA's Annual Energy Outlook 2013 (U.S. EIA, 2013c) data includes projections for electricity demand and cost through 2040. The EIA predictions show that between 2011 and 2040, the production of electricity will increase at approximately 0.9 percent per year. In 2035, when adjusted to remove the effects of inflation, the national average retail price across all sectors of the economy for electricity is predicted to be between 10.1 and 11.9 cents per kilowatt hour.

Coal production, mining methods and cost of electricity to the consumer can vary greatly between regions. Variations in coal production and mining methods are discussed at length in Section 3.1 of this chapter. As production of coal from the 25 states within the coal-producing regions contributes over 38 percent of the energy required for the production of electricity in the Nation, the scope of the discussion of costs of electricity must include all regions within the U.S.

3.12.1.2.1 Regional Electricity Production and Costs

Given that coal is the dominant energy source for the production of electricity in the U.S., the scope of analysis of this issue must extend beyond the coal-producing states to include the country at large. This section will draw on the regional census division and state-specific information presented in the EIA's Electric Power Monthly for July 2013, released in September 2013. Table 3.12-1 shows the total electricity production by state, total electricity production from coal by state, and average retail price of electricity across all sectors of the economy as of July 2013.

Table 3.12-1. Electricity Production and Costs by Region and by State

Census Division and State	Net Electricity Production by State - All Sectors (Thousand Megawatt hours)	Net Electricity Production From Coal by State - All Sectors (Thousand Megawatt hours)	Average Retail Price of Electricity - Al Sectors (Cents per Kilowatt hour)

	July 2013	July 2013	July 2013
Washington	11,277	723	6.98
Pacific Noncontiguous	1,349	178	26.87
Alaska	487	46	17.06
Hawaii	861	131	32.49
U.S. Total	393,753	153,330	10.71

Notes: Values for 2013 are preliminary. Totals may not equal sum of components because of independent rounding. Source: U.S. EIA, 2013g. Tables 1.6.A, 1.7.A, and 5.6.A; Electric Power Monthly, September 2013, with data for July 2013, U.S. Department of Energy.

NM = Not meaningful due to large relative standard error or excessive percentage change.

A review of data in Table 3.12-1 (above) shows that while the average retail price for electricity across all sectors of the U.S. economy was 10.71 cents per kilowatt hour, the regional and state variations in this price are quite wide. Washington is at the low end of the spectrum at 6.98 cents per kilowatt hour and Hawaii is at the high end at 32.49 cents per kilowatt hour. The data further reveals that on a state-by-state basis, coal is of widely varying importance to the production of electricity. On the low end of the spectrum, coal is not used to produce electricity in Vermont or Rhode Island while, on the high end of the spectrum, coal is used to produce 95 percent of the electricity generated in West Virginia.

3.12.2 Appalachian Basin Coal Region Transportation

The Appalachian Basin spans eight states: Maryland, Ohio, Pennsylvania, West Virginia, Kentucky, Virginia, Alabama, and Tennessee. It is subdivided into smaller coal regions: North, Central, and South, the distinguishing factor primarily being the sulfur content of the coal. Table 3.12-2 shows the number of short tons of coal originating in each of these states in the year 2012 (U.S. EIA, 2012d).

Table 3.12-2. Short Tons of Coal Originating in Appalachian Basin States in 2012

Short Tons by State (All Modes)	Total
Alabama	8,974,000
Kentucky (East)	35,598,000
Maryland	2,165,000
Ohio	28,702,000
Pennsylvania	39,071,000
Tennessee	1,276,000
Virginia	10,882,000
West Virginia	74,066,000
Total Short Tons Appalachian Basin	200,734,000

Source: U.S. EIA, 2012d. Domestic Distribution of U.S. Coal by Origin States, Consumer, Destination and Method of Transportation, 2012 Quarterly Reports.

Table 3.12-3 identifies the primary modes of coal transport and historic use of those modes within the Appalachian Basin, based on where the coal originates (U.S. EIA, 2012d).

Table 3.12-3. Primary Modes of Coal Transport by State – Appalachian Basin

Source: U.S. EIA, 2012d. Domestic Distribution of U.S. Coal by Origin States, Consumer, Destination and Method of Transportation, 2012 Quarterly Reports.

The eastern portion of Kentucky is considered to be part of the Appalachian Basin, while the western portion of Kentucky is considered to be part of the Illinois Basin (and the far western portion is in the Gulf region, but no coal is mined in that part of the state). For purposes of this report, transportation statistics have been generated by county. Statistics for Kentucky counties located within the Appalachian Basin are presented in this section, and statistics for Kentucky counties located within the Illinois Basin are presented below.

The transportation requirements of each mode within the Appalachian Basin are summarized below.

3.12.2.1 Rail Requirements

The *National Rail Freight Infrastructure Capacity and Investment Report* prepared for the Association of American Railroads by Cambridge Systematics (2007) provided an assessment of the long-term capacity expansion needs for continental U.S. freight railroads. The report included assessments of current and future demand for rail freight transportation through 2035. For the Appalachian Basin as a whole, train volumes from the year 2005 were below practical capacity (Level of Service (LOS) A, B, and C), with the exception of a small section of rail in northeastern Alabama/southern Tennessee that was near capacity (LOS D).

Without capital improvements, by 2035, it is estimated that the Appalachian Basin as a whole would be composed primarily of rail operating at LOS of A, B, and C (Cambridge Systematics, 2007). Without improvements, by 2035 some areas of west-central Pennsylvania and south-central Kentucky would be downgraded to LOS D (near capacity), and some areas in south-central Tennessee/northern Alabama would be downgraded to LOS F (over capacity). The study concluded that with improvements, the entire Appalachian Basin would be composed of rail operating at LOS A, B, and C, with the exception of a small section of rail in northeastern Alabama/southern Tennessee that would be operating at capacity (LOS E) (Cambridge Systematics, 2007).

The previously referenced the EIA's Quarterly Reports provide details of domestic distribution of U.S. coal by origin state, consumer, destination, and method of transport for the year 2012. Information provided in these reports included that quoted herein regarding usage of rail, barge, and roadway infrastructure for coal transportation in coal-producing regions. The information indicated that mines located in the eight states within the Appalachian Basin shipped nearly 105 million short tons of coal by rail in 2012. This represents approximately 17 percent of the total tonnage of coal shipped by rail nationwide in 2012.

3.12.2.2 Barge Requirements

Mines located in the eight states within the Appalachian Basin shipped nearly 62 million short tons of coal by river in 2012. This represents approximately 59 percent of the total short tons of coal shipped by river nationwide in 2012, making the Appalachian Basin the predominant user of river transportation.

3.12.2.3 Roadway Requirements

Mines located in the eight states within the Appalachian Basin shipped over 24 million short tons of coal by truck in 2012. This represents approximately 36 percent of the total short tons of coal shipped by truck nationwide in 2012.

3.12.3 Colorado Plateau Region Transportation

The Colorado Plateau spans four states: Arizona, Colorado, New Mexico, and Utah. Table 3.12-4 shows the number of short tons of coal originating in each of these states in the year 2012 (U.S. EIA, 2012d).

Table 3.12-4. Short Tons of Coal Originating in Colorado Plateau States in 2012

Short Tons by State (All Modes)	Total
Arizona	7,460,000
Colorado	20,595,000
New Mexico	22,941,000
Utah	15,264,000
Total Short Tons Colorado Plateau	66,260,000

Source: U.S. EIA, 2012d. Domestic Distribution of U.S. Coal by Origin States, Consumer, Destination and Method of Transportation, 2012 Quarterly Reports.

Table 3.12-5 identifies the primary modes of coal transport and historic use of those modes within the Colorado Plateau, based on where the coal originates (U.S. EIA, 2012d).

Table 3.12-5. Primary Modes of Coal Transport by State – Colorado Plateau

Originating Coal Haul State	Originating Mode of Transport	Statistics for Primary Modes of Coal Transport (approximate percentage of coal transported by mode by state of origin)
Arizona	Rail	91
	Barge	None
	Road	9
	Other	None
Colorado	Rail	85
	Barge	0
	Road	14
	Other	1
New Mexico	Rail	40
	Barge	None
	Road	60
	Other	None
Utah	Rail	42
	Barge	None
	Road	44
	Other	14

Source: U.S. EIA, 2012d. Domestic Distribution of U.S. Coal by Origin States, Consumer, Destination and Method of Transportation, 2012 Quarterly Reports.

The transportation requirements of each mode within the Colorado Plateau are summarized as follows.

3.12.3.1 Rail Requirements

Data within the *National Rail Freight Infrastructure Capacity and Investment Study* (Cambridge Systematics, 2007) showed that within the Colorado Plateau as whole, train volumes for the year 2005 were below practical capacity (LOS A, B, and C) with the exception of northeastern Colorado, where rail was near capacity (LOS D).

Without capital improvements, it is estimated that the rail corridors bisecting New Mexico and Arizona and in northeastern Colorado and southwestern Utah will be operating at LOS F (over capacity) by 2035

(Cambridge Systematics, 2007). The study concluded that with improvements, the entire Colorado Plateau rail system would operate at LOS A, B, and C, with the exception of a small section of rail in southwestern New Mexico (outside the coal-producing region of New Mexico) that would be operating near capacity (LOS D).

Mines located in the four states within the Colorado Plateau shipped nearly 40 million short tons of coal by rail in 2012. This represents approximately seven percent of the total tonnage of coal shipped by rail nationwide in 2012. Within the Colorado Plateau, rail is the predominant mode of coal transport; more than 50 percent more coal is shipped by rail (40 million short tons) than by all other modes of transport in this region (26 million short tons).

3.12.3.2 Barge Requirements

Mines located in the four states within the Colorado Plateau did not record shipments of coal by river in 2012.

3.12.3.3 Roadway Requirements

Mines located in the four states within the Colorado Plateau shipped over 23 million short tons of coal by truck in 2012. This represents approximately 23 percent of the total short tons of coal shipped by truck nationwide in 2012.

3.12.4 Gulf Coast Region Transportation

Over 99 percent of current mining in the Gulf Coast region occurs within the states of Louisiana, Mississippi, and Texas. Table 3.12-6 shows the number of short tons of coal originating in each of these states in 2012.

Table 3.12-6. Short Tons of Coal Originating in Gulf Coast States in 2012

Short Tons by State (All Modes)	Total
Louisiana	3,961,000
Mississippi	3,185,000
Texas	43,215,000
Total Short Tons Gulf Coast	50,361,000

Source: U.S. EIA, 2012d. Domestic Distribution of U.S. Coal by Origin States, Consumer, Destination and Method of Transportation, 2012 Quarterly Reports.

Table 3.12-7 identifies the primary modes of coal transport and historic use of those modes within the Gulf Coast, based on where the coal originates (U.S. EIA, 2012d).

The transportation requirements of each mode within the Gulf Coast are summarized as follows.

Table 3.12-7. Primary Modes of Coal Transport by State – Gulf Coast

Originating Coal Haul State	Originating Mode of Transport	Statistics for Primary Modes of Coal Transport (approximate percentage of coal transported by mode by state of origin)
Louisiana	Rail	None
	Barge	None
	Road	16
	Other	84
Mississippi	Rail	4
	Barge	None
	Road	96
	Other	None
Texas	Rail	35
	Barge	None
	Road	36
	Other	294

Source: U.S. EIA, 2012d. Domestic Distribution of U.S. Coal by Origin States, Consumer, Destination and Method of Transportation, 2012 Quarterly Reports.

3.12.4.1 Rail Requirements

Data within the *National Rail Freight Infrastructure Capacity and Investment Study* (Cambridge Systematics, 2007) showed that within the Gulf Coast, as a whole, train volumes from the year 2005 were already at capacity (LOS A, B, and C) or near capacity (LOS D). Areas of southwestern Texas and southwestern Louisiana contain the bulk of lines nearing capacity (LOS D). Areas in northern Mississippi/southwestern Tennessee are above capacity (LOS F).

Without capital improvements, it is estimated that most of the rail corridors along the Gulf Coast will be operating at LOS F (over capacity) by 2035 (Cambridge Systematics, 2007). The study concluded that with improvements, the entire Gulf Coast would be composed of rail operating at LOS A, B, and C (Cambridge Systematics, 2007).

Mines located in the three states top producing states within the Gulf Coast shipped over 15 million short tons of coal by rail in 2012, most of which originated in Texas. Approximately 120 thousand tons originated in Mississippi. This represents approximately two percent of the total tonnage of coal shipped by rail nationwide in 2012.

3.12.4.2 Barge Requirements

Mines located in the three top producing states within the Gulf Coast coal region did not record shipments of coal by river in 2012.

3.12.4.3 Roadway Requirements

Mines located in the three top producing Gulf Coast states shipped over 19 million short tons of coal by truck in 2012. This represents approximately 20 percent of the total short tons of coal shipped by truck nationwide in 2012. This is the preferred method of coal transportation in the Gulf Coast region.

3.12.5 Illinois Basin Region Transportation

The Illinois Basin spans three states: Illinois, Indiana, and western Kentucky. Table 3.12-8 shows the number of short tons of coal originating in each of these states in the year 2012.

Table 3.12-8. Short Tons of Coal Originating in Illinois Basin States in 2012

Short Tons by State (All Modes)	Total
Illinois	32,856,000
Indiana	34,983,000
Kentucky (West)	39,052,000
Total Short Tons Illinois Basin	106,891,000

Source: U.S. EIA, 2012d. Domestic Distribution of U.S. Coal by Origin States, Consumer, Destination and Method of Transportation, 2012 Quarterly Reports.

Table 3.12-9 identifies the primary modes of coal transport and historic use of those modes within the Illinois Basin, based on where the coal originates (U.S. EIA, 2012d).

The transportation requirements of each mode within the Illinois Basin are summarized as follows.

Table 3.12-9. Primary Modes of Coal Transport by State – Illinois Basin

Originating Coal Haul State	Originating Mode of Transport	Statistics for Primary Modes of Coal Transport (Approximate percentage of coal transported by rail, barge, or road-sorted by state of origin)
Illinois	Rail	33
	Barge	47
	Road	10
	Other	10
Indiana	Rail	69
	Barge	13
	Road	19
	Other	<1
Kentucky (West)	Rail	35
	Barge	48
	Road	18
	Other	< 1

Source: U.S. EIA, 2012d. Domestic Distribution of U.S. Coal by Origin States, Consumer, Destination and Method of Transportation, 2012 Quarterly Reports.

3.12.5.1 Rail Requirements

Data within the *National Rail Freight Infrastructure Capacity and Investment Study* (Cambridge Systematics, 2007) showed that within the Illinois Basin as a whole, train volumes from the year 2005 were below capacity (LOS A, B, and C), with the exception of notable river crossings where they were near or at capacity (LOS D and E). Rail transport within the northeast Illinois region was at capacity (LOS E).

Without capital improvements, by 2035 the study estimates that most of the Illinois Basin will be downgraded to at or above capacity (LOS E and F) (Cambridge Systematics, 2007). The study concluded that, with improvements, the entire Illinois Basin would be composed of rail operating at LOS A, B, and C (Cambridge Systematics, 2007).

Mines located in the three states within the Illinois Basin shipped over 48 million short tons of coal by rail in 2012. This represents approximately eight percent of the total tonnage of coal shipped by rail nationwide in 2012. Rail is the predominant mode of coal haul from Indiana.

3.12.5.2 Barge Requirements

Mines located in the three states within the Illinois Basin shipped slightly more than 38 million short tons of coal by river in 2012. This represents approximately 37 percent of the total short tons of coal shipped by river nationwide in 2012. Barge is the predominant mode of coal haul from Illinois and western Kentucky.

3.12.5.3 Roadway Requirements

Mines located in the three states within the Illinois Basin shipped slightly less than 17 million short tons of coal by truck in 2012. This represents approximately 17 percent of the total short tons of coal shipped by truck nationwide in 2012. In Illinois, approximately ten percent of the coal produced in the state is shipped over public roadways.

3.12.6 Northern Rocky Mountains and Great Plains Region Transportation

The Northern Rocky Mountains and Great Plains region spans Montana, North Dakota, and Wyoming. Table 3.12-10 shows the number of short tons of coal originating in each of these states in the year 2012.

Table 3.12-10. Short Tons of Coal Originating in Northern Rocky Mountains and Great Plains States in 2012

Short Tons by State (All Modes)	Total
Montana	20,147,000
North Dakota	27,720,000
Wyoming	402,671,000
Total Short Tons Northern Rocky Mountains and Great Plains	450,538,000

Source: U.S. EIA, 2012d. Domestic Distribution of U.S. Coal by Origin States, Consumer, Destination and Method of Transportation, 2012 Quarterly Reports.

Table 3.12-11 identifies the primary modes of coal transport and historic use of those modes within the Northern Rocky Mountains and Great Plains, based on where the coal originates (U.S. EIA, 2012d).

The transportation requirements of each mode within the Northern Rocky Mountains and Great Plains are summarized as follows.

Table 3.12-11. Primary Modes of Coal Transport by State – Northern Rocky Mountains and Great Plains

Originating Coal Haul State	Originating Mode of Transport	Statistics for Primary Modes of Coal Transport (approximate percentage of coal transported by mode by state of origin)
Montana	Rail	59
	Barge	0
	Road	2
	Other	39
North Dakota	Rail	10
	Barge	None
	Road	41
	Other	49
Wyoming	Rail	96
	Barge	1
	Road	< 1
	Other	3

Source: U.S. EIA, 2012d. Domestic Distribution of U.S. Coal by Origin States, Consumer, Destination and Method of Transportation, 2012 Quarterly Reports.

3.12.6.1 Rail Requirements

Data within the *National Rail Freight Infrastructure Capacity and Investment Study* (Cambridge Systematics, 2007) showed that within the Northern Rocky Mountains and Great Plains region as a whole, train volumes from the year 2005 were below practical capacity (LOS A, B, and C), with the exception of a small section of rail in southeastern Montana that was near capacity (LOS D).

Without capital improvements, by 2035 it is estimated that the Northern Rocky Mountains and Great Plains will experience rail operations at or above capacity (LOS E and F) for much of the region (Cambridge Systematics, 2007). The 2007 study concluded that, with improvements, the entire Northern Rocky Mountains and Great Plains area would be composed of rail operating at LOS A, B, and C, with the exception of a portion of northeastern Wyoming that would operate near capacity (LOS D) (Cambridge Systematics, 2007).

Mines located in the three states within the Northern Rocky Mountains and Great Plains shipped over 401 million short tons of coal by rail in 2012. This represents approximately 66 percent of the total tonnage of coal shipped by rail nationwide in 2012. Wyoming is the predominant source of coal within the region (and the U.S.), with over 95 percent of coal originating in Wyoming shipping by rail.

The Powder River Basin in the Northern Rocky Mountains and Great Plains is the principal source of coal originating on both the BNSF and UP railroads. More than 90 percent of all BNSF's coal tons originate from the Powder River Basin. UP also ships coal from other coal regions, including the Colorado Plateau (Colorado and Utah) and the Illinois Basin (Illinois) (NETL, 2010).

3.12.6.2 Barge Requirements

Mines located in two of the three states within the Northern Rocky Mountains and Great Plains use barge transportation. Montana and Wyoming shipped coal by barge (4.1 million short tons). This represents approximately four percent of the total short tons of coal shipped by river nationwide in 2012.

3.12.6.3 Roadway Requirements

Mines located in the three states within the Northern Rocky Mountains and Great Plains shipped slightly less than 13 million short tons of coal by truck in 2012. This represents approximately 13 percent of the total short tons of coal shipped by truck nationwide in 2012.

3.12.7 Northwest Region Transportation

Although the Northwest region includes the states of Oregon, Washington, and Alaska, there are no currently producing mines in Oregon or Washington. Consequently, this discussion will focus on the state of Alaska. There is currently one coal-producing area in this region, which is located in Alaska. Table 3.12-12 shows the number of short tons of coal originating from the region in 2012.

Table 3.12-12. Short Tons of Coal Originating in Northwest Region in 2012

Short Tons by State (All modes)	Total
Alaska	956,000
Total Short Tons Northwest	956,000

Source: U.S. EIA, 2012d. Domestic Distribution of U.S. Coal by Origin States, Consumer, Destination and Method of Transportation, 2012 Quarterly Reports.

Table 3.12-13 identifies the primary modes of coal transport and historic use of those modes within the Northwest, based on where the coal originates (U.S. EIA, 2012d).

Table 3.12-13. Primary Modes of Coal Transport by State – Northwest

Originating Coal Haul State	Originating Mode of Transport	Statistics for Primary Modes of Coal Transport (Approximate percentage of coal transported by mode by state of origin)
Alaska	Rail	87
	Barge	None
	Road	13
	Other	None

Source: U.S. EIA, 2012d. Domestic Distribution of U.S. Coal by Origin States, Consumer, Destination and Method of Transportation, 2012 Quarterly Reports.

The transportation requirements of each mode within the Northwest region are summarized as follows.

3.12.7.1 Rail Requirements

Rail was the predominant mode of coal haul within the Northwest region. Mines located in the Northwest shipped 828,000 short tons of coal by rail in 2012. Coal was shipped by the Alaska Railroad Corporation to the coal loading facility in Seward, Alaska. Coal produced in this region represents less than 0.1 percent of the total short tons of coal shipped by rail nationwide in 2012. Rail congestion data for Alaska were not available in the Cambridge Systematics 2007 report, which covers only the lower 48 states.

3.12.7.2 Barge Requirements

Mines located within the Northwest region did not record shipments of coal by river in 2012.

3.12.7.3 Roadway Requirements

Mines located in the Northwest shipped 128,000 short tons of coal by truck in 2012. This represents less than 0.5 percent of the total short tons of coal shipped by truck nationwide in 2012.

The interstate shipment of coal produced in Yukon-Koyukuk County, Alaska, is limited by huge distances, difficult climate and topography, and numerous environmental, socioeconomic, and economic limitations. Yukon-Koyukuk County is roughly the same size as the relatively large state of Montana, and the population density is less than one person per 20 square miles. The only road connecting to the remainder of the state is State Route 11, with 40.6 miles of interstate and arterial road in the census area connecting south to Fairbanks and the Dalton Highway. Roads are gradually being built throughout Alaska, and coal extraction and truck transport is expected to be made more viable as road resources increase.

3.12.8 Western Interior Region Transportation

The Western Interior region spans four states: Arkansas, Kansas, Missouri, and Oklahoma. The region is subdivided into smaller coal regions, the distinguishing factor primarily being sulfur content of the coal. Table 3.12-14 shows the number of short tons of coal originating in each of these states in the year 2012.

Table 3.12-15 identifies the primary modes of coal transport and historic use of those modes within the Western Interior region, based on where the coal originates (U.S. EIA, 2012d).

Table 3.12-14. Short Tons of Coal Originating in Western Interior States in 2012

Short Tons by State (All Modes)	Total
Arkansas	106,000
Kansas	18,000
Missouri	310,000
Oklahoma	755,000
Total Short Tons Other Western Interior	1,189,000

Source: U.S. EIA, 2012d. Domestic Distribution of U.S. Coal by Origin States, Consumer, Destination and Method of Transportation, 2012 Quarterly Reports.

Table 3.12-15. Primary Modes of Coal Transport by State – Other Western Interior

Originating Coal Haul State	Originating Mode of Transport	Statistics for Primary Modes of Coal Transport (approximate percentage of coal transported by mode by state of origin)
Arkansas	Rail	None
	Barge	None
	Road	100
	Other	None
Kansas	Rail	None
	Barge	None
	Road	100
	Other	None
Missouri	Rail	None
	Barge	None
	Road	100
	Other	None
Oklahoma	Rail	35
	Barge	None
	Road	65
	Other	None

Source: U.S. EIA, 2012d. Domestic Distribution of U.S. Coal by Origin States, Consumer, Destination and Method of Transportation, 2012 Quarterly Reports.

The transportation requirements of each mode within the Other Western Interior region are summarized as follows.

3.12.8.1 Rail Requirements

The Western Interior serves as a major junction of freight rail. Central sections are currently near or at capacity (LOS D and E). Without capital improvements, the *National Rail Freight Infrastructure Capacity and Investment Study* (Cambridge Systematics, 2007) has estimated that rail conditions in the Other Western Interior will continue to degrade, with central sections being downgraded to at or above capacity (LOS E and F) by 2035. The study concluded that, with improvements, Western Interior would operate at levels similar to those of the present day (Cambridge Systematics, 2007).

Mines located in the four states within the Western Interior shipped approximately 261,000 short tons of coal by rail in 2012. This represents less than 0.05 percent of the total tonnage of coal shipped by rail nationwide in 2012.

3.12.8.2 Barge Requirements

Mines located within the Western Interior region did not record shipments of coal by river in 2012.

3.12.8.3 Roadway Requirements

Mines located in the four states within the Western Interior shipped slightly less than one million short tons of coal by truck in 2012. This represents approximately one percent of the total short tons of coal shipped by truck nationwide in 2012. Truck transport was the predominant mode of coal haul with the region.

3.13 Archaeology, Paleontology and Cultural Resources

Historic and archaeological resources are sometimes broadly categorized as "cultural resources." Cultural resources consist of prehistoric and historic districts, sites, structures, artifacts, and other physical evidence of human activities considered important to a culture, subculture, or community for scientific, traditional, religious, or other reasons. Prehistoric and historic archaeological resources are locations where human activity measurably altered the earth or left deposits of physical remains. Typical environments in which archaeological resources can be found include rock shelters, terraces, floodplains, and ridge tops. Architectural and historic period resources, which may include dams, bridges, and other structures having historic or aesthetic importance, generally must be older than 50 years to be considered for protection under existing federal cultural resource laws. Cultural resources that may be present within mine sites include cemeteries, historical sites and structures, archeological sites, public parks, Native American burial mounds, and other features of cultural significance to surrounding communities (U.S. EPA et al., 2003).

For the purposes of this discussion, "paleontological resources" are distinct from archaeological resources. Specifically, paleontological resources are "any fossilized remains, traces, or imprints of organisms, preserved in or on the earth's crust, that are of paleontological interest and that provide information about the history of life on earth" (NPS, 2009a).

3.13.1 Appalachian Basin Region

3.13.1.1 Paleontology

The potential for paleontological resources is almost entirely dependent on the type and age of geological formations present in a specific region. A more thorough discussion of regional geology is presented in Section 3.2. Though regional geologic trends occur, each state, and even specific areas within each state can contain significantly different paleontological resources. The preservation of plant and animal fossils depends on a variety of circumstances. However, the speed with which they were covered and the nature of the covering materials often determine the quality of preservation, if any. Generally, the types of fossils encountered by coal mining include plants (such as ferns and trees) in the coal seams and scattered fossils of Tertiary age in the overburden. The following information on paleontological resources in each Appalachian Basin state was compiled from the Paleontology Portal Website (National Science Foundation et al., 2003).

3.13.1.1.1 Alabama

Paleontological resources in Alabama range from Late Cambrian to Quaternary in age, with gaps during the Precambrian, Jurassic, and Triassic. The first fossils of note in Alabama are Late Cambrian in age. Fossils from these periods can be found throughout northern Alabama and reflect the marine environment of Alabama at the time. The Devonian is less represented in Alabama's fossil record. The Mississippian saw a return to life-filled seas, and crinoids and brachiopod fossils are common in rocks of this age. Broad coastal plains that developed during the Pennsylvanian resulted in a wealth of plant and terrestrial fossils that are found throughout the northern portion of the state.

3.13.1.1.2 Kentucky

Paleontological resources present in Kentucky range from Ordovician to Tertiary in age, with a gap from the Permian through the Jurassic. Shallow tropical seas covered most of Kentucky from the Ordovician to the Pennsylvanian. Pennsylvanian rocks are present in the Eastern and Western Coal fields and may have once covered much of the state. Peat deposits during this age are responsible for the coal beds, and the fluctuating sea levels resulted in a variety of both marine and terrestrial fossils.

3.13.1.1.3 Maryland

Paleontological resources in Maryland span nearly the entire known range for fossil remains, with the exception of the Precambrian and possibly the Permian. Beginning in the Cambrian and lasting through much of the Ordovician, much of Maryland was covered by a shallow warm sea. By the Late Paleozoic Mississippian and Pennsylvanian Periods, fluctuating sea levels and mountain building events had created extensive swamps, low coastal regions, and a continuation of shallow seas. Fossils from these ages are found predominantly in the extreme western edge of the panhandle, coincident with coal-bearing land. These fossils include brachiopods, bivalves, and bryozoans from the marine deposits and horsetail rushes and scale trees from the terrestrial deposits.

3.13.1.1.4 Ohio

The majority of paleontological resources from Ohio are Cambrian to Permian in age, with later Quaternary also known from the Ordovician through the Mississippian. Nearly the entire state was covered by a shallow sea, with fluctuating levels of mud as a result of mountain building to the east. Fossils from these periods are found in the eastern half of the state (including coal-bearing lands) and include a variety of marine organisms such as brachiopods, bryozoans, corals, crinoids, trilobites, gastropods, and cephalopods. Permian plant fossils in southern parts of the state commonly include horsetails and ferns.

3.13.1.1.5 Pennsylvania

Paleontological resources in Pennsylvania are similar to those in much of the Appalachian Basin. Paleozoic fossils are well represented, and include both marine and terrestrial plants and animals. Delta creation continued into the Pennsylvanian, and included the development of extensive swamps. Pennsylvanian age rocks are found extensively throughout the western half of the state and contain fossil deposits that include amphibians and plants such as scale trees, ferns, and horsetail rushes.

3.13.1.1.6 Tennessee

Tennessee's paleontological resources include fossils from Cambrian to Quaternary in age, with an erosional gap in the record in the Early Mesozoic. Devonian and Mississippian age rocks with a similar range of fossils are present in the western and central portions of the state, respectively. Beginning in the Pennsylvanian, mountain building to the east transformed the shallow seas that had covered most of the state into vast deltas and coastal swamps. Fossils from this period include scale trees, horsetail rushes, and other plants.

3.13.1.1.7 Virginia

The Virginia Department of Historic Resources provided updated cultural resource information in their August 14, 2015 DEIS comments. This information is included in the following discussions.

Archaeological evidence shows that people have been living in what is now Virginia as far back as 16-22,000 years ago. In the late 1500s, Euro-American explorers entered the area in search of rivers, a route to the sea, and trade possibilities. When the English first explored Virginia, they discovered that the paramount chiefdom controlled by Powhatan included over 30 tribes. Other tribes were identified outside of Powhatan's control, including the Patawomeck and Doeg/Taux in Northern Virginia plus the Monacans and Manahoacs west of the Fall Line. As explorations extended westward, colonists identified additional tribes such as the Tutelo, Saponi, Meherrin, Nottoway and Cherokee. Fur traders, government officials, and frontier settlers learned the distinctions between different groups, in order to negotiate for food, furs, land, and peace.

The Pamunkey Indian Tribe was acknowledged as a federally recognized Indian tribe in July 2015. The Pamunkey Indian Tribe has occupied a land base in southeastern King William County, Virginia shown on a 1770 map as “Indian Town” since the Colonial Era in the 1600s. The 1677 Treaty of Middle Plantation formalized a dedicated state reservation. Today's Pamunkey and Mattaponi reservations date back to that treaty, and some preceding agreements.

Virginia’s modern day tribes were firmly established in ancestral lands long before the English arrived to settle at Jamestown. Jamestown, Virginia, settled in 1607, is America’s first permanent English settlement, though the western portions of Virginia, including areas of Virginia with coal, were not settled until the 1700s. Architectural resources in the state reflect Virginia’s history, beginning in the late 1600s, and encompass the many building and structural types built since.

3.13.1.1.8 West Virginia

The paleontological resources of West Virginia are almost exclusively Paleozoic and Quaternary in age.

Throughout the Carboniferous (Mississippian and Pennsylvanian), fluctuating sea levels and mountain building events to the east resulted in large deltas and swamps in addition to the shallow sea that covered much of West Virginia. Fossils from the Mississippian and Pennsylvanian are exposed over much of the state. They include marine brachiopods, gastropods, blastoids, and bryozoans, freshwater sharks, and terrestrial horsetail rushes and scale trees. Permian rocks are present across the western two-thirds of the state and indicate the development of extensive flood plains as a result of erosion during the mountain-building event that created the Appalachian Mountains. Permian fossils in West Virginia include *Calamites* (related to modern horsetail rushes), ferns, scale trees, amphibians, and tracks from the terrestrial reptile *Dimetrodon.*

3.13.1.2 Archaeology and Cultural Resources

Generally, the history of the various coal regions can be divided into broad categories or cultural manifestations. These divisions cut across state lines and in some cases cross-cut coal regions.

3.13.1.2.1 Prehistory

Within the Appalachian Basin, prehistoric peoples occupied various areas within the states of Alabama, Kentucky, Maryland, Ohio, Pennsylvania, Tennessee, Virginia, and West Virginia since at least ca. 10,000 B.C. and as early as ca. 13,000 B.C. (Fagan, 1991). Archaeologists have generally divided the prehistoric period into three broad periods: Paleo-Indian, Archaic, and Woodland. The exact timing of each period differs within each state, but the material manifestations are similar enough to warrant treating the region as a single resource area.

Generally, archaeological resources dating to the Paleo-Indian Period indicate that prehistoric peoples during this period were highly mobile. These people have occupied areas near several large waterways (Fagan, 1991). For example, Paleo-Indian sites clustered in northern Alabama, along the Tennessee River (University of Alabama, 2005) while in Tennessee, artifacts of this time period are found in the Cumberland and Lower Tennessee River valleys (Anderson and Sullivan, n.d.). Sites dating to this period are identified through the presence of such projectile points as Clovis and Folsom points. Other resource associations include isolated finds, simple tool scatters, and rock shelters, as well as some association with large extinct mammals and the occasional camp features (West Virginia Division of Culture and History, 2013a). It is generally believed that subsistence activities included the hunting of large game and gathering of local resources.

The next 7,000 years (8000 to 1500 BC) are characterized by the Archaic Period, in which archaeological sites are more numerous, larger, and more developed. Spring and summer camp sites are located in river valleys (University of Alabama, 2005). Larger base camp sites are found at the fall lines of streams and at estuaries (Maryland ACL, 2009). Archaic Period archaeological resources represent a shift in subsistence practices. This appears to be partly due to climactic shifts. Prehistoric peoples of this period employed a more diversified tool-kit and exploited a larger suite of resources than Paleo-Indian. Adaptive strategies shifted to those focusing on forest resources as woodlands expanded. In addition, hunter-gatherer groups increased in size and in number (Lewis, 1996). In some areas, mounds with burials and grave goods become more elaborate over time. As populations grew, foraging ranges became more restricted and peoples were more sedentary. The bow and arrow was introduced in the area and true farming began to develop (Fagan, 1991; Ohio History Central, n.d.). Pottery use becomes more common.

Evidence of human occupation and activity during the Eastern Woodland Period, lasting from approximately 1000 B.C. to A.D. 1650 is evident in West Virginia and much of the eastern U.S. and Canada (Fagan, 1991). Woodland Period peoples continued the trend toward fidelity to living in one place for a long time. Settlements were clustered along the banks of large and small rivers (University of Alabama, 2005; Fagan, 1991). Maize became the most important food crop, and most people lived in large, often stockaded settlements (Ohio History Central, n.d.). Village sites become common as did the use of bow and arrow and an increased reliance on agriculture. In addition, burials become more complex and earthen structures appeared. Woodland Period archaeological sites in Pennsylvania date from 1000 B.C. to A.D. 1550. From A.D. 1000 to 1600 in Tennessee, larger and more stable populations lived in organized villages and ruled through a strong structure of chiefdoms. They built large, flat-topped mounds, worked extensive agricultural fields, and completed other communal projects. Villages, frequently found on high ground on river and stream terraces, were large and included round, oval, and rectangular houses made of wooden post walls, with bark or mat roofing, and the settlements were sometimes palisaded (Pennsylvania Historical & Museum Commission, 2013a). These structures, in the form of mounds and effigies, become more complex and common with time. Grave goods associated with burials indicate expansive trade networks and complex social structures. This culminated in the Mississippian cultures in the Late Woodland Period. The Mississippian Period flourished from A.D. 1000 to 1600 in Virginia with larger and more stable populations living in permanent villages. During this period, social complexity reached the level of low-level chiefdoms. However, the initial exploration of the new world by Euro-Americans and subsequent colonization disrupted and displaced many Late Woodland groups.

3.13.1.2.2 Protohistoric-Historic

In general, during the late prehistoric period into the protohistoric, Native Americans came into indirect contact with European goods followed by direct contact with people. At contact, many Indian tribes were in conflict with one another and in turn with the French and English explorers and colonists in the eastern U.S.and the Spanish in the south and west.

The protohistoric contacts (early Native American contact with Europeans) and the historic period development can be considered unique to each state. Beginning in the early 1500s in the eastern portions of North America and later in the west, European influences directed the development of the country. Broad patterns of exploration, settlement development, transportation development, agricultural and industrial development, and western expansion occurred. The American Revolutionary and Civil wars (as well as other regional wars and conflicts) contributed to formulation of state boundaries and characteristics. State specific protohistory and history overview discussions are presented below.

3.13.1.2.3 Alabama

The Alabama territory was occupied by seven different Native American tribes at the time of contact, which was in 1540 when the Spaniard De Soto traveled through the area. These were the Alabama, Biloxi, Cherokee, Chickasaw, Choctaw, Koasati, and Musogee (Creek) tribes (Access Genealogy, 2013a). As of the mid-1500s, the Alabama tribe inhabited a large area in central Alabama, focused on the upper Alabama River (Native Languages of the Americas, 2011a; Access Genealogy, 2013b). The Choctaw Tribe temporarily inhabited southwestern Alabama and hunted there, while most of their territory was in middle and southern Mississippi (Access Genealogy, 2013c). The Koasati lived in north-central and northeastern Alabama, along the Tennessee River. On contact with Europeans, many of the Koasati moved south, to settle along the Coosa and upper Alabama River. The Muscogee (Creek) Tribe lived throughout the eastern one-third of Alabama from at least the 1500s through the early 1800s on the Coosa, Tallapoosa, Chattahoochee, and Ocmulgee rivers (Access Genealogy, 2013d).

When the Spanish expeditions began in the area in the 1500s, occasional battles with the resident Native American tribes occurred. In the early 1700s, the French arrived (Access Genealogy, 2013d; Jackson, 2010). British and American colonial settlement followed. Every historic-period archaeological resource imaginable might be found. Such cultural resources will be frequently located adjacent to streams (Gamble, 1990). Architectural resources in Alabama reflect its history, beginning in the early 1700s, and encompass the many building and structural types built since that time. These include vernacular dwellings such as dogtrot houses, I-houses, Creole cottages, and Spraddle Roof houses, as well as high style Victorian types, Arts and Crafts, modern, and other styles of residential, commercial, industrial, governmental, and military buildings constructed through the mid-twentieth century (Gamble, 1990). In addition, many historic bridges over streams and rivers still stand.

3.13.1.2.4 Kentucky

As Euro-American explorers entered the area from Virginia, in search of rivers, Shawnee and Iroquois tribes were the Kentucky area occupants. Shawnee had been established along the Cumberland River since some unknown time before 1770 (Access Genealogy, 2013e; Lazzerini, 2005a). Euro-Americans built their first settlements in Kentucky in the mid 1770s. Kentucky is known for its frontier history and sites, reflecting its early settlement. In settlements, retail shops, churches, public spaces, government buildings, streets, and roads existed. Grist and other kinds of mills driven by water wheels are a particular resource for which streams were integral parts. Their remains will be frequently located adjacent to streams. Architectural resources in the state reflect Kentucky's history, beginning in the late 1600s, and encompass the many building and structural types built since that time. These include single- and double-household log cabins, plantation houses, with associated slave quarters, smokehouses, outhouses, warehouses, packing houses, various kinds of mills, blacksmith shops, workshops, small and middle-sized farm houses, barns, and other outbuildings (Lewis, 1996). Military forts, with associated battlements, trenches, and bridges from the American Revolutionary and Civil Wars may also be present (Lewis, 1996).

3.13.1.2.5 Maryland

Maryland's architectural resources reflect its history, beginning in the mid-1600s, and encompass the many building and structural types built since that time. These include vernacular dwellings such as I-houses, tobacco sheds, one-room planter's houses, log cabins, plantation houses, slave cabins, and outbuildings. Maryland also has high-style Colonial, Victorian, Arts and Crafts, modern and other style residential, commercial, industrial, governmental, and military buildings from the eighteenth to the mid-twentieth century (Upton, 1986).

3.13.1.2.6 Ohio

Historical and other cultural resources may date back to 1650 in Ohio, at which time French exploration began, quickly followed by the British (Ohio History Central, n.d.). Throughout the 1800s, farms and factories developed, as did transportation systems such as turnpike roads, canals, and railroads. These, plus larger towns and cities established from the late 1800s through the mid-1900s, provide a large body of historic cultural resources in Ohio. Ohio's architectural resources reflect its settlement history, beginning in the mid-1700s, and encompass the many building and structural types built since that time.

3.13.1.2.7 Pennsylvania

First contact between the Europeans and the Native Americans of Pennsylvania occurred around 1550 (Pennsylvania Historical & Museum Commission, 2013b). More than six agricultural tribes lived in the region at the time including: Honniasont, Huron, Iroquois (especially Seneca and Oneida), Leni Lenape, Munsee, Shawnee, Susquehannock (Access Genealogy, 2013f). The lifestyles of all the Pennsylvania tribes were similar, as all were village and town dwellers who practiced agriculture, hunting, and trade for their livelihoods.

Pennsylvania's historic period began in 1608, with the visit of Captain John Smith to the Susquehannock tribe. Settlement followed in 1643, with the establishment of two Swedish forts near present-day Philadelphia (U.S. History, 2013). For the past 200 years, every historic-period archaeological resource imaginable might be found, including log cabin foundations and ruins, Native American villages and campsites, quarters, smokehouses, and outbuildings, small and middle-sized farm sites, barns, and towns, villages, roads, trails, bridges, industrial sites, fishing sites, canneries, military sites and battlegrounds from the French and Indian War, Revolutionary War, War of 1812, and Civil War. Such cultural resources will be frequently located adjacent to streams. Sites from the late 1700s to the mid-1900s will also include urban remains, coal- and iron-mining sites, and steel mills. Pennsylvania's architectural resources reflect its history, beginning in the mid-1600s, and encompass the many building and structural types built since that time.

3.13.1.2.8 Tennessee

Native Americans in Tennessee were first introduced to Europeans in 1540 (Tennessee4me, 2013). Six tribes occupied the area at the time of contact – the Cherokee, Chickasaw, Koasati, Quapaw, Shawnee, and Yuchi tribes (Native Languages of the Americas, 2011b). All Tennessee tribes were sedentary, farming groups. Archaeological resources from this period include remains of large, walled towns with or without mounds along major rivers. Tennessee's first permanent settlement by Euro-Americans occurred in the early 1770s (Thingstodo.com, 2012; Tennessee Department of State, 2011). Architectural resources reflect Tennessee's history, beginning in the late 1770s, and encompass the many building and structural types built since that time (Murray, 1995).

3.13.1.2.9 Virginia

The Virginia Department of Historic Resources provided updated cultural resource information in their August 14, 2015 DEIS comments. This information is included in the following discussions.

Archaeological evidence shows that people have been living in what is now Virginia as far back as 16-22,000 years ago. In the late 1500s, Euro-American explorers entered the area in search of rivers, a route to the sea, and trade possibilities. When the English first explored Virginia, they discovered that the paramount chiefdom controlled by Powhatan included over 30 tribes. Other tribes were identified outside of Powhatan's control, including the Patawomeck and Doeg/Taux in Northern Virginia plus the Monacans and Manahoacs west of the Fall Line. As explorations extended westward, colonists identified additional tribes such as the Tutelo, Saponi, Meherrin, Nottoway and Cherokee. Fur traders, government officials, and frontier settlers learned the distinctions between different groups, in order to negotiate for food, furs, land, and peace.

The Pamunkey Indian Tribe was acknowledged as a federally recognized Indian tribe in July 2015. The Pamunkey Indian Tribe has occupied a land base in southeastern King William County, Virginia shown on a 1770 map as "Indian Town" since the Colonial Era in the 1600s. The 1677 Treaty of Middle Plantation formalized a dedicated state reservation. Today's Pamunkey and Mattaponi reservations date back to that treaty, and some preceding agreements.

Virginia's modern day tribes were firmly established in ancestral lands long before the English arrived to settle at Jamestown. Jamestown, Virginia, settled in 1607, is America's first permanent English settlement. Some western portions of Virginia, including areas of Virginia with coal, were not settled until the 1700s.

Architectural resources in the state reflect Virginia's history, beginning in the late 1600s, and encompass the many building and structural types built since.

3.13.1.2.10 West Virginia

During the Late Prehistoric Period, native tribes began to come into indirect contact with European goods and people. At the time of contact, the Shawnee and the Delaware moved into the Ohio River Valley within West Virginia. Much of the 1600s and 1700s in West Virginia were dominated by warfare between the Iroquois Confederacy and the Shawnee and Delaware tribes. Warfare also existed between the Indian tribes and British, French, and other Colonists. After the Revolutionary War, most Native Americans moved out of West Virginia (West Virginia Division of Culture and History, 2013b). Land grants in West Virginia were first given to loyal supporters of King Charles II in 1669. After the Proclamation of 1763, settlement of West Virginia rapidly increased. During the 1700s most of Euro-American settlers in West Virginia were farmers (West Virginia Division of Culture and History, 2013c).

Architectural resources in the state reflect West Virginia's history, including single-family houses, plantation houses, slave quarters, smokehouses, outhouses, warehouses, packing houses, various kinds of mills, blacksmith shops, workshops, small and middle-sized farmhouses, barns, and other outbuildings.

3.13.2 Colorado Plateau Region

3.13.2.1 Paleontology

3.13.2.1.1 Arizona

The fossil record for Arizona begins in the Precambrian with stromatolites found in limestones deposited under shallow marine conditions. Most of the state was covered by shallow seas throughout the Devonian, Mississippian, and Pennsylvanian, and, as a result, a diverse and abundant fossil record is present for these periods.

Fossils for this portion of the Paleozoic include placoderms (armored fish), corals, crinoids, bryozoans, brachiopods, gastropods, and bivalves. Rare plant fossils can also be found in some Devonian age rocks, indicating that some terrestrial environments were present as well.

3.13.2.1.2 Colorado

Colorado was covered by a shallow sea through much of the Early and Middle Paleozoic. These seas expanded during the Carboniferous, and mountain building events resulted in the rise of the Ancestral Rockies and the Uncompahgre Range. A rich array of paleontological resources are known from this time, including sharks, trilobites, brachiopods, crinoids, conifers, lycopods, and the huge horsetail *Calamites*. The end of the Paleozoic is marked by a retreat of sea levels; the development of Permian Age fossils can be found in the western half of the state and include track ways from insects and reptiles.

3.13.2.1.3 New Mexico

Fossil resources in New Mexico range in age from Cambrian to Quaternary. During the Carboniferous, portions of the state were still covered by shallow seas, but a significant portion of the state was above sea level as an archipelago. Clams, brachiopods, and pelecypods are common marine fossils from this time, while seed ferns and amphibians represent the terrestrial environments.

3.13.2.1.4 Utah

Paleontological resources within Utah span the entirety of geologic time since the Precambrian. The Mississippian shales and sandstones in Utah are the most fossiliferous in the state and contain foraminiferans, corals, brachiopods, conodonts, bryozoans, snails, clams, cephalopods, and, more rarely, fish.

3.13.2.2 Archaeology and Cultural Resources

The Colorado Plateau includes Arizona's northeast quarter, the north and west portions of New Mexico, the southwest corner of Colorado and the southeast portion of Utah.

3.13.2.2.1 Prehistory

Current archaeological evidence shows that the Paleo-Indian were the first humans to occupy the Colorado Plateau region sometime around 13,000 years ago until about 7,500 years ago (11,000 B.C. to 5500 B.C.). New Mexico is home to both the Clovis and Folsom Paleo-Indian type sites and dozens of these sites have been identified across the region. Cultural resources associated with this period may include open lithic scatters, rock shelters, lake shore camps, and large game butchering sites (Alexander, 2013; Grahame and Thomas, 2002; New Mexico Office of the State Historian, 2013).

The southwestern Archaic Period on the Colorado Plateau begins around 7,500 years ago (5500 B.C.) and is characterized by nomadic hunter-gathers who followed seasonal food sources across the landscape. The Archaic Period persisted for approximately 6,000 years or until about A.D. 400. Potential cultural resources that may be encountered from this period include open lithic scatters, rock shelters, small village sites, pinyon nut gathering sites, and rock art (Grahame and Thomas, 2002). Prehistoric cultural resources in Utah share many characteristics with the rest of the Colorado Plateau as summarized above, and include important caves (Danger Cave, Cowboy Cave, and Hogup Cave), cliff dwellings, and rock art sites.

Following the Archaic is the Late Prehistoric Period, which was dominated by the Anasazi culture on the Colorado Plateau. In Arizona, Hohokam peoples established an agricultural society complete with canals and other irrigation features, and numerous villages such as those at Pueblo Grande, Mesa Grande, and Casa Grande in Coolidge (The Arizona Republic, 2011; Native American Netroots, 2010). To the north, the Anasazi built cliff dwellings and large pueblos such as those at Montezuma's Castle and Navajo National Monument. Prehistoric cultural resources for the states include a wide variety of agricultural and village sites. The Anasazi occupied the Colorado Plateau area from about A.D. 400 to about 1300. Some of the most well-known examples of Anasazi ruins include Chaco Canyon in New Mexico, Pueblo Grande in Arizona, and Mesa Verde in Colorado. Some of the anticipated cultural resources associated with this period include cliff dwellings, kivas, pithouses, large administrative centers, small villages, camps, agricultural fields, rock art, open lithic scatters, and road systems connecting settlements (Hurst, 2013).

Within the Colorado Plateau, five major tribes of Native Americans have occupied the region since the collapse of the Anasazi culture in circa A.D. 1300 to present. Among these five are the Zuni and the Hopi. Both groups are Pueblo people and are considered to be direct descendants of the Anasazi. The Zuni are primarily located in the northwestern portion of New Mexico and have occupied parts of that area since A.D. 400. The Hopi are located in the northeastern portion of Arizona and have made this region their home since circa A.D. 500 (Grahame and Thomas, 2002; Hurst, 2013). The Navajo Indians have occupied most of northern New Mexico, portions of southern Utah, and part of northern Arizona since at least A.D. 1500. Anthropologists consider Navajos to be Apachean people who migrated into the area approximately 500 years ago. The Ute and the Southern Paiute tribes are Numic tribes who are said to have migrated from the southern California area between 500 and 1,000 years ago. At the time of contact with Europeans in the 1500s, the Utes occupied most of Utah and western Colorado. The Southern Paiutes entered the western Colorado Plateau region between 1100 and 1200 A.D. (Grahame and Thomas, 2002). Some of the cultural resources associated with the above ethnographic people include abandoned villages, pithouses, pueblos, agricultural fields, sheep herding camps (later period), pinyon nut gathering sites, resource use sites, and open lithic scatters.

3.13.2.2.2 Protohistoric – Historic

The Spanish were the first Europeans to make contact with native people on the Colorado Plateau, beginning in the mid-1500s. The Spanish were the dominant Euro-American influence of the area until the mid-1800s. Mormon settlement began in Utah in 1847. Mining booms gripped portions of southwestern Colorado from the 1870s through the 1890s. Sites expected from this period may include missions, forts, military camps, wagon roads, railroads, town sites, irrigation ditches, outhouse pits, abandoned houses, mill foundations, old mines, cemeteries, cowboy line camps, and telegraph lines (Bauman, 2013; Husband, 2006; Old and Sold, n.d.).

All manner of buildings associated with the history and prehistory of the area may be expected in the region. Architectural styles draw on the varied cultural influences of a given region, including the Spanish, Puebloan, and northern European influences.

3.13.2.2.3 Arizona

Spanish explorers, missionaries and settlers came into Arizona from Mexico throughout the sixteenth to nineteenth centuries, bringing with them missions, presidio, pueblos, and ranchos. Mexico controlled Arizona until the end of the Mexican-American War of 1846 to 1848. The railroad arrived in Arizona in 1881, and with it, mass settlement and development. The Roosevelt Dam completed in 1911, Hoover Dam completed in 1935, and the Glen Canyon Dam completed in 1966 typify the reclamation projects that helped develop Arizona desert lands for agricultural and urban uses. Historic age sites include the early missions and forts to more modern constructions.

3.13.2.2.4 Colorado

The historic period in Colorado begins with the first Spanish visitors in the late 1700s. Later they established the failed settlement of San Carlos in the south near the city of Pueblo (Ubbelohde et al., 2006). In 1803, the U.S. acquired the territory through the Louisiana Purchase; however, this conflicted with claims held by Spain (Ubbelohde et al., 2006). The early part of the 1800s saw the area that was to become Colorado explored and exploited by trappers and settlers. Trading forts were established near extant Native American populations. After defeating Mexico in the Mexican-American War of 1846 to 1848, the U.S. took control of the southern portion of the state, as well as portions of New Mexico and Arizona. In the late 1840s, gold discoveries fueled interest in the eastern slopes of Colorado. Colorado became a state in 1876. Mining continued to be of great import throughout the late 1800s and was the stimulus for multiple labor disputes and violent uprisings due to working conditions. These disputes were most apparent at coal mining operations where several massacres, such as the one at Ludlow, occurred (Ubbelohde et al., 2006; Whiteside, 1990). Historic age sites may include missions, forts, military camps, wagon roads, railroads, town sites, irrigation ditches, outhouse pits, abandoned houses, mill foundations, old mines, cemeteries, cowboy line camps, and telegraph lines.

3.13.2.2.5 New Mexico

The historical period in New Mexico began with the exploration of this region by Francisco Vasquez de Coronado from 1540 to 1542 (World Atlas, 2013; Smithsonian Magazine, 2007; National Humanities Center, 2006). Over 50 years later, Juan de Oñate founded the first permanent European settlement: the San Juan colony on the Rio Grande. As part of New Spain, settlements and towns continued to grow, and during the Mexican War of Independence, the province of New Mexico passed to now-independent Mexico. The Spanish Trail, an important trade route from Los Angeles, California to Santa Fe, New Mexico, was established in 1829. Following the Mexican-American War in 1846 to 1848, portions of what would become the modern state of New Mexico was ceded to the U.S., and for the next 50 years the region saw much conflict between Native Americans, the U.S. government, cattle ranchers, sheepherders, homesteaders, and other settlers. New Mexico became a state in 1912. More modern history includes the establishment of the Los Alamos Research center in 1943, high altitude experiments near Roswell in 1947, and the development of extensive nuclear, solar, and geothermal energy industries. Historical cultural resources in the state range from settlements from the time of Spanish exploration and settlement, to sites related to the nuclear industry.

3.13.2.2.6 Utah

Historic age cultural resources in Utah are associated with early exploration and cross-continental travel, Mormon settlement, mining, and other industries. Spanish exploration of Utah began in 1776 with Fathers Silvestre Velez de Escalante and Francisco Atanasio Dominguez, but Euro-American settlement did not begin in earnest until the 1820s through the 1840s when fur trappers and traders moved into the region, and overland routes such as the Old Spanish Trail were established (State of Utah, 2013). Mormon settlement began in Utah in 1847. Manti, Utah was the first of numerous Mormon settlements on the Colorado Plateau, settled in 1849. Silver and lead were discovered in Bingham Canyon in 1863, though open pit mining did not begin until 1906. In 1869, the Union Pacific and Central Pacific Railroad Lines met at Promontory, and, in 1896, Utah became the 45th state.

3.13.3 Gulf Coast Region

3.13.3.1 Paleontology

3.13.3.1.1 Louisiana

Carboniferous age fossils from mollusks, crinoids, brachiopods, and trilobites are known to exist in gravels that eroded and were deposited in rivers. Shallow seas and coastal plains dominated the Tertiary landscape, and fossil camels, mastodons, and other mammal fossils are known to exist throughout the state.

3.13.3.1.2 Mississippi

Paleontological resources in Mississippi are known from the Late Devonian through the Quaternary, with significant gaps in the Late Paleozoic and Early Mesozoic.

Fossils from the Tertiary can be found throughout the central portion of the state. Marine fossils from this time include mollusks, whales, sharks, bony fish, and dugongs. Fossils of shells of various terrestrial and freshwater snails and other mollusks, and fossil of manatees, hippos, and the short-faced bear have been recovered from Quaternary loess deposits throughout the state.

3.13.3.1.3 Texas

Paleontological resources from Texas are known from the Cambrian to the Quaternary. During the Paleozoic, Texas was covered by a shallow sea. Cambrian rocks contain trilobites, brachiopods, bivalves, sponges, gastropods and bryozoans. Late Carboniferous (Pennsylvanian) fossils are exposed in north-central Texas and commonly contain brachiopods, trilobites, gastropods, corals, and other marine organisms. Rocks from the Permian are also well exposed in the north-central portion of the state and contain fossil evidence of marine invertebrates such as brachiopods, and terrestrial vertebrates such as *Dimetrodon* and other reptiles, amphibians, and sharks.

Mammalian diversity exploded in the Tertiary, and this can be seen in the fossil record from this time.

3.13.3.2 Archaeology and Cultural Resources

3.13.3.2.1 Prehistory

The archaeological pattern within the Gulf Coast region can be characterized by an increase in sedentism and material complexity. Several archaeological periods have been identified within the states of Louisiana, Mississippi, and Texas. All three states have Paleo-Indian sites dating to ca. 10,000 B.C. Due to decay, erosion and the changing geography and environment, Paleo-Indian sites are not common (Neuman and Hawkins, 1993). Following the Paleo-Indian Period, the archaeological record reflects a more diversified subsistence strategy.

In Louisiana, the archaeological record links to three overlapping periods: (1) Paleo-Indian (12,000 to 6000 B.C.), (2) Meso-Indian (6500 to 2000 B.C.), and (3) Neo-Indian (2500 to 1500 A.D.). The Meso-Indian culture lived in small nomadic hunter gatherer groups. According to radiocarbon dating, samples from Louisiana Meso-Indian mound sites are the earliest mounds in North America (Neuman and Hawkins, 1993).

The Neo-Indian culture (2000 B.C. to 1100 A.D.) is distinguished by population expansion, a more sedentary lifestyle, stone and ceramic vessels, and many decorative ceremonial objects (Neuman and Hawkins, 1993; Gregory and Webb, 1990). They produced refuse piles called shell middens, which is a very valuable and informative resource in the archaeological record (Gibson, 1996). Around, 2,000 years ago during the Woodland Period, the Hopewell (Mound building) culture dominates in the Mississippi area. The Mississippian Period is characterized by large temple mounds denoting ceremonial sites that appear, along with extensive villages, multi-level societies called chiefdoms, agriculture, trade and gradually increasing warfare (Morgan, 2002; Mississippi Department of Archives and History, n.d.). Within Texas, complexity is not as great. The Late Prehistoric Period (A.D. 700 to 1500) is particularly noticeable in archaeological sites across the state, with the period more similar to the Plains Village site of the Western Interior region. Long distance trade, best reflected in the distribution of artifacts made of obsidian, a material that does not occur naturally in the region, is one distinctive aspect of the period (Thomas and Turner, 2013).

3.13.3.2.2 Protohistoric - Historic

3.13.3.2.2.1 Louisiana

The first descriptions of Louisiana Indians are contained in accounts kept by members of Hernando De Soto's Spanish expedition in the 1540s. The next recorders of Indian life were the French in the 1700s. Some of the historic tribes first encountered by Euro-Americans were the Caddo, the Tunica, the Natchez, the Houma, the Atakapa, the Choctaw, and the Chitimacha. Several of Louisiana's present-day Indian tribes, such as the Tunica-Biloxi, Choctaw, and Koasati entered the state in the second half of the eighteenth century (Gregory and Webb, 1990; KnowLA Encyclopedia of Louisiana, 2013).

In 1714, the town of Natchitoches (along the Red River in present-day northwest Louisiana) was established by Louis Juchereau de St. Denis, making it the oldest permanent European settlement in the Louisiana Purchase territory. Major historical conflicts affecting the development of the state of Louisiana include the War of 1812, the Seminole Indian War, the Mexican-American War (1846 to 1848) and the U.S. Civil War (1861 to 1865). These activities left a very rich historical archaeological record, including colonial French, English, and Spanish fortification and settlement, European/Native American trade (glass beads, salt, horses, etc.), Euro-American homesteading, railroading, logging, and petroleum activities (Gregory and Webb, 1990; KnowLA Encyclopedia of Louisiana, 2013). In Louisiana, historic buildings and examples of many classic and unusual architectural styles are abundant. Architectural styles throughout the state include French Creole, Spanish Colonial, Antebellum, Greek Revival, Gothic Revival, Italianate, East Lake, Queen Anne Revival, Beaux Arts, Neoclassical, Bungalow, Hispanic Revival, Empire and Art Deco. Some of the region's common house styles are the Planter's cottage, Dog Trot or Dog Run house, the Shotgun house, and wood plank or log cabins (Fricker et al., 1998; Reichard, 2013).

3.13.3.2.2.2 Mississippi

The first European contact with Native Americans in the present-day state of Mississippi occurred in 1540 when the Spanish explorer Hernando De Soto entered the region in a search for gold, wintering with the Chickasaw tribe. Next, in the late 1670s, French Canadians sailed down the Mississippi River and into the area from the north. By that time, disease had killed thousands of natives, and in the early 1700s the French encountered what may have been the last mound cultures in the Mississippi delta, the Natchez tribe (Lamendola, n.d.). High points in Mississippi history include the French and Indian War (1754 to 1763), the completion of Spanish withdrawal from Mississippi territory (1798), the War of 1812 (1812 to 1815), and statehood in 1817. This state has a rich historical archaeological context including Colonial French, Spanish, and English fortification and colonization, Euro-American homesteading (Territorial Period), railroading, and logging activities (Mississippi Department of Archives and History, 2010; Lamendola, n.d.; Mississippi Department of Archives and History, 2013). Mississippi architecture encompasses a wide spectrum of significant buildings ranging from pioneer log and plank cabins, Antebellum, to Art Deco skyscrapers (Lamendola, n.d.). The first permanent house form in Mississippi is the Creole Cottage. Some of the region's other historic house styles are the Planter's Cottage, the Dog Trot or Dog Run house, and the Shotgun house (Sanders, 2009).

3.13.3.2.2.3 Texas

First contact of Native American and European peoples in the present day region of Texas was the result of European exploration of the Gulf area. Spanish and French parties accessed the region from the Gulf of Mexico on mapping and military expeditions. Later, throughout the 18th century, Spain continuously established Catholic missions throughout the region, which in many cases resulted in first contact with many Indian tribes who occupied the region between the Rio Grande to the south and the Red River to the north (Lone Star Junction, 2009).

The earliest documented settlements in present day Texas are the Spanish mission Isleta (1681) in modern day El Paso, followed by the French Fort St. Louis (1685) on the Gulf Coast. Approximately ten years after Texas won its independence from Mexico, it was annexed to the U.S. in 1846. The U.S.-Mexican war began shortly after because of disagreements about the definition of the boarder between Texas and Mexico. Two years later, the signing of the Treaty of Guadalupe-Hidalgo ended the war, and Mexico officially recognized Texas as part of the U.S. (Bullock Museam, 2015). Agriculture, logging, and ranching flourished throughout the 1800s, and oil was discovered in January of 1901 at the Spindletop field near Beaumont, adding considerably to the archaeological record (Lone Star Junction, 2009).

Historic Texas architecture reflects a variety of cultural influences from a long period of colonization and settlement, organized into six distinct periods from pre-colonial to modern (Robinson, 2013).

3.13.4 Illinois Basin Region

3.13.4.1 Paleontology

3.13.4.1.1 Illinois

Paleontological resources for Illinois range in age from Cambrian to Quaternary in age, with a gap in the fossil record of the Mesozoic. During the Mississippian, sea levels fluctuated across the state. In the Pennsylvanian, Illinois was covered by a large delta and extensive swamps. The fossils from this time include ferns, seed ferns, and extinct relatives of spiders, millipedes, giant dragonflies, jellyfish, shrimp, horseshoe crabs, clams, sharks, brachiopods, and bony fishes.

3.13.4.1.2 Indiana

Paleontological resources for much of the Paleozoic and Cenozoic are present within the state of Indiana. A shallow sea covered much of the state during the Early and Middle Paleozoic, with more terrestrial environments developing during the Carboniferous. Large reefs are common from the Silurian in Indiana. During the Carboniferous, swamps and deltas developed along with the shallow sea, allowing for the preservation of both marine and terrestrial fossils. These include crinoids, bryozoans, brachiopods, gastropods, bivalves, lycopods, Cordaites (conifer relatives), and seed ferns and are exposed in wide swaths across the northern and western portions of the state.

3.13.4.1.3 Kentucky

A description of the paleontological resources in Kentucky can be found in Section 3.13.2.1.

3.13.4.2 Archaeology and Cultural Resources

3.13.4.2.1 Prehistory

The prehistory of the Illinois Basin region can generally be separated into four major prehistoric traditions that are shared by much of the eastern U.S. These traditions are the Paleo-Indian Tradition, the Archaic Tradition, the Woodland Tradition, and the Mississippian Tradition. The oldest of these begins with the oldest human occupations in the area from at least 10,000 B.C., and lasts until about 8000 B.C. Sites in the Illinois Basin from this tradition are likely to be limited to isolated fluted points, often found on erosional surfaces and older landforms (Keller, 1993).

The Archaic Tradition (8000 B.C. to 1000 B.C.) is mostly characterized by widespread changes, particularly increased population, broadened subsistence strategies, increased technological sophistication, and greater residential stability (Keller, 1993). Sites from this period reflect these changes and commonly include rock shelters, shell mounds, cemetery areas, and residential campsites.

The greatest factors that distinguish the Archaic Tradition from the Woodland Tradition (1000 B.C. to A.D. 900) are the addition of pottery and the increase and spread of burial mounds and other ceremonial practices (Keller, 1993). Other important shifts during this period in the Illinois Basin region include the use of the bow and arrow by A.D. 700 and the emergence of agriculture, maize in particular, by A.D. 900 (Fowler and Hall, 1978). Most of the burial mounds in Indiana are associated with the Woodland Tradition (1000 B.C. to A.D. 900) (Kellar, 1998). Artifacts from this period reflect increased craft specialization and ceremonialism, as well as the expansion of trade networks (Keller, 1993).

The Mississippian Tradition (A.D. 900 to 1600) in the Illinois Basin is dominated by the influence of the Cahokia site in western Illinois, near St. Louis (Fowler and Hall, 1978; Keller, 1993). The Cahokia site was the cultural center for this area and dominated the development of the Mississippian Tradition (A.D. 900 to 1600) (Fowler and Hall, 1978; Keller, 1998). Cahokia covered nearly six square miles with population estimates ranging from 20,000 to 40,000. Many of the sites are confined to the broad floodplains of the Illinois Basin, possibly due to the presence of better farmland (Keller, 1993). In Indiana, the Mississippian Tradition includes settled town life in Indiana, expressed with the presence in some areas of flat-surfaced mounds on which were erected important structures. A distinctive pottery complex further defines this tradition (Kellar, 1998).

3.13.4.2.2 Protohistoric – Historic

The French were the first Europeans in the Illinois Basin in the late 1600s. The Illinois tribe's traditional territory included most of the state of Illinois, including a large area within the Mississippi River basin. The Chickasaw tribe occupied western Kentucky (Illinois State Museum, 2000). Rapid Euro-American population growth in the 1700s led to the establishment of Indiana territory in 1800 (which included Illinois and Indiana). Industries in the region included coal mining, railroads, steel manufacturing, and meat packing. Cultural resources expected from this period may include forts, houses, farmsteads, barns, trails/roads, canals, railroads, bridges, factories, mills, and mines (Center for History, 2010; Lazzerini, 2005a; Lazzerini, 2005b).

Architectural styles draw on the varied cultural influences of a given region. For this region those influences include the French and English on initial settlement. Later, a wide range of industries attracted

German, Jewish, Irish, Scandinavian, and Slavic immigrants to the area. Their influences are also apparent in the architectural styles of the region. Architectural resources of this region will include forts, cabins, farm houses, barns, covered bridges, schools, churches, courthouses, hospitals, libraries, theaters, high-rises, gas stations, commercial buildings, railroad stations, factories, and mills (Center for History, 2010; Lazzerini, 2005a; Lazzerini, 2005b).

3.13.4.2.3 Illinois

The first European explorers to reach Illinois were the French Jacques Marquette and Louis Jolliet in 1673 (Lazzerini, 2005b). Settlement began in earnest with the erection of Fort Crevecoeur in 1680 by Rene-Robert Cavalier, sieur de La Salle, though the fort fell to mutiny later that year. After the French and Indian War, the land that would become Illinois came under English control. Early historic-age sites in Illinois are related to seventeenth and eighteenth century French and English exploration and occupation of the region. They include forts, cabins and homesteads, trading posts, and other sites associated with exploration and the fur trade (Center for History, 2010; Lazzerini, 2005b). After the American Revolution, Illinois became a U.S. territory, and achieved statehood in 1818 (History, 2015).

3.13.4.2.4 Indiana

The first European explorer to reach Indiana was Rene-Robert Cavalier, sieur de La Salle in December 1679 (Center for History, 2010). The fur trade became important in Indiana throughout the eighteenth century, and forts and trading posts soon were constructed across the landscape. The end of the French and Indian War (1754 to 1763) resulted in Indiana being turned over to the English. By the end of the American Revolution in 1783, the Ohio Valley was part of the U.S. Historic-age sites in Indiana include forts and trading posts related to both the fur trade and the various wars associated with early American history. Other sites include cabins, schools, churches, homesteads and towns related to early and continued settlement, as well as a full range of more modern industrial and mining related activities (Center for History, 2010).

3.13.4.2.5 Kentucky

A description of the archaeological and architectural resources in Kentucky can be found in Section 3.13.2.2.

3.13.5 Northern Rocky Mountains and Great Plains Region

The coal-bearing counties in the intermountain region are within Colorado, Wyoming, Montana, and North Dakota. Physiographically, the coal-bearing counties in the intermountain region are within the northern Great Plains (portions of Colorado and Wyoming, and all counties in Montana and North Dakota), and northeastern Colorado Plateau (portions of Colorado and Wyoming) (Mehls, 1984; Schmidt and Vermeer, 2002).

3.13.5.1 Paleontology

3.13.5.1.1 Colorado

Paleontological resources from Colorado are described in Section 3.13.2.1.

3.13.5.1.2 Montana

Paleontological resources in Montana are known from nearly all periods of geologic time. Shallow seas covered much of Montana from the Precambrian through the Early Paleozoic. Fossil evidence of these seas include stromatolites, algae, trilobites, crinoids, bryozoans, brachiopods, gastropods, mollusks, conodonts and, later in time, over a hundred species of fish. During the Cenozoic, the environment in Montana ranged from hot and arid to more humid with seas, including the Cretaceous Interior Western Seaway, covering the state for portions of this era. Important fossil resources from this time include a wide range of plants and animals. Dinosaur fossils are perhaps the best known and include *Deinonychus*, *Tyrannosaurus rex,* and the state fossil *Maiasaura peeblesorum* (including evidence of their nests, eggs, and young). Fossils from the Quaternary reflect variable climate conditions and include titanotheres, dogs, mammoths, dire wolves, and musk ox. Carboniferous fossils in Montana are known from exposures in the central portion of the state. Because shallow-to-deep seas again covered Montana during the Mississippian, the fossils from this time include algae, sponges, worms, arthropods, bivalves, cephalopods, brachiopods, and nearly 100 species of fish.

3.13.5.1.3 Wyoming

The oldest fossils in Wyoming are Precambrian in age and consist of stromatolites. Fluctuating sea levels and periods of uplift and erosion were present from the Cambrian through the Paleozoic, leaving a range of paleontological resources that include trilobites, brachiopods, corals, sponges, pelycopods, conodonts, crinoids, algae, fish and trace fossils. Mesozoic paleontological resources are known from both marine and terrestrial environments and include oysters, belemnites and other marine invertebrates, and theropod dinosaur trackways. The sediments of the world-famous Jurassic-age Morrison Formation are known to contain many dinosaurs, including *Apatosaurus*, *Stegosaurus*, *Allosaurus*, *Diplodocus*, *Camarasaurus*, as well as the fossils of fish, frogs, salamanders, lizards, crocodiles, pterosaurs, and small mammals. Cretaceous age fossils can be found in rock exposures throughout the state and include a wide variety of animals such as fish, frogs, salamanders, turtles, crocodiles, pterosaurs, mammals, and birds. Well known dinosaur finds include *Tyrannosaurus*, *Triceratops*, *Ankylosaurus*, *Troodon*, *Edmontosaurus*, *Pachycephalosaurus*, *Edmontonia*, *Dromaeosaurus*, and *Ornithomimus.* Tertiary rocks and sediments cover much of the state and contain evidence of lush forests, some of which are the source of coal deposits in the state. Fossils from this age include the state fossil, the fish *Knightia eocaena*, as well as flamingos, crocodiles, boas, and bats. Quaternary deposits include fossils of mammoth, horse, camel, bison, and Pronghorn antelope, as well as fossil pollens.

3.13.5.1.4 North Dakota

The oldest fossils in North Dakota are Precambrian in age and consist of stromatolites. During the Pennsylvanian and Permian, the sea levels started to recede. Rocks of this age can be found throughout the state and contain brachiopods, sponges, horn corals, bryozoans, pelecypods, gastropods, belemnites, ostracods, conodonts, and fish. Jurassic rocks are exposed throughout the state and are rich in fossils. These paleontological resources include oysters, belemnites and other marine invertebrates. Theropod dinosaur trackways are also known. Tertiary rocks and sediments cover much of the state and contain evidence of lush forests, some of which are the source of coal deposits in the state. Fossils from this age include the state fossil, the fish *Knightia eocaena*, and flamingos, crocodiles, boas, and bats.

3.13.5.2 Archaeology and Cultural Resources

3.13.5.2.1 Prehistory

This section draws primarily from the *Handbook of North American Indians, Volume 13* (DeMallie and Sturtevant, 2001) and various state preservation plans (Gregg et al., 2008; Wyoming State Preservation Office, 2007) and historic contexts (Fraserdesign, 2006; Grady, 1984).

Archaeology within the region has been divided between the Paleoindian (10,000 to 8000 B.C.) and Archaic (8000 to 500 B.C.). At this point archeological patterns in the Great Plains and Colorado Plateau differ. The archaeology of the plains has been divided into the Plains Woodland (500 B.C. to 1000 A.D.), Plains Village (1,000 A.D. to contact), and historic period (contact to 1950). The archeology of the Colorado Plateau consists of the Formative (A.D. 300 to 1300) and Protohistoric (A.D. 1300 to contact) Periods (DeMallie and Sturtevant, 2001*)*.

During the Paleoindian Period, distinct artifact types are representative such as Clovis Points, Folsom Points, Hell Gap/Agate Basin, and Cody points. More ancient Paleoindian sites and isolated artifacts have been associated with river basins where Pleistocene glaciers released their outwash, and in areas where Pleistocene landforms have been preserved. As glaciers melted, Paleoindians expanded their territory to take advantage of new environments. Beginning around 5500 B.C., patterning within the archaeological record of the region shifts, both in the tools present and spatial patterning (Grady, 1984). Within the Great Plains, perishable artifacts such as basketry, dart shafts, and digging sticks have been recovered from caves in Wyoming. Other features common during this period are stone circles, or tepee rings, pictographs and petroglyphs, and occasionally burials.

Starting at the end of the Archaic Period, the archeology of the plains diverges from that of the Colorado Plateau. From 500 B.C. to contact, the archaeologists have adopted the Eastern Woodlands and Plains Village Traditions. Ceramics first appear during the Plains Woodlands Period. Plains Village archaeological sites have many similarities with Woodland sites. Villages became semi-permanent, with large, rectangular houses. Villages were placed in defensible positions and often had palisades. Large tracts of land on flood plains were used for crop production, and horticulture was equally as important as hunting and gathering. In addition, buffalo were hunted in large numbers.

Prehistoric cultural resources in Montana reflect those found throughout the Northern Rocky Mountains and Great Plains region, as summarized above. Prehistoric cultural resources in North Dakota reflect those found throughout the Northern Rocky Mountains and Great Plains region, as summarized above, and include isolate finds, small campsites, and kill sites as well as larger camps and the important Knife River flint source. Prehistoric cultural resources in Wyoming reflect those found throughout the Northern Rocky Mountains and Great Plains region, as summarized above, and include perishable artifacts such as basketry, dart shafts, and digging sticks that have been recovered from caves within the state.

For Colorado, from A.D. 300 to contact, archaeologists have identified the Formative and Protohistoric Periods. The Formative Period is confined to the western portion of Colorado and southwestern Wyoming. Archaeological sites dating to this period indicate native peoples were more sedentary than during the Archaic Period. These groups are generally ascribed the term Fremont. As early as A.D. 900 the archaeological pattern of the Formative Period begins to be replaced by more mobile hunter-gatherers.

With the exploration of North America and its subsequent colonization, several old-world diseases were introduced to Native populations. This, along with encroachment by settlers, has resulted in the displacement of many Native American groups indigenous to the Great Plains and Colorado Plateau. Within the Intermountain region of the Great Plains, eight Native American groups have been identified. These are the Assinibonie, Blackfoot, Crow, Gros Venture, Hidatsa, Mandan, Cheyenne, and Arapaho. Two Native American groups are present in the Colorado Plateau portion of the study area. These are the Eastern Shoshone and the Ute. Within Wyoming, the Eastern Shoshone occupied a territory which stretched the entire length of the state. The Ute occupied the western half of Colorado.

3.13.5.2.2 Protohistoric – Historic

3.13.5.2.2.1 Colorado

Archaeological and Cultural resources from Colorado are described in Section 3.13.3.2.

3.13.5.2.2.2 Montana

Historic resources reflect exploration, cattle ranching, railroads, and mining. The Lewis and Clark Expedition of 1804 to 1806 was the first group of American explorers to cross Montana. Fur trappers, traders, and Roman Catholic missionaries soon followed, as did the establishment of Saint Mary's Mission in the Bitterroot Valley, thought to be the first permanent settlement in Montana. Gold brought many prospectors into the area in the 1860s, and Montana became a territory in 1864. The rapid influx of people led to boomtowns that grew rapidly and declined just as quickly when the gold ran out. Cattle ranches flourished in the 1860s and 1870s, leading to conflicts with Native Americans, culminating in the 1876 Battle of the Little Bighorn. During the 1880s, railroads crossed Montana and the territory became a state in 1889. Hardrock mining also began at this time. Butte became famous when silver and copper were discovered. The Anaconda Copper Company, owned by Marcus Daly, became one of the world's largest copper mining companies and exercised inordinate influence in the state (State of Montana, 2010).

3.13.5.2.2.3 North Dakota

North Dakota was first visited by the French in 1738. In 1803, the territory was transferred to the U.S. through the Louisiana Purchase. Lewis and Clark explored this area in 1804 and 1806, and several Roman Catholic missions were established in the territory during the 1810s. Several trading posts were established in the subsequent years, and, in 1832, the first steam ship arrived in the territory, bringing settlers and trappers. In 1889, North Dakota was admitted into the union. Since statehood, North Dakota has been the scene of ranching and farming. Historic sites found in the state include ranches, homesteads, trading posts, and battle fields, among others.

3.13.5.2.2.4 Wyoming

Historic age resources are related to exploration, mining, and westward expansion. Wyoming was first visited by Europeans during the mid-1700s, but it was not until 1807 that the first American, John Colter, entered Wyoming. During the 1800s, settlers began crossing the area via the Oregon Trail, and by 1825, fur trapping and trading was a significant activity in the area. The first town, Ft. Supply, was established in 1853, and the construction of the transcontinental Telegraph in 1861 led to the establishment of several army forts and trading posts. In 1868, the Wyoming territory was created, and in 1872, Yellowstone National Park was established. Gold discoveries in the late 1860s also brought more settlers into the territory. In 1890, Wyoming became a state. In the early 1900s, mining operations began extracting uranium and other minerals.

3.13.6 Northwest Region

Although the Northwest region includes the States of Oregon, Washington, and Alaska, there are no active or proposed mines in Oregon or Washington. Consequently, this discussion is limited to the State of Alaska.

3.13.6.1 Paleontology

3.13.6.1.1 Alaska

Paleontological resources in Alaska begin with finds from the Precambrian. Fossils from the Permian are entirely marine in nature and include brachiopods, ammonoids, and snails. Volcanic activity in the Triassic resulted in the formation of volcanic island arcs, around which reefs formed. Fossil evidence of these reefs can be found in the southern portion of the state, as can fossils of mollusks, ichthyosaurs, and early bony fish. Coastal swamps and shallow marine conditions during the Cretaceous resulted in a fossil record that includes dinosaurs and marine organisms. The Alaska state fossil, *Mammuthus primigenius*, is also from the Quaternary.

3.13.6.2 Archaeology and Cultural Resources

3.13.6.2.1 Prehistoric

3.13.6.2.1.1 Alaska

The Paleo Arctic Tradition (8000 to 6000 B.C.) is widespread throughout the state and is characterized by lithic artifact assemblages based on a core and blade/micro-blade technology, distinctive micro-cores, and burins (small engraving tools) (NPS, 2013c; Sturtevant and Damas, 1985). Numerous other cultural sequences followed, including traditions from the Pacific Coast, the Aleutian Region, the Pacific Eskimo Stages, Southwest Alaska Coastal, and Mainland (Totem and Potlatch People) (Alaska Native Heritage Center, 2013; Athropolis, 2005; Sturevant and Damas, 1985).

3.13.6.2.2 Protohistoric - Historic

The known history of modern Alaska is short due to its relatively recent discovery by the developed world halfway through the 18th century (Alaska Public Lands Information Center, 2015). The first historic contact with Alaskan Native Americans was made by the fur trade expedition of the Russians Aleksei Chirikov and Vitus Bering in 1741. The major Alaskan Indian groups at the time consisted of the Athabascan, Yup'ik, Cup'ik, Inupiaq, Aleut, Alutiiq, Eyak, Tlingit, Haida, and Tsimshian tribes (History Timelines, 2012; Athropolis, 2005; Sturevant and Damas, 1985).

Other significant milestones in Alaskan history include the beginning of coal mining activities in 1857, the U.S. purchase of Alaska from Russia in 1867, construction of the Alaskan Rail Road from 1914 to 1923, salmon and other fish canneries beginning around 1882, and the influx of prospective miners in search of gold such as during the Klondike Gold Rush of 1897-1900.

All manner of buildings associated with the history and prehistory of the area may be expected in the region. Architectural styles draw on the varied cultural influences of a given region. More notable influences include the Russian American, Victorian, and later the Craftsman Movement (NPS, 2009b).

3.13.7 Western Interior Region

3.13.7.1 Paleontology

3.13.7.1.1 Arkansas

The fossil record in Arkansas begins in the Early Paleozoic. During this time, the state was covered by a shallow sea. The extensive seas of the Mesozoic were still present, but less extensive during the Cenozoic. As sea levels fell throughout the Tertiary, swamps formed throughout southern Arkansas. Fossils from this period are present in rocks in the southern and eastern portions of the state and include oysters and shark teeth.

3.13.7.1.2 Kansas

Paleontological resources in Kansas are absent for the Precambrian, the Early Paleozoic and the Early Mesozoic. However, the Carboniferous, Permian, Cretaceous, Tertiary, and Quaternary are well represented in the fossil record for the state. Shallow seas that likely covered much of the state during the Paleozoic experienced fluctuating levels during the Carboniferous, resulting in the formation of swamps along the coasts. Fossils from this period are exposed in a broad band of rocks covering the eastern edge of the state, and include crinoids, brachiopods, bryozoans, echinoids, bivalves, gastropods, corals, trilobites, amphibians, early reptiles, and many primitive plants. Sea levels continued to fluctuate during the Permian, and similar life forms persisted. The Tertiary in Kansas was marked by a wetter and milder climate than today, and a more savannah-like environment. Tertiary fossils are present in rocks in the western portion of the state and include rhinoceros, camel, and tortoise species.

3.13.7.1.3 Missouri

Paleontological resources in Missouri range from Paleozoic marine invertebrates to Quaternary mastodons. The most extensive fossil deposits from the Paleozoic are from the Carboniferous. Rocks of this age cover nearly the entirety of the northern and western portion of the state and include both marine and terrestrial fossils. The Missouri state fossil, the crinoid *Delocrinus missouriensis*, is from the early Carboniferous.

3.13.7.1.4 Oklahoma

The earliest fossils in Oklahoma are Cambrian in age. During most of the Paleozoic, a shallow sea covered much of the state, and the fossil resources for this period reflect that environment. Mississippian fossils are known from the northeastern portion of the state and include blastoids, brachiopods, echinoids, corals, trilobites, and other tropical marine invertebrates. Permian rocks cover much of the state and reflect a retreat of the shallow sea that had covered the state for much of the Paleozoic. Fossils from these rocks include rare amphibians and reptiles, and vertebrate footprints.

3.13.7.1.5 Texas

A description of the paleontological resources in Texas can be found in Section 3.13.4.1.

3.13.7.2 Archaeology and Cultural Resources

3.13.7.2.1 Prehistoric

The Western Interior region is in a transition zone between the Great Plains and the Eastern Woodlands called the Osage Plains. The Western Interior region includes the western edge of Arkansas, the eastern edge of Kansas, northwestern Missouri. In this region, the Paleo-Indian period begins roughly 13,500 years ago (11,500 B.C.) and transitions into the Archaic pPeriod around 7500 B.C. The people of this period practiced a hunter-gatherer subsistence pattern that emphasized a high degree of mobility and hunting of Pleistocene Mega Fauna and, later in the period, large game. Clovis, Folsom, and Dalton points are three of the projectile point types most closely associated with this period in this region. Because Paleo-Indian groups were highly mobile, isolated finds, small campsites, and kill sites are present in a variety of physiographic contexts throughout the larger Plains region, including the Osage Plains (Brown et al., 1987; Marchand, 1993). Paleo-Indian Period resources are present in Missouri in the form of isolated finds and cave sites. Sites such as Arnold Research Cave are located along near drainages. In Arkansas, temporary camps such as at La Crosse, and rock art sites such as at Rock House Cave evidence Paleo-Indian occupations. Sites such as La Crosse are located along river drainages. Paleo-Indian Period resources are present in Oklahoma in the form of isolated finds, open camps, and kill sites. Sites such as Jakes Bluff and the Domebo Canyon Site are located along rolling hills near drainages.

The Archaic Period begins approximately 9,500 years ago (7500 B.C.). Cultural materials from this period may include stone bowls, groundstone, dart-sized projectile points, knife blades, stone scrapers, drills, fish-hooks, stone sinkers, awls, and atlatls (Alex, 2002; Trubitt, 2010). Towards the end of the Archaic, some sites might include base camps, village sites, and mound sites (Alex, 2002; Trubitt, 2010).

The transition into the Woodland Period begins around 2,600 years ago (600 B.C.) and persists until about A.D. 1000. The construction and use of burial mounds and ceremonial complexes, the production and use of ceramic vessels, the development of exchange networks (i.e., importation of copper) and intensified use of agriculture are considered Woodland developments. Expected sites from this period include villages, lodges, smaller structures, burial mounds, ceremonial mounds, and small non-mound villages (Mainfort, 2011). Some of the more notable Arkansas Woodland sites include Nodena and Toltec Mound; while in Missouri, Fairfield Mound is a notable site.

Archaeologists designate the period from about A.D. 900 to 1600 as the Plains Village Tradition. This period is marked by extensive maize (corn) farming. After about A.D. 900, sites containing features such as earthen lodges, village sites, stockades, farmsteads, temples, platform mounds, and storage pits become common (Nebraskastudies.org, 2011; Nebraska State Historical Society, 1998). The Mississippian people lived in chiefdoms, traded for copper and marine shell, lived a sedentary lifestyle, built mounds, and conducted warfare. An example is the Duncan Site in Oklahoma.

3.13.7.2.2 Protohistoric – Historic

Native American groups from the contact period to the historic period in this region include at least ten different tribes. The Osage tribal territory encompasses most of the Western Interior region. The Quapaw is on at the southeastern edge of the region. The Wichita and Kiowa are just along the western edge of the region. The Kansa, Missouria, Otoe, and Iowa are clustered at the northern portion of this region. The Omaha and Pawnee are located at the northwestern periphery of the region. At the time of European contact in the 1700s, these tribes and their neighbors were in a state of geographic flux.

3.13.7.2.2.1 Arkansas

Spanish explorer, Hernando De Soto was the first European to reach Arkansas in 1541. At the time its Native American population was peaking with thousands of people in villages along the Mississippi River. The first European settlement was established by the French in 1686. Arkansas became part of the U.S. in 1803 with the Louisiana Purchase, and gained statehood in 1836 (Arkansas Department of Parks & Tourism, 2015).

Historic sites date to as early as A.D. 1540. Sites within Arkansas include the Pakin Site, a village that many suspect was visited by de Soto, grist mills, settlements, Civil War battle fields, Civil Conservation Corps camps and projects, and buildings important to the civil rights movement such as Little Rock High School.

3.13.7.2.2.2 Kansas

The first European explorer to travel to this region was Francisco de Coronada in 1541. This area was claimed by France in 1682, ceded to Spain in 1763, reverted to France in 1800, and finally became part of the U.S. as a result of the Louisiana Purchase in 1803. After disagreements over the practice of slavery in the area Kansas' statehood became a national debate, but in 1861 Kansas was granted statehood (Information Please Database, 2014).

Historic sites date to as early as the 1540s. Historic era sites within Kansas include settlements, trading outposts, forts, ranches, and travel routes.

3.13.7.2.2.3 Missouri

In 1673, the French explorers Jaques Marquette and Louis Joliet were the first Europeans to explore this region. In the same manner as Kansas, Missouri was claimed by both Spain and France throughout the 17^{th} and 19^{th} centuries (Missouri Office of the Secretary of State, 2015). This area was acquired by the U.S. as a result of the Louisiana Purchase of 1803, and acquired statehood in 1821 as a result of the Missouri Compromise (History, 2015).

Historic sites date to as early as the early 1500s. Historic era sites within Missouri include settlements, trading outposts, forts, ranches, and travel routes.

3.13.7.2.2.4 Oklahoma

European explorer, Francisco Coronado, is believed to have reached Oklahoma in 1541 (History, 2015). Several Native American tribes populated the area but the Europeans did not settle in this region. Oklahoma became part of the U.S. as a result of the Louisiana Purchas in 1803, and gained statehood in 1907 (Information Please Database, 2014).

Historic sites date to as early as A.D. 1450. Historic era sites within Oklahoma include settlements, trading outposts, forts, ranches, and travel routes.

3.13.7.2.2.5 Texas

A description of the Archaeology and Cultural resources in Texas can be found in Section 3.13.4.2.

3.14 Socioeconomic Conditions

This section characterizes the socioeconomic features of the seven coal regions: the Appalachian Basin, the Colorado Plateau, the Gulf Coast, the Illinois Basin, the Northern Rocky Mountains and Great Plains, the Northwest, and the Western Interior. Within these geographic areas, a total of 285 counties were identified as coal-producing counties. This section describes the demography and regional economic profile of the coal-producing counties, organized by coal region. For context, the socioeconomic profiles of the coal regions are compared with those of the broader statewide and national economies.

Section 3.14.1 describes regional demography, including population, age, race, and ethnicity. Section 3.14.2 characterizes the regional economic environment, such as income and employment statistics by industry, including the coal mining industry, and coal-related severance tax rates and associated revenues. While this section contains some information on trends in coal production and related employment levels, a detailed description of recent trends in the coal mining industry is provided in Section 3.1. Section 3.14.3 focuses specifically on the economic profiles of potentially-affected tribal populations. This information informs the socioeconomic impact analysis in Section 4.3.1, as well as the Environmental Justice analysis in Section 4.4, which evaluates the extent to which the Action Alternatives may generate disproportionately high and adverse human health or environmental effects on minority and low-income populations. Section 4.3.1 includes a discussion of the coal industry's contribution to the quality of life within mining-dependent regions.

3.14.1 Demography

Demographic information is broken down into three specific areas of interest: population trends, ethnic composition, and age composition. This FEIS evaluates trends in these demographic characteristics using 1990, 2000, and 2010 U.S. Census data.

As described in Table 3.14-1, the populations of coal-producing counties experienced relatively low population growth compared to the U.S. as a whole between 1990 and 2010. Specifically, the rate of population growth in coal-producing counties was roughly half the nationwide growth during that time period. Approximately 6.4 percent of the nationwide population lived within coal-producing counties in 2010.

As highlighted in Table 3.14-2, coal-producing counties are generally less racially diverse than the nationwide population. Approximately 83.9 percent of the population living in coal-producing counties self-identifies as "white." With the exception of American Indians and Alaska Natives, every reported minority is underrepresented in coal-producing counties compared to the broader U.S.

The age composition of coal-producing counties conforms closely to that of the broader country. Across the eight age groups described in Table 3.14-3, only one group (senior citizens) constitutes more than a single percentage-point difference from the age composition of the national population. The following sections provide more information on demography by coal region.

Table 3.14-1 Population Trends in Coal Regions, 1990 – 2010

Coal Region[1]	Geography	Population Growth 1990 - 2000 (%)	Population Growth 2000 - 2010 (%)	2010 Population
Appalachian Basin	Coal-producing Counties	1.4	0.1	10,437,566
	Statewide – all counties	8.1	6.4	55,331,661
Colorado Plateau	Coal-producing Counties	26.3	14.3	743,834
	Statewide– all counties	32.2	20.5	16,244,277
Gulf Coast	Coal-producing Counties	21.3	15.0	885,209
	Statewide– all counties	18.4	15.9	32,646,230
Illinois Basin	Coal-producing Counties	6.4	6.6	4,208,144
	Statewide– all counties	9.1	4.9	23,653,801
Northern Rocky Mountains and Great Plains	Coal-producing Counties	27.7	21.4	1,109,303
	Statewide– all counties	22.2	14.4	7,254,828
Northwest[2]	Coal-producing Counties	***	-3.5	1,826
	Statewide– all counties	14.0	13.3	710,231
Western Interior	Coal-producing Counties	14.1	8.5	404,473
	Statewide– all counties	10.1	7.6	15,509,314
Total U.S.	Within All Coal Counties	5.5	4.1	17,713,505
	Nationwide – Coal and Non coal states	13.2	9.7	308,745,538

[1] Counties within a state (such as certain counties in Kentucky and Colorado) that cross regional boundaries are counted in the region where they fall.

[2] Northwest data includes only Alaska; no population data exists for Denali County, AK from the 1990 Census.

Source: U.S. Census Bureau, 2013. Census 2010. U.S. Department of Commerce.

3.14.1.1 Appalachian Basin

There are 145 coal-producing counties in the eight states that make up the Appalachian Basin region. More than half of the people living in coal-producing counties nationwide are located in the Appalachian Basin region. The population in these counties accounts for 18.9 percent of the population within the eight Appalachian Basin states. Among the seven coal regions, coal-producing counties within the Appalachian Basin experienced the lowest positive rates of population growth between 1990 and 2010 (Table 3.14-1). Population within these counties remained stable, growing by less than two percent between 1990 and 2000 and less than one percent between 2000 and 2010. The eight Appalachian Basin states likewise experienced less growth than the nationwide population; however, statewide growth rates are greater than those of coal-producing counties in the region.

The Appalachian Basin is the least racially diverse of the seven coal regions. Approximately 88.4 percent of the regional population is white. The largest minority population in the region is black or African-American, making up 8.0 percent of the total population. Statewide estimates more closely resemble the national racial composition, with greater percentages for every reported minority population. While 16.3 percent of the national population is of Hispanic origin, only 2.2 percent of people within coal-producing counties in the Appalachian Basin self-identify as Hispanic.

The Appalachian Basin population is older on average than the statewide and nationwide populations. Approximately 16.2 percent of the population in coal-producing counties is over 65 years of age. Age groups below 45 years of age are all underrepresented when compared with statewide and national age distributions.

3.14.1.2 Colorado Plateau

There are 16 coal-producing counties in the 4 states that make up the Colorado Plateau coal region. Within these states, 4.6 percent of the population lives within a coal-producing county. The Colorado Plateau demonstrated the greatest rates of population growth among the seven coal regions. Population within these counties grew by 26.3 percent between 1990 and 2000, and by 14.3 percent between 2000 and 2010. This growth was greater than national population growth over the same time periods. The states encompassing the Colorado Plateau were subject to even greater rates of population growth than the coal-producing counties within this region.

Coal-producing counties in this region include a significant Hispanic population, approximately 14.8 percent. In addition, 20.9 percent of the population self-identifies as American Indian or Alaska Native, the greatest proportion among all seven coal regions. The black or African American population, both in coal-producing counties (0.6 percent) and in the states encompassing this region (3.3 percent), is disproportionately small when compared with the Nation as a whole (12.6 percent).

The Colorado Plateau population is slightly younger on average than the national population, with only 12.9 percent of the population over 65 years of age, as opposed to 13 percent nationwide. The population under 14 years of age is relatively great in coal-producing counties (22.1 percent), mirroring statewide age composition for the states encompassing the region (21.8 percent); in comparison, 19.8 percent of the national population is under 14.

3.14.1.3 Gulf Coast

There are 22 coal-producing counties in the three states that make up the Gulf Coast region. Coal-producing counties account for 2.7 percent of the population in the three states. States within the Gulf Coast region experienced high growth rates during the 1990 to 2000 timeframe and again from 2000 to 2010; the coal-producing counties experienced similar growth rates of 21.3 percent between 1990 and 2000 and 15.0 percent between 2000 and 2010. These rates were much higher than the nationwide rates over the same time periods.

The Gulf Coast region supports a significant Hispanic population, approximately 46.4 percent. This estimate is considerably greater than the corresponding statewide statistic (29.8 percent). Coal-producing counties in the Gulf Coast are also more predominantly white (77.2 percent) than the broader Gulf Coast states (68.3 percent).

The Gulf Coast population is younger on average than the national population; 23.8 percent of the population in the region is under 14 years of age, while 19.8 percent of the Nation as a whole is under 14.

3.14.1.4 Illinois Basin

There are 67 coal-producing counties in the three states that make up the Illinois Basin region. The population within coal-producing counties constitutes 17.8 percent of the total population of these three states. Coal-producing counties experienced stable but low growth, with growth rates of six to seven percent both between 1990 and 2000, as well as between 2000 and 2010. The coal-producing counties in this region did not experience the slowdown in population growth experienced by both the Illinois Basin states and the country as a whole.

The Illinois Basin is less racially diverse than the country as a whole, with 85.3 percent of the population self-identifying as white. The largest minority group in the region is black or African-American (8.9 percent). As a whole, the three Illinois Basin states are more racially diverse than the coal-producing counties within them, with greater representation across all reported minority groups.

The age composition of the Illinois Basin population closely conforms to both statewide and national statistics.

3.14.1.5 Northern Rocky Mountains and Great Plains

There are 24 coal-producing counties in the four states that make up the Northern Rocky Mountains and Great Plains coal region. Within the four states, 15.3 percent of the population lives in coal-producing counties. The rate of population growth in this region was considerable between 1990 and 2010, growing 27.7 percent between 1990 and 2000 and 21.4 percent between 2000 and 2010. To a lesser degree, statewide populations also experienced an increase in population growth.

The Northern Rocky Mountains and Great Plains region is less racially diverse than the rest of the country. Approximately 81.0 percent of the population within coal-producing counties is white, and the region had the lowest percentage of black or African-American citizens (1.8 percent) within all seven coal regions. The region includes a relatively large population self-identifying as an Asian, Native Hawaiian, Pacific Islander, or “Other”; these groups make up 11.9 percent of the larger population.

The population of the Northern Rocky Mountains and Great Plains region is slightly younger on average than the national population. Coal-producing counties have a relatively great percentage of children under 14 years of age (22.7 percent compared to 19.8 percent nationally) and a relatively small percentage of senior citizens 65 years of age or older (10.0 percent compared to 13 percent nationally).

3.14.1.6 Northwest

The Northwest region includes one coal-producing county in Alaska (see Section 3.0.2 of this FEIS which discusses Northwest region). Denali County accounts for less than one percent of the population in the state. The population in this county experienced a decrease in population over the past ten years of negative 3.5 percent, while the rest of the country experienced population growth. Population growth calculated on a statewide basis in the northwest region was also greater than the growth in the region’s coal-producing counties. The Northwest region is the only coal region with a lesser percentage of the population self-identifying as white (66.7 percent) than the broader U.S. (72.4 percent). However, in the coal-producing county, an overwhelming majority identify as white (89.6 percent). The two other largest racial and ethnicity groups are either self-identified two or more races (4.4 percent) or American Indian and Alaska Native (3.6 percent). This racial distribution is not reflected in the statewide estimates for Alaska, which identify a greater percentage of people self-identifying as “white” or “American Indian and Alaska Native” than the coal-producing counties.

The middle-aged population in the Northwest coal region is relatively large, with age groups between 25 and 54 accounting for a greater portion of the population (43.2 percent) than in the broader U.S. (41.2

percent). Both the coal-producing county and the state encompassing the region support relatively small populations 65 years of age or older.

3.14.1.7 Western Interior

There are 11 coal-producing counties in the four states that make up the Western Interior region. Within these states, coal-producing counties support 2.6 percent of the population. Population growth in coal-producing counties was greater than that of the Western Interior states, but similar to the national trend, with 14.1 percent growth between 1990 and 2000, and 8.5 percent growth between 2000 and 2010.

The Western Interior region includes a significant population self-identifying as American Indian or Alaska Native (approximately 8.4 percent). Compared with the national racial composition, all other reported minority groups are underrepresented in the Western Interior, with the white population accounting for 77.4 percent of the total population. Coal-producing counties have relatively smaller white and black or African-American populations than the states encompassing the region.

The senior population (65 years or older) of the Western Interior region represents 14.8 percent of the total population (compared with a slightly less 13 percent nationwide). The age composition of this region generally conforms closely to that of the broader statewide and national populations.

3.14.2 Economic Conditions

This section describes per capita income, median household income, median home value, unemployment, employment and payroll by industry, severance tax rates, and severance tax revenues for each of the seven coal regions. The data are from the American Community Survey 2007-2011 Five-Year Estimates; the Bureau of Labor Statistics 2012 Annual Averages; the U.S. Census Bureau County Business Patterns 2001 and 2011 data releases; individual state tax codes and revenue reports; and the U.S. Census Bureau 2010 Annual Survey of State Government Tax Collections.

In general, the population in coal-producing counties is slightly less affluent than the broader U.S. population (Table 3.14-4). Per capita income and median household income are both slightly less in coal-producing counties than in the national population except in the Northwest region. Median home value in coal-producing counties, however, is 18.6 percent less than the national average. Table 3.14-5 provides statistics on poverty and unemployment. Poverty rates in coal-producing counties are generally comparable to poverty rates for the country as a whole, with 14.9 percent of the population in these counties living below the poverty line compared with 14.3 percent nationally. The unemployment rate across coal-producing counties was slightly below the national rate in 2011 (7.9 percent compared with 8.1 percent nationwide).

Figure 3.14-6 highlights 15-year trends in coal production within the seven coal regions. Most prominent among these trends are the long-term shifts away from production in the Appalachian Basin region and toward production in the Northern Rocky Mountains and Great Plains region. Table 3.14-6 describes employment and annual payroll in the coal mining industry for states with active mining. In 2014, coal mining accounted for 0.06 percent of national employment and 0.1 percent of national income (U.S. Census Bureau, 2014; U.S. EIA, 2016a). Between 2005 and 2015, 15 states experienced a reduction in coal mining sector employment and, at the national scale, coal mining sector employment decreased by 5.49 percent during this time. Coal mining employment trends, described in Figure 3.14-7, generally corresponded with regional shifts in production, with the exception of the rise in coal mining employment in the Appalachian Basin between 2010 and 2011. As discussed below, a shift toward the more labor-intensive underground mining in the Appalachian region, combined with an overall depletion of the most readily accessible surface reserves, led to an offsetting increase in coal mining employment during this time. Figure 3.14-7 highlights that coal mining-related employment levels are significantly higher in the Appalachian Basin than in the other coal regions. As discussed in Table 3.14-6, this result is driven by the relatively high level of coal mining employment in West Virginia and Kentucky (these states account for approximately 25 percent and 16 percent of total nationwide coal mining employment, respectively). A detailed discussion of trends and existing conditions in the coal mining industry is provided in Section 3.1.

Tables 3.14-7 and 3.14-8 describe tax rates and revenues by source for coal-producing states. Policies on taxing the coal mining industry vary from state to state. Many states levy a direct severance tax on extracted minerals. Severance taxes are taxes levied by state and tribal governments on the value or volume of on non-renewable resources produced (including coal). Severance taxes in some states are levied in the form of a percent of the value of the resources removed or sold and, in other states, as a per-ton fee (National Conference of State Legislatures (NCSL), 2012). Revenues are often shared between state and local governments according to various formulas, with some revenues from severance taxes flowing to school districts, county and municipal governments, as well as local grant programs (Temte, 2010; West Virginia Department of Revenue, 2015). The states with the most coal production generally collect the most tax revenue on coal severance. Exhibit 6-8 reports recent coal severance tax revenues by state, for the most current year available. As shown, a total of $935 million in coal severance taxes were collected in 2015, with the majority of tax revenue levied on coal severance in this year collected by West Virginia ($376 million), Wyoming ($270 million), and Kentucky ($180 million). However, for most states that levy a severance tax on coal, coal severance taxes contributed less than one percent to total state tax revenues. That is not the case in all states, however. The contribution of severance taxes to total state taxes is larger in some coal producing states, with the largest dependence on severance taxes occurring in Wyoming (12 percent), West Virginia (seven percent), and Montana (two percent).

Local governments may also levy other taxes on coal production. In particular, counties in some states, including Colorado, Texas, and Wyoming, allow local governments to collect ad valorem (property) taxes on coal property, including the volume of coal produced and/or the value of the reserves (Kent, 2010). For example, in Wyoming, in addition to severance taxes, a county gross products tax (an ad valorem property tax) is collected based on the taxable value of the previous year's production. In FY 2015, Wyoming reports that approximately $240 million was collected in ad valorem taxes, which was similar to the amount collected for severance taxes $276 million (State of Wyoming Department of Revenue, 2015). Ad valorem taxes on coal property can be an important source of income for counties, accounting for 10 to 30 percent of their annual revenue, which is often used to fund education (Kent, 2010). For example, in Wyoming approximately 70 percent of statewide ad valorem property taxes were used for K-12 education in the 2009 tax year (Temte, 2010). Such taxes are not allowed in some states, for example, Maryland or North Dakota (Kent, 2010). Additional taxes, such as workers compensation taxes, corporate income taxes, sales and use taxes are also levied on coal companies.

In Western states, where coal is produced on federal lands, federal mineral royalties and coal lease bonuses can be important. Approximately 49 percent of federal mineral royalties from coal production on federal lands is also returned to the states (Temte, 2010; Raimi and Newell, 2014). Local governments can also generate revenues by leasing public lands for coal (as well as oil and gas) development (Raimi and Newell, 2014).

In addition to the above, two coal-related excise taxes are currently imposed by the federal government (The Abandoned Mine Land Reclamation Fee—also known as the reclamation fee or AML fee—and the Black Lung Excise Tax) may also occur. Whether these taxes will continue to be imposed prior to and during the study period is uncertain (30 U.S.C. § 1232(a)).[11]

The Abandoned Mine Reclamation Fund, also known as the Abandoned Mine Land (AML) Fund, is a federal tax that is financed by fees levied per ton of domestically produced coal. The reclamation fee currently imposes a tax of $0.28 per ton of coal produced by surface mining, $0.12 per ton of coal produced by underground mining, $0.08 per ton for lignite (30 U.S.C. § 1232(a)).[12] The reclamation fee is deposited into the AML Fund, which is managed by the Secretary of the Interior. In general, the moneys in the AML Fund are distributed as grants to approved states and tribes, certain health care plans that are part of the United Mine Workers of America (UMWA) Health and Retirement Funds, and OSMRE for national programs to reclaim land and water impaired by coal mining activities prior to the implementation of SMCRA.

The Black Lung Excise Tax (BLET) is a federal tax that began in 1978 to finance the Black Lung Disability Trust Fund, which pays the medical costs for miners (including their survivors and dependents) plagued with black lung disease. Other than a few exceptions, BLET is taxed at a rate of $1.10 on coal from underground mines, and $0.55 on coal from surface mines, not to exceed 4.4 percent of coal sold by the producer (26 U.S.C. § 4121).[13] The Internal Revenue Service (IRS) reports collecting $574.4 million in 2014 for this fee (IRS, 2016). These taxes are further discussed in Section 4.3.1.6.

The following sections provide more information on the affected environment in terms of economic conditions for each of the seven coal regions.

[11] Collection of the reclamation fee is scheduled to end September 30, 2021.

[12] The reclamation fee may be based on a percentage of the value of the coal if that specified percentage is less than the per ton rate.

[13] There are three exemptions from the BLET: lignite, imported, and exported coal.

Table 3.14-4. Per Capita Income, Median Household Income, and Median Home Value in Coal Regions, 2011

Coal Region1	Geography	Per Capita Income[3]	Median Household Income[3]	Median Home Value[4]
Appalachian Basin	Coal-producing Counties	$23,702	$43,161	$112,413

Table 3.14-7a. Coal Severance Tax Rates by State, 2015 – Appalachian Basin

State	Severance Tax Type	Rate
Alabama (a)	State Coal Severance Tax	$0.335 per ton for the state.
	Local Coal Severance Tax	$0.20 per ton in Jackson and Marshall County.
Kentucky (b)	Coal Severance and Processing Tax	4.5% of gross value with a minimum tax of $0.50 per ton. A credit is given to thin seam coal extraction on a scale from 2.25% to 3.75% of the coal value.
Maryland (c)	No Coal Severance Tax	-
Ohio (d)	Coal Severance Tax	Base rate of $0.10 per ton, plus an additional $0.012 per ton on surface mined coal. An additional $0.12 to $0.16 per ton is levied on operations without a full cost bond and changes based on the amount remaining in the state Reclamation Forfeiture Fund at the end of each state budget biennium.
Pennsylvania	No Coal Severance Tax	-
Tennessee (e)	Coal Severance Tax	$0.75 per ton on entire production of coal products in the state, regardless of place of sale or outside-of-state delivery.
Virginia (f)	Local Coal Reclamation Tax	Any county or city may impose a severance tax on all coal within its jurisdiction. The rate of tax shall not exceed 1% of the gross receipts from such coal or gases.
West Virginia (g)	Natural Resources Severance Tax	5% of gross value, with the following reduced rates for thin seam underground mining: 2% of gross value for seams with thickness between 37 and 45 inches and 1% of gross value for seams with thickness less than 37 inches.

Table 3.14-7b. Coal Severance Tax Rates by State, 2015 – Colorado Plateau

State	Severance Tax Type	Rate
Arizona	No Coal Severance Tax	-
Colorado (h)	Coal Severance Tax	$0.842 per ton.
New Mexico (i)	Coal Severance Tax	$0.57 per ton on surface coal and $0.55 per ton on underground coal. The state also imposes a surtax on coal, which is increased on July 1 each year. The surtax in effect in Fiscal Year (FY) 2009 was $0.83 per ton. Post-2011 renegotiated contracts are not subject to the surtax.
Utah	No Coal Severance Tax	-

Table 3.14-7c. Coal Severance Tax Rates by State, 2015 – Gulf Coast

State	Severance Tax Type	Rate
Louisiana (j)	Natural Resources Severance Tax	$0.12 per ton of lignite.
Mississippi	No Coal Severance Tax	-
Texas	No Coal Severance Tax	-

Table 3.14-7d. Coal Severance Tax Rates by State, 2015 – Illinois Basin

State	Severance Tax Type	Rate
Illinois	No Coal Severance Tax	-
Indiana	No Coal Severance Tax	-
Kentucky (b)	Coal Severance and Processing Tax	4.5% of gross value with a minimum tax of $0.50 per ton. A credit is given to thin seam coal extraction on a scale from 2.25% to 3.75% of the coal value.

Table 3.14-7e. Coal Severance Tax Rates by State, 2015 – Northern Rocky Mountains and Great Plains

State	Severance Tax Type	Rate			
Colorado (h)	Coal Severance Tax	$0.842 per ton	$0.842 per ton	$0.842 per ton	$0.842 per ton
Montana (k)	Coal Severance Tax	Heat Content	Surface	Auger	Underground
		<7,000 BTU	10% of value	3.75% of value	3% of value
		7,000+ BTU	15% of value	5% of value	4% of value
North Dakota (l)	Coal Severance Tax	$0.375 per ton plus $0.02 per ton for the Lignite Research Fund. Reduced rates apply to coal used in cogeneration facilities. No tax on coal used for the following: (1) to heat state buildings; (2) used by the state or political subdivision of the state; or (3) agricultural processing. Counties may also grant a partial or complete exemption from the counties' 70% portion of the $0.375 tax for coal shipped out of state.			
Wyoming (m)	Coal Severance Tax	7% of taxable valuation of surface coal and 3.75% of taxable valuation of underground coal, with a maximum tax of $0.60 per ton of surface coal and $0.30 per ton of underground coal.			

Table 3.14-7f. Coal Severance Tax Rates by State, 2015 – Northwest

State	Severance Tax Type	Rate
Alaska (n)	Mining License Tax on Net Income	No tax if net income is $40,000 or less; $1,200 plus 3% of net income over $40,000; $1,500 plus 5% of net income over $50,000; and $4,000 plus 7% of net income over $100,000.
	Production Royalty on State Lands	3% on same net profits as license tax is based on.

Table 3.14-7g. Coal Severance Tax Rates by State, 2015 – Western Interior

State	Severance Tax Type	Rate
Arkansas (o)	Natural Resources Severance Tax	$0.02 per ton of coal, lignite and iron ore plus an additional $0.08 per ton on coal.
Kansas (p)	Minerals Severance Tax	$1.00 per ton coal produced. Severance or production of the first 350,000 tons of coal at any mine is exempt from taxation.
Missouri	No Coal Severance Tax	-
Oklahoma	No Coal Severance Tax	-

Sources for Tables 3.14.8a-g:
U.S. Census Bureau, 2014. 2015 Annual Survey of State Government Tax Collections; Individual state revenue reports.
* State Coal Severance Tax Revenues are reported for the FY ending September 30, 2015. Total State Tax Revenues are reported for the calendar year ending December 31, 2014. These tax values do not include revenues collected by tribal governments.
** State Coal Severance Tax Revenues are reported for the FY ending June 30, 2015. The Total State Tax Revenues are reported for the calendar year ending December 31, 2014. These tax values do not include revenues collected by tribal governments.
[+] State does not collect coal severance taxes.
Notes for Tables 3.14.8a-g:
[a] Alaska - Severance tax revenues listed are those by the Usibelli Coal Mine, the only active coal mine in the state (can be accessed at http://www.usibelli.com/pdf/McDowell-Report-Statewide-Socioeconomic-Impacts-of-UCM-2015l.pdf).
[b] Arkansas - Severance tax revenues were not available for FY 2015 and the values listed represent FY 2012.
[c] Kansas - Coal severance tax revenues are calculated as the Special County Mineral Tax Production Fund, of which coal severance revenues are a percentage.
[d] Kentucky and Colorado - Two coal mining regions are present in Kentucky (Appalachia and Illinois Basin) and Colorado (Northern Rocky Mountains and Great Plains). Severance tax revenues are reported as a statewide total. Therefore, it is not possible to determine the severance tax contributions by each of the two coal mining regions in these states.
[e] New Mexico - Severance tax revenues listed are net of the Intergovernmental Tax Credits (ITC) afforded to taxed coal entities.
[f] Virginia - While counties and municipalities may impose taxes on coal extracted, no coal severance tax revenues were reported in 2015.

3.14.2.1 Appalachian Basin

Both per capita income and median household income are relatively low in the Appalachian Basin. Under both measures of income, 2011 data for coal-producing counties in this region demonstrates slightly lesser income levels than the respective statewide and the national populations. The Appalachian Basin had a relatively low median home value of $112,413 in 2011, which was 39.6 percent lower than the national median home value. Similarly, in 2011, 15.9 percent of the population of coal-producing counties was living below the poverty line. Poverty in this region was slightly more prevalent than in the broader statewide and national populations. The 2011 unemployment rate was comparable in this region with the broader U.S. (7.8 percent compared with 8.1 percent nationally).

Table 3.14-9 lists the industries contributing the most to employment and annual payroll in the Appalachian Basin. Healthcare and Social Assistance, Manufacturing, and Retail Trade are the top industries in this region. Mining (including but not limited to coal mining), Quarrying, and Oil and Gas Extraction made up 1.9 percent of employment in the region and 3.7 percent of regional income in 2011, significantly greater than statewide and national percentages. Employment and annual payroll increased in these industries between 2001 and 2011. As described in Table 3.14-6, of the Appalachian Basin states, coal mining contributes most to employment and annual payroll in West Virginia and Kentucky. In 2014, coal mining accounted for 3.19 percent of total employment and 6.96 percent of statewide annual payroll in West Virginia. In 2011 in Kentucky, employment related to coal mining accounted for 0.77 percent of statewide employment and 1.42 percent of statewide annual payroll. Coal mining contributed less than one percent to employment and annual payroll in all other Appalachian Basin states in this same year. Between 1998 and 2012, coal production fell dramatically in the Appalachian Basin (Figure 3.14-8). Over this 15 year span, employment in the coal industry initially decreased due to less coal production. A shift toward underground mining led to an offsetting increase in coal mining employment through 2012. Between 2012 and 2014 coal mining employment decreased again as production continued to decline.

State governments in Alabama, Kentucky, Ohio, Tennessee, West Virginia, and Virginia require that direct severance taxes be paid on extracted coal. Severance tax rates are listed in Table 3.14-7. Table 3.14-8 shows severance tax revenue for state governments in 2015. In the Appalachian Basin, severance tax revenue as a fraction of total tax revenue was greatest in West Virginia and Wyoming, at 6.98 percent and 11.91 percent respectively. Maryland and Pennsylvania do not levy severance taxes on coal.

Table 3.14-9. Employment and Annual Payroll by Industry in the Appalachian Basin, 2011

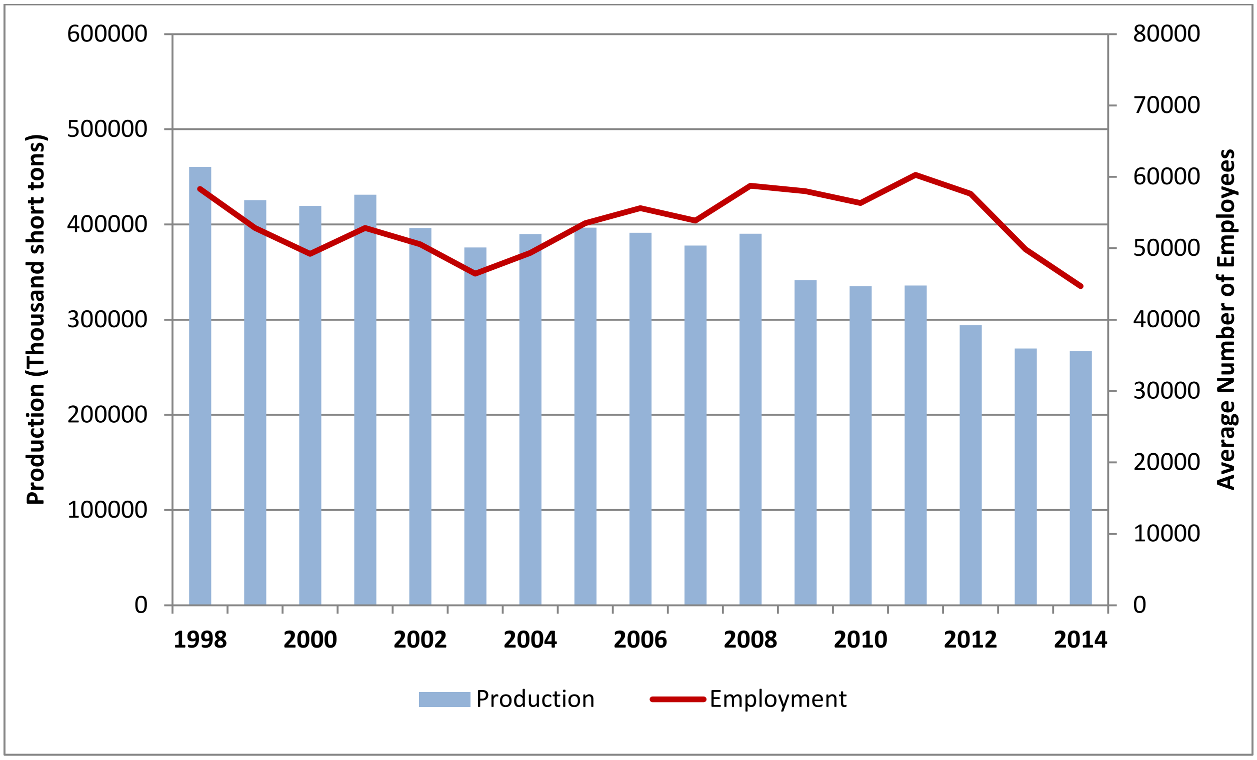
[1] Counties within a state that cross regional boundaries are counted in the region where they fall. The data for these counties is therefore included in both regions and therefore the populations of each coal region do not sum to the total population within all coal regions.

Figure 3.14-8. Coal Production and Employment Trends in the Appalachian Basin Region, 1998-2014



Source: U.S. Energy Information Administration, Annual Coal Reports 1998 – 2014 (EIA-0584).

Note: Employment includes all employees engaged in production, preparation, processing, development, maintenance, repair shop, or yard work at mining operations, including office workers. Employment excludes preparation plants with fewer than 5,000 employee hours per year, which are not required to provide data.

3.14.2.2 Colorado Plateau

Income levels are slightly less in the Colorado Plateau than in the U.S. as a whole. The median household income for coal-producing counties in the region is about 1.5 percent less than the national average. Median home value is in these counties ($193,367) is on par with the broader U.S. ($186,200), but less than in the four Colorado Plateau states ($209,077). The Colorado Plateau has the greatest level of unemployment of all seven coal regions, with an unemployment rate of 8.9 percent. Poverty is also slightly more prevalent within coal-producing counties (17.3 percent below the poverty line) than in both the states encompassing the region (14.6 percent) and the broader U.S. (14.3 percent).

Table 3.14-10 lists the top industries in the Colorado Plateau. Healthcare and Social Assistance, Construction, and Retail Trade account for the highest contributions to annual payroll in this region; Healthcare and Social Assistance, Retail Trade, and Accommodation and Food Services account for the greatest employment levels. Employment and annual payroll in Mining, Quarrying, and Oil and Gas Extraction grew in this region between 2001 and 2011. These industries account for 4.2 percent of employment and 10.1 percent of annual payroll within coal-producing counties, more than double the statewide percentages and four times the national contribution for employment from the same industries. Coal mining constitutes between 1.0 percent and 2.0 percent of statewide employment and income in each state within the region (Table 3.14-6). Both coal production and employment in the coal mining industry remained relatively stable between 1998 and 2008 but production declined from 2009-2012 and has increased slightly in recent years in the Colorado Plateau (Figure 3.14-9).

In Colorado and New Mexico, direct severance taxes are levied on extracted coal. Table 3.14-7 lists severance tax rates. Table 3.14-8 describes state severance tax revenues in 2015. Tax revenue from coal severance makes up 0.14 percent of total tax revenue in New Mexico. Colorado reports approximately 0.07 percent of total tax revenue from coal severance taxes. Arizona and Utah do not collect severance taxes on extracted coal.

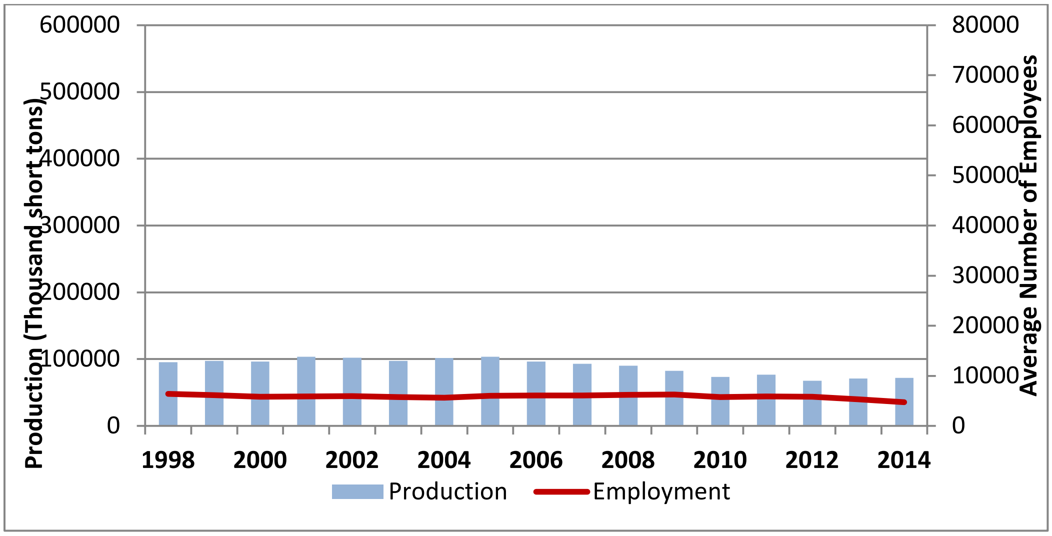
[1] Counties within a state that cross regional boundaries are counted in the region where they fall. Three Colorado counties overlap both the Colorado Plateau and Northern Rocky Mountains and Great Plains regions. The data for these counties is therefore included in both regions and therefore the populations of each coal region do not sum to the total population within all coal regions.

Figure 3.14-9. Coal Production and Employment Trends in the Colorado Plateau Region, 1998-2014



Source: U.S. Energy Information Administration, Annual Coal Reports 1998 – 2014 (EIA-0584).

Note: Employment includes all employees engaged in production, preparation, processing, development, maintenance, repair shop, or yard work at mining operations, including office workers. Employment excludes preparation plants with fewer than 5,000 employee hours per year, which are not required to provide data.

3.14.2.3 Gulf Coast

The Gulf Coast region has the lowest income levels among all seven coal regions. Per capita income within coal-producing counties is $18,756, approximately 33 percent less than per capita income of the broader U.S. Median household income ($40,660) and median home value ($96,084) in the coal-producing counties are also significantly lesser than the corresponding national estimates ($52,762 and $186,200, respectively). With 22.0 percent of the population in coal-producing counties living below the poverty line, the Gulf Coast has the highest prevalence of poverty among all seven coal regions. Despite these statistics, there is slightly less unemployment (7.2 percent) in the Gulf Coast region than in the U.S. as a whole (8.1 percent).

The top three industries contributing to annual payroll in the region are Manufacturing, Healthcare and Social Assistance, and Mining, Quarrying, and Oil and Gas Extraction (Table 3.14-11). In coal-producing counties, Mining, Quarrying, and Oil and Gas Extraction make up 5.1 percent of total employment and 12.7 percent of annual payroll, considerably more than statewide and national percentage contributions from coal mining. Employment and annual payroll in these industries grew between 2001 and 2011. As described in Table 3.14-6, the coal mining industry does not measurably contribute to statewide employment or annual payroll in any of the three states. Employment in the coal mining industry remained relatively stable between 1998 and 2005, but decreased in regional coal production toward the end of the 15 year span (Figure 3.14-10).

Louisiana levies a natural resource severance tax of $0.12 per ton of extracted lignite coal (Table 3.14-7). Tax revenue on coal severance makes up approximately one hundredth of one percent of total tax revenue in Louisiana (Table 3.14-8). Mississippi and Texas do not levy severance taxes on coal.

Employment excludes preparation plants with fewer than 5,000 employee hours per year, which are not required to provide data.

3.14.2.4 Illinois Basin

Income levels are relatively low in the Illinois Basin coal region. Per capita income and median home value are lower in coal-producing counties than in the broader Illinois Basin states (Table 3.14-4). Per capita income and median home value are all slightly less in coal-producing counties than in the country as a whole. The poverty rate is the same in coal-producing counties (8.6 percent) and Illinois Basin states (8.6 percent) and slightly greater than the rest of the country as a whole (8.1 percent). Unemployment is slightly more prevalent in this region than in the broader U.S. (8.6 percent compared with 8.1 percent).

Table 3.14-12 lists the top industries in the Illinois Basin. Healthcare and Social Assistance, Manufacturing, and Retail Trade contribute most to employment and annual payroll in this region. The Mining, Quarrying, and Oil and Gas Extraction industries account for 0.5 percent of employment and 1.2 percent of annual payroll in coal-producing counties. In Kentucky, coal mining constitutes 0.3 percent of statewide employment and 2.1 percent of statewide annual payroll (Table 3.14-6). Coal mining makes up less than 0.2 percent of employment and less than 0.3 percent of annual payroll in Indiana and Illinois. As shown in Figure 3.14-11, employment in the Illinois Basin coal mining industry decreased between 1998 and 2000 but increased steadily between 2000 and 2011, in response to a similar trend in regional coal production. Production and employment dropped again in 2012, but increased again in 2013 and 2014.

Kentucky levies a coal severance tax, collecting 4.5 percent of the gross value of extracted coal with a minimum of $0.50 per ton (Table 3.14-7). As shown in Table 3.14-8, severance tax revenue makes up 1.62 percent of the total tax revenue collected by the state of Kentucky. Illinois and Indiana do not levy coal severance taxes.

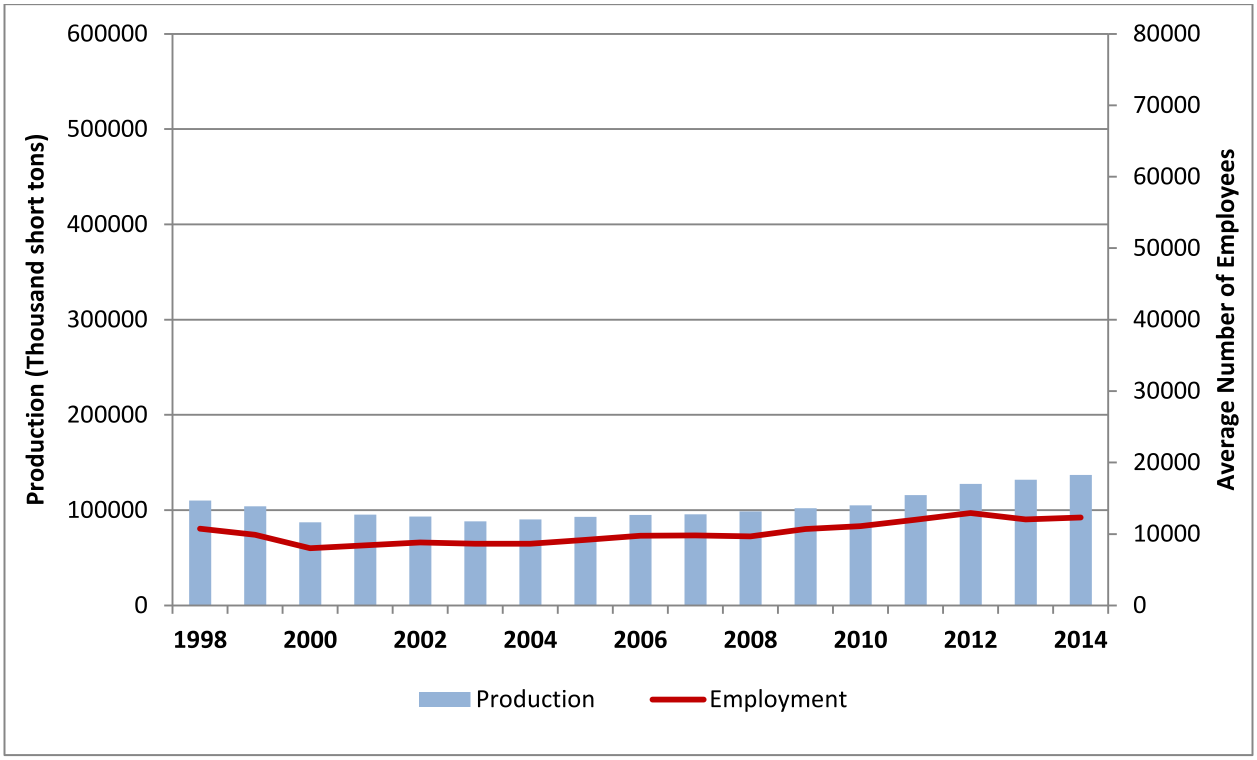
[1] Counties within a state that cross regional boundaries (such as in KY) are counted in the region where they fall. The data for these counties is therefore included in both regions and therefore the populations of each coal region do not sum to the total population within all coal regions.

Figure 3.14-11. Coal Production and Employment Trends in the Illinois Basin Region, 1998-2014



Source: U.S. Energy Information Administration, Annual Coal Reports 1998 – 2014 (EIA-0584).

Note: Employment includes all employees engaged in production, preparation, processing, development, maintenance, repair shop, or yard work at mining operations, including office workers. Employment excludes preparation plants with fewer than 5,000 employee hours per year, which are not required to provide data.

3.14.2.5 Northern Rocky Mountains and Great Plains

In the Northern Rocky Mountains and Great Plains region, per capita income in coal-producing counties is less than that of the states encompassing the region and national per capita income (Table 3.14-4). Median household income is greater in the coal-producing counties ($57,375) than in the broader Northern Rocky Mountains and Great Plains states ($55,129) and the U.S. as a whole ($52,762). Median home value is less in this region ($199,665) than in the states encompassing the region ($213,776) and greater than the broader U.S. ($186,200). Unemployment in this coal region is in line with the broader U.S. (Table 3.14-5). Poverty in the region and statewide (12.8 percent and12.6 percent, respectively) are less than in the greater U.S.

Construction, Retail Trade, and Mining, Quarrying, and Oil and Gas Extraction are the major industries in the region (Table 3.14-13). Mining, Quarrying, and Oil and Gas Extraction in this region contributes a greater share of employment and annual payroll than in any other coal region, accounting for 5.7 percent of employment and 10.9 percent of total annual payroll in coal-producing counties. In Wyoming, employment related to coal mining makes up 3.4 percent of statewide employment and 6.5 percent of statewide annual payroll (Table 3.14-6). Coal mining employment accounted for less than 0.4 percent of statewide employment in Montana and North Dakota; coal mining related payroll data are not available for these states. Between 1998 and 2012, mining related employment grew by more than 60 percent in the Northern Rocky Mountains and Great Plains region, corresponding with considerable growth in regional coal production (Figure 3.14-12).

All four states in the Northern Rocky Mountains and Great Plains region levy severance taxes on coal (see Table 3.14-7). Coal severance tax revenues make up a relatively great share of total tax revenue in this region, accounting for 11.91 percent of Wyoming tax revenue, 2.33 percent of Montana tax revenue, 0.18 percent of North Dakota tax revenue, and 0.07 percent of Colorado tax revenue (Table 3.14-8).

Source: U.S. Energy Information Administration, Annual Coal Reports 1998 – 2014 (EIA-0584).

Note: Employment includes all employees engaged in production, preparation, processing, development, maintenance, repair shop, or yard work at mining operations, including office workers. Employment excludes preparation plants with fewer than 5,000 employee hours per year, which are not required to provide data.

3.14.2.6 Northwest

This section describes the socioeconomic conditions of the current and reasonably foreseeable future coal mining activity in the region (i.e., Alaska). The socioeconomic metrics described in Tables 3.14-4 and 3.14-5 indicate that people living in the Northwest coal region are, on average, more affluent than the general population. Alaska is better off than the general population in terms of average income, home values, unemployment, and poverty rates. Per capita income in coal-producing counties is $38,669, the greatest among all coal regions and more than 38 percent greater than national per capita income. Median household income is also the greatest in the Northwest coal region. Median home value in coal-producing counties is $394,197, more than double the national median home value. These counties have a lower prevalence of poverty and unemployment than the rest of the country (Table 3.14-5).

Table 3.14-14 demonstrates that due to the small area in Alaska where coal operations take place, minimal data is available related to the employment and annual payroll of the region. Of available and reported data, Accommodations and Food Services, Transportation and Warehousing, and Retail Trade are the top contributors to annual payroll in the Northwest coal region. Transportation and Warehousing, Retail Trade and construction are the top industries contributing to employment in the region. The

Mining, Quarrying, and Oil and Gas Extraction industries did not report figures for the 2001 to 2011 time period in this region (Table 3.14-6). Additionally, as shown in Figure 3.14-13, regional coal production and employment dropped precipitously between 2006 and 2007, reflecting the termination of coal production in Washington.

Alaska levies a license tax on net income earned from mining. The tax rate varies based on the amount of income earned. Alaska also collects royalties from production on state land (Table 3.14-7). Less than 0.01 percent of total tax revenue collected by the state of Alaska comes from the mining license tax (Table 3.14-8).

Note: Employment includes all employees engaged in production, preparation, processing, development, maintenance, repair shop, or yard work at mining operations, including office workers. Employment excludes preparation plants with fewer than 5,000 employee hours per year, which are not required to provide data.

3.14.2.7 Western Interior

The Western Interior coal region has the second lowest per capita income and second lowest median home value among all coal regions (Table 3.14-4). Per capita income within coal-producing counties is $22,050. Median home value in these counties is $104,353, approximately 44 percent less than the national median home value. Per capita income, median household income, and median home value are all less in coal-producing counties than Western Interior states and the broader U.S. The Western Interior has a greater prevalence of poverty than the national population, with 16.8 percent of the population in coal-producing counties living below the poverty line, compared with 14.3 percent nationwide. These counties have an unemployment rate (6.9 percent) comparable to the broader Western Interior states (6.4 percent) but less than the national rate (8.1 percent).

Table 3.14-15 lists the top industries in the Western Interior by employment and annual payroll. Manufacturing, Healthcare and Social Assistance and Retail Trade contribute most to employment and annual payroll in the region. The Mining, Quarrying, and Oil and Gas Extraction industries contribute more to employment and annual payroll in this region than in the states encompassing the region and in the broader U.S., making up 2.4 percent of employment and 4.2 percent of annual payroll in coal-producing counties. As described in Table 3.14-6, coal mining does not contribute measurably to employment or annual payroll in any of the four states within the region. Between 1998 and 2011, employment in the coal mining industry varied, reaching a low point of 186 employees in 2002 and a high point of 403 employees in 2007 (Figure 3.14-14). Corresponding with a fall in regional coal production, coal mining employment fell between 2007 and 2009 but then rose significantly in 2012 in response to an increase in production.

Arkansas and Kansas levy severance taxes on extracted coal. Severance tax rates are listed in Table 3.14-7. Severance tax revenues for 2015 are listed in Table 3.14-8. Severance tax revenue makes up less than 0.1 percent of tax revenue in Arkansas and 0.12 percent in Kansas. Missouri and Oklahoma do not collect tax revenue from coal severance.

Table 3.14-15. Employment and Annual Payroll by Industry in the Western Interior, 2011

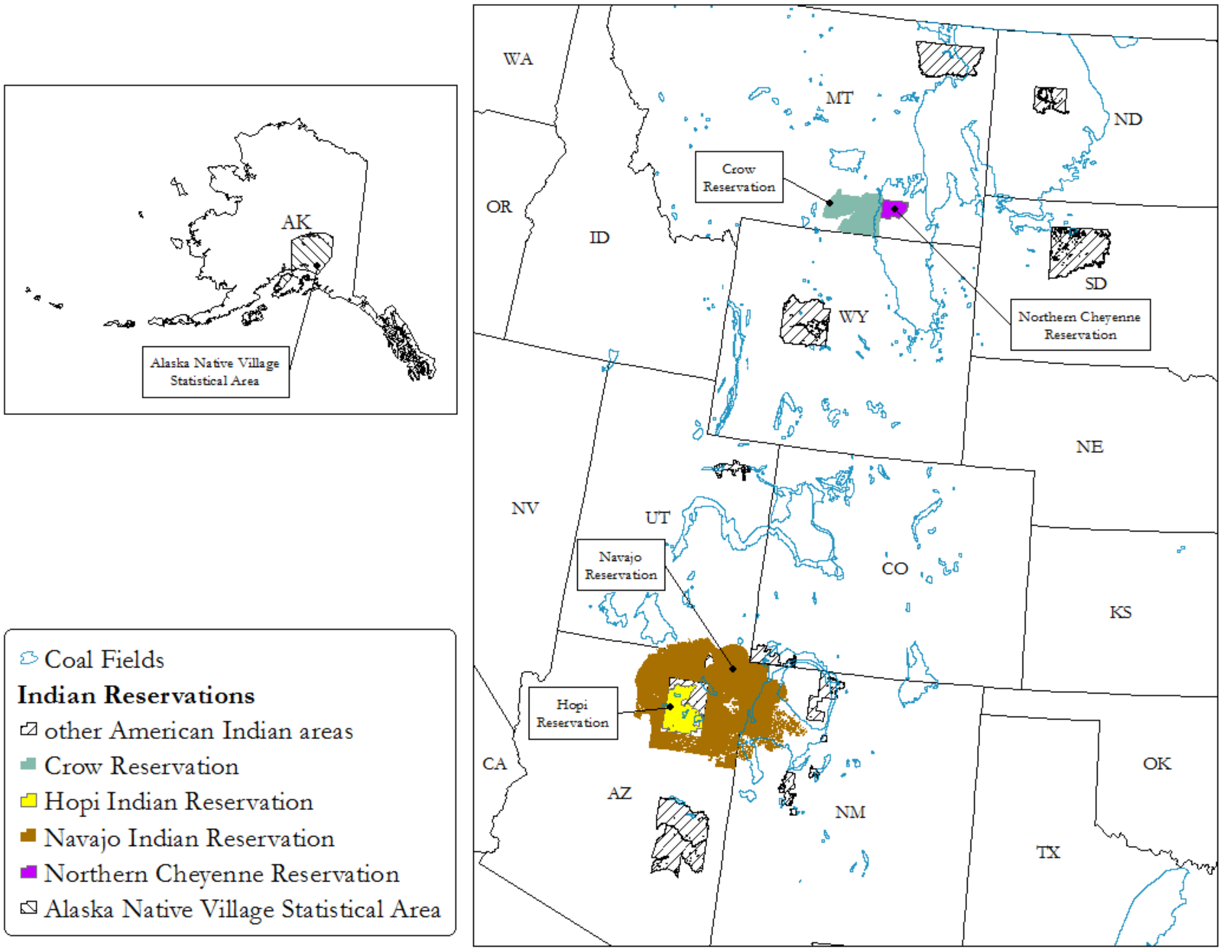
Employment excludes preparation plants with fewer than 5,000 employee hours per year, which are not required to provide data.

3.14.3 Tribal Populations

This section characterizes socioeconomic factors similar to the previous two sections but focuses more specifically on the Native American and Native Alaskan populations potentially affected by the Action Alternatives. Sections 4.3 (describing impacts on socioeconomic conditions) and 4.4 (environmental justice analysis) evaluate potential impacts of the Action Alternatives on Native American populations.

The U.S. Census identifies 20 "American Indian Areas" and six "Alaska Native Village Statistical Areas" (ANVSA) within the study area for this analysis. These include reservations, off reservation trust lands (ORTLs), and statistical areas that include populations of Native Americans and Alaska Natives. These areas, mapped in Figure 3.15-6, overlap potentially minable coal within coal-producing counties across the U.S. Socioeconomic data for the "American Indian Areas" and ANVSAs are from the 2000 and 2010 U.S. Censuses and the American Community Survey 2007-2011 Five Year Estimates. This characterization focuses on the "American Indian Areas" and ANVSAs; there may be additional tribal subdivisions that overlap the area of analysis but are not separately characterized in this report.

Figure 3.14-15. American Indian Areas Overlapping Coal Regions



Source: U.S. Census Bureau 2010a TIGER/Line® Shapefiles. U.S. Department of Commerce. https://www.census.gov/geo/maps-data/data/tiger-line.html; USGS, 2001a. Coal Fields of the United States: National Atlas of the United States, Reston, VA, Eastern Energy Team; John Tully (comp.), August 2001. http://nationalatlas.gov/mld/coalfdp.html

This discussion gives particular emphasis to the socioeconomic profiles of the Navajo, Hopi, Northern Cheyenne, and Crow Tribes, the four tribes listed in section 710(i) of SMCRA (30 U.S.C. § 1300(i)). The Navajo Nation Reservation occupies northeastern Arizona, southeastern Utah, and northwestern New Mexico. The Hopi Reservation lies entirely within the Arizona portion of the Navajo Reservation. The Northern Cheyenne Reservation and ORTL and Crow Reservation and ORTL lie adjacent to one another in southeastern Montana.

3.14.3.1 Demography

Population trends vary across Native American tribes between 2000 and 2010 (Table 3.14-16). Of all the "American Indian Areas" examined, the Mississippi Choctaw Reservation experienced the greatest population growth (43.3 percent), while the Adais Caddo State Designated Tribal Statistical Area experienced the greatest percent decline in population (93.6 percent). The Navajo Nation has, by far, the largest population of the four tribes listed in section 710(i) of SMCRA; the population living on the Navajo Nation Reservation and ORTL declined by 3.8 percent between 2000 and 2010. The population living on the Crow Reservation and ORTL remained stable, declining by less than one percent over the same time period. The populations of the Hopi Reservation and ORTL and Northern Cheyenne Reservation and ORTL increased by 3.4 percent and 7.1 percent respectively between 2000 and 2010.

The populations of the six ANVSAs experienced varying degrees of growth and decline. Between 2000 and 2010, the Knik ANVSA experienced the greatest population increase (105 percent), whereas the Tyonek ANVSA population declined (16.1 percent).

The populations of the Navajo Nation, the Hopi, the Northern Cheyenne, the Crow, Atqasuk, Chicaloon, Knik, Tyonek, and Wainwright are all typically younger than the general U.S. population, with relatively large segments of their respective populations making up the younger age groups. The age distributions for the 20 examined "American Indian Areas" and six ANVSAs are listed in Table 3.14-17.

3.14.3.2 Economic Baseline

In general, the potentially affected Native American tribes are less affluent than the broader national population. Median household income is less than the national statistic in 18 of the 20 examined "American Indian Areas," with the Southern Ute Reservation and Uinta and Ouray Reservation being the exceptions (Table 3.14-18). Per capita income falls between $10,000 and $12,000 on the Navajo Nation Reservation and ORTL and the Northern Cheyenne Reservation and ORTL, which is less than 57 percent of the national average. The Hopi Reservation and ORTL per capita income is slightly greater than $12,000. Per capita income on the Crow Reservation and ORTL is approximately $14,000, close to half the national figure. The Kickapoo Reservation is subject to the lowest median household income statistic, standing at $22,941, whereas the Fort Apache Reservation has the lowest per capita income at $9,738. The Navajo Nation reports a median household income of $27,022, the lowest of the four tribes listed in section 710(i) of SMCRA. Median home value falls between $60,000 and $80,000 for the Navajo, Crow, and Northern Cheyenne. Median home value for the Hopi is $108,600, still more than $65,000 below the national median home value.

Table 3.14-18. Per Capita Income, Median Household Income, and Median Home Value in American Indian Areas in Coal Regions, 2011

Coal Region	American Indian Area	Per Capita Income[1]	Median Household Income[1]	Median Home Value[2]
Appalachian Basin	Echota Cherokee SDTSA	$24,030	$50,806	$124,400
Colorado Plateau	Jicarilla Apache Nation AIR/ORTL	$15,882	$42,214	$59,600
	Uintah and Ouray AIR/ORTL	$23,080	$56,100	$168,800
	Southern Ute AIR	$27,777	$58,855	$263,100
	Ute Mountain AIR/ORTL	$12,456	$28,355	$91,100
	Fort Apache AIR	$9,738	$26,134	$78,600
	Zuni AIR/ORTL	$10,575	$31,050	$55,500
	Navajo Nation AIR/ORTL	$10,864	$27,022	$64,100
	Hopi AIR/ORTL	$12,363	$34,904	$108,600
Gulf Coast	Mississippi Choctaw AIR	$11,501	$38,058	$57,500
	Kickapoo AIR	$10,782	$22,941	$44,300
	Adais Caddo SDTSA	$16,835	$31,058	$62,400
Northern Rocky Mountains and Great Plains	Fort Berthold AIR	$20,490	$44,637	$59,400
	Crow AIR/ORTL	$13,998	$43,846	$78,100
	Northern Cheyenne AIR/ORTL	$11,843	$36,219	$67,300
	Fort Peck AIR/ORTL	$16,075	$35,794	$58,700
	Turtle Mountain AIR/ORTL	$10,672	$25,469	$45,100
Northwest	Atqasuk ANVSA	$18,747	$56,500	$141,700
	Chickaloon ANVSA	$30,087	$72,844	$227,200
	Knik ANVSA	$28,996	$69,666	$213,100
	Ninilchik ANVSA	$29,039	$53,886	$215,100
	Tyonek ANVSA	$20,976	$28,750	$87,200

[1] Per capita income and median household income are reported in 2011 inflation adjusted dollars.
[2] Median reported value of owner occupied housing units.

In the potentially affected ANVSAs, general economic characteristics are mixed. The Chicakloon, Knik, and Ninilchik populations are all generally more affluent than the broader national population, whereas the Atqasuk, Tyonek, and Wainwright populations are generally less affluent. The Chickaloon ANVSA per capita income exceeds $30,000 with a median household income of nearly $73,000. The median home value is also 22 percent greater than the broader nation. However, the Atqasuk, Tyonek and Wainwright ANVSAs have per capita incomes of approximately $20,000, almost $8,000 less than the national average. These three ANVSAs also have home values significantly less than the national average, ranging from $87,200 to $141,700.

The statistics listed in Table 3.14-19 also demonstrate relatively high poverty rates among Native Americans. In 16 of the 26 examined areas, more than 20 percent of the population lives below the poverty line. The poverty rate reaches as great as 46.8 percent and 43.4 percent in the Fort Apache and Turtle Mountain Reservations, respectively. The poverty rate falls between 25 percent and 40 percent for the Navajo Nation, the Hopi, and the Northern Cheyenne, and the Crow Reservation and ORTL. The unemployment rate varies widely across the examined American Indian Areas, ranging from 0.0 percent in the Kickapoo Reservation, to 33.8 percent in the Fort Apache Reservation. Unemployment is relatively prevalent among the four tribes listed in section 710(i) of SMCRA. Over 20 percent of the labor force is unemployed in the Crow and Northern Cheyenne Reservations and ORTLs. The unemployment rates for the Navajo Nation Reservation and ORTL and the Hopi Reservation and ORTL are 18.7 percent and 17.7 percent, respectively.

Table 3.14-20 describes employment by industry for the 20 American Indian areas and six ANVSAs. While specific data regarding employment in the coal mining industry is not available for these populations, the Agriculture, Forestry, Fishing, and Hunting, and Mining (including but not limited to coal mining) industries account for 18 percent of total employment in the Uintah and Ouray Reservation and ORTL. In the Navajo Nation and Northern Cheyenne Reservations and ORTLs, Agriculture, Forestry, Fishing, and Hunting, and Mining account for nearly four percent of total employment, respectively. In the Crow and Hopi Reservations and ORTLs, these industries make up 14.4 percent and 4.6 percent of total employment, respectively.

Chapter 4. Environmental Consequences

4.0 Introduction

This chapter evaluates the effects of the Alternatives on the natural, social, and economic resources introduced in Chapter 3. The description of each Alternative is provided in Chapter 2. Specifically, the analysis of environmental consequences is organized by resource as follows:

- Mineral Resources and Mining
- Natural Resources
  - Water Resources
  - Biological Resources
  - Topography, Geology, and Soils
  - Air Quality, Greenhouse Gas Emissions, and Climate Change
- Social and Economic Resources
  - Socioeconomic Conditions
  - Land Use, Utilities, Infrastructure, Visual Resources and Noise
  - Recreation
  - Public Health and Safety
  - Archaeology and Cultural Resources
- Environmental Justice

4.0.1 Description

This chapter describes the potential effect of the Alternatives, including the No Action Alternative, on the natural and human environment. The White House Council on Environmental Quality's (CEQ's) National Environmental Policy Act (NEPA) regulations (40 CFR 1508) describe three categories of effects[1] to be measured in an Environmental Impact Statement (EIS):

- **Direct Effects** are effects that are caused by the action and which occur at the same time and place;
- **Indirect Effects** are effects that are caused by the action but which occur later in time or farther removed in space, but which are still reasonably foreseeable; and
- **Cumulative Effects** are the impacts on the environment which results from the incremental impact of the action when added to other past, present, and reasonably foreseeable future actions regardless of what agency (federal or non-federal) or person undertakes such other actions. Cumulative impacts can result from individually minor but collectively significant actions taking place over a period of time.

[1] As in NEPA regulations, the terms "effects" and "impacts" are used interchangeably throughout this chapter.

The definition of "effects" is broad, and can include ecological, aesthetic, historic, cultural, economic, social, or human health effects.

In accordance with NEPA regulations, Sections 4.1 through 4.7 of this chapter assess the direct, indirect, and cumulative effects of the Alternatives. Specifically, this chapter addresses the following requirements of an Environmental Consequences analysis as described by the CEQ NEPA regulations (40 CFR 1502 and 1508):

- **Environmental impacts of the Alternatives and their significance.** Environmental impacts are the focus of Sections 4.2 through 4.4.
- **Possible conflicts between the Proposed Action and objectives of federal, state, and local plans, policies, and controls.** Each resource-specific analysis considers the potential effects of every Alternative in the context of existing and planned actions and objectives within the study area.
- **Cumulative effects.** Section 4.5 examines the effects of the Alternatives when considered in combination with other past, present, and reasonably foreseeable actions.
- **Any irreversible or irretrievable commitments of resources which would be involved should the proposal be implemented.** A resource commitment is considered "irreversible" when impacts from its use limit future use options. A resource commitment is considered "irretrievable" when the use or consumption of the resource is neither renewable nor recoverable for use by future generations. Section 4.6 identifies those categories of impacts that constitute an irreversible and irretrievable commitment of resources.
- **Identification of any adverse impacts which cannot be avoided should the proposal be implemented.** Section 4.6 also identifies the categories of impacts described in Sections 4.2 through 4.4 for which adverse environmental effects cannot be avoided.
- The relationship between the short-term use of man's environment and the maintenance and enhancement of long-term productivity. The resource-specific analyses of the significance of the impacts considers the duration of impact.

All of these analyses are developed in accordance with 43 CFR Part 46, which contain the Department of the Interior's regulations for implementing NEPA.

In addition to addressing the NEPA requirements for the Environmental Consequences portion of an EIS, this chapter was developed in accordance with Executive Order (E.O.) 12866, which directs federal agencies to provide an assessment of both the social costs and benefits of proposed regulatory actions:

In deciding whether and how to regulate, agencies should assess all costs and benefits of available Alternatives, including the Alternative of not regulating. Costs and benefits should be understood to include both quantifiable measures (to the fullest extent that these can be usefully estimated) and qualitative measures of costs and benefits that are difficult to quantify, but nevertheless essential to consider.

In accordance with E.O. 12866, a detailed Regulatory Impact Analysis (RIA) has been developed for this rule and is provided under separate cover.

4.0.2 Analytic Framework

This section describes the study area for the environmental consequences analysis, summarizes the overarching method for the resource-specific impact analyses, and details the approach to evaluating the relative significance of impacts across the affected resources. The detailed approach to analysis of each resource is discussed in each respective section.

4.0.2.1 Study Area

As described in Chapter 3 of this EIS, coal resources in the U.S. are widely distributed throughout the country. However, not all coal resources are accessible with current technologies. Further, some potentially mineable coal resources are unlikely to be mined in the near term because of economic conditions. To establish a reasonable boundary for the geographic areas likely to be affected by this rule, the geographic scope was defined as outlined below. In general, the geographic scope identified is likely to be over-inclusive; it may overestimate the areal extent of mining, unless otherwise noted.

- Spatial data compiled by the U.S. Geological Survey (USGS) Eastern Energy Resources Center on potentially minable coal fields defined the initial extent of the study area. Coal fields were identified as potentially minable if they contained coal of sufficient quality and energy content to justify extraction, based on existing data (USGS, 2001b).
- From the practicably minable coal fields data, areas considered likely to produce coal within the timeframe for this analysis include areas within counties that:
  - Reported coal production between 2007 and 2012 in Energy Information Administration (EIA) Annual Coal Reports;
  - Contain pending but administratively complete Surface Mining Control and Reclamation Act (SMCRA) permits in the Office of Surface Mining Reclamation and Enforcement (OSMRE) Applicant/Violator System (AVS) as of September 2011;
  - The Mine Safety and Health Administration (MSHA) reports as containing active coal mines as of April 2013 (MSHA, 2013b); or
  - State-level mining assessments, geographic data, or tabular data report as containing active coal mining activity as of August 2012. State-level information contributed additional counties in Colorado (Colorado Division of Reclamation Mining and Safety, 2010), Illinois (Illinois State Geological Survey, 2011), Kentucky (Kentucky Department of Natural Resources, 2011), Ohio (Ohio Department of Natural Resources, 2011), West Virginia (West Virginia Department of Environmental Protection, 2011), Texas (Railroad Commission of Texas, 2011), and Alaska (Alaska Department of Natural Resources, 2011).[2, 3]
- Urban areas, lakes, and ponds were removed from the study area, as mining is not expected to take place in these areas (U.S. Census Bureau, 2002; USGS, 2011b). However, some mining may take place under or adjacent to lakes and ponds, so the study area may slightly under-represent the areal extent of mining in this respect.

---

[2] The program description for the Alaska Coal Regulatory Program states that active mining currently only occurs near Healy, AK, in the Denali Borough.

[3] State-specific data for other states were examined where available, but contributed no additional counties beyond those listed by EIA.

Figure 4.0-1 Study Area for Analysis

4.0.2.2 Method

The specific methods and data relevant to the impact analyses vary significantly by resource category. A detailed description of the methods applied in each impact analysis is provided for each relevant resource in Sections 4.2 through 4.4. Each resource-specific impact analysis in this chapter includes:

- A review of market and regulatory conditions and projected resource impacts under the No Action Alternative;
- A discussion of the Action Alternatives and key elements that may affect the resource;
- A description of the analytic methods;
- The results of quantitative and qualitative analyses;
- A summary of the effects of each Alternative; and
- A discussion of potential minimization and mitigation measures relevant to the impacts described.

For some resource categories, the analysis describes impacts in quantitative terms (e.g., dollars, number of jobs, stream miles impacted, acres affected). Where data limitations prevent reliable quantification of impacts to a given resource, potential impacts are discussed qualitatively. The quantitative analyses apply a common method to estimate the costs or benefits of changes in mine management methods due to the Alternatives, as follows:

Step 1: Estimate compliance costs and changes in coal production under each of the Alternatives, including the No Action Alternative. This step involves assessing how each Alternative results in change to mine operator behavior at typical mines (model) in each of the coal regions. This analysis includes changes in administrative and operational costs, as well as changes in the tonnage of coal expected to be produced (where relevant). The "model mine" analysis is discussed in Section 4.1.[4]

Step 2: Estimate the change in affected natural resources across Alternatives at a typical mine. Parallel to the compliance cost analysis, this step involves estimating the changes in impacts to natural resources caused by the mining operations at typical mines in each coal region. This step includes estimating changes to forest cover, stream miles filled, and other relevant metrics. For the land use and water resources metrics in particular, historical GIS data on land cover and mine locations are combined with information on mining impacts from the model mine analysis for surface and underground mines to estimate the change in natural resource impacts by mine type (i.e., surface and underground) for each region.[5]

Step 3: Express the change in the affected natural resource parameters per ton of coal produced at each typical mine. Model mine analysis results are used to estimate the expected changes in impacts to resources per ton of coal produced. In some cases, data sources in addition to the model mines analysis are used to understand impacts of the proposed action on resources (e.g., analysis of employment impacts).

Step 4: Forecast regional shifts in coal production associated with compliance costs quantified in Step 1. This FEIS relies on a complex integrated system of energy models to evaluate the impacts of the proposed action on quantity of coal demanded, coal supply, and prices. Employing detailed information on a multitude of factors that affect coal production and consumption, these models simulate how changes in market conditions may cascade through different parts of the coal market, affecting both supply of coal and quantity of coal demanded. Detailed assumptions and findings are presented in the RIA. Specifically, these behavior changes may: decrease coal production at a particular site or region; affect the mining method or techniques used (e.g., shift from surface to underground extraction methods); or change the cost-competitive nature of coal mining across coal regions (i.e., shift production between regions). Section 4.1 discusses the mine sector model analysis and results.

Step 5: Estimate total regional impacts. Multiply total expected coal production by the per-ton metrics developed in Step 3 to estimate total impacts of each Alternative by region.

Generally, environmental impacts of the rule may be generated via two pathways. First, mines may continue to extract coal, but operational changes may change how the mining affects environmental resources. Second, to the extent that coal production changes in a region, environmental effects are associated with the changed intensity of mining in the region. Comparing the anticipated coal production

[4] For Alternative 2, the model mine analysis assumes that sufficient offsite storage is available to allow for continued operations at the two Central Appalachian Region surface model mines. See Regulatory Impact Assessment (RIA) Appendix B.

[5] For the historical data analysis, the U.S. Geological Survey's National Land Cover Database (NLCD) and the National Hydrography Dataset (NHD) are used for the land cover and streams analyses, respectively. The NLCD contains data from 1992 and includes 21 classes of land cover. The NHD's data on streams by type (i.e., intermittent, perennial, ephemeral) across the nation allow analysis of the breakdown of identified streams in areas of potentially mineable coal.

and model mine operations-related environmental impacts for the No Action Alternative to the anticipated coal production and model mine operational environmental impacts for each Action Alternative captures both of the effects.

4.0.2.3 Categories of Impact

With respect to impacts evaluated as part of an EIS, CEQ defines "significantly" in terms of context (i.e., geographic scope of effect, as well as length of effect in terms of short-term versus long-term) and intensity (i.e., severity of effect) (40 CFR 1508.27). This determination refers to all types of effects of the Alternatives, including the direct, indirect, and cumulative effects.

Communicating the relative significance of impacts of the Alternatives across the diverse categories of affected resources presents unique challenges. For example, this chapter describes quantified effects on water quality in terms of stream miles impacted, effects on employment in terms of number of jobs, while effects on visual resources are described qualitatively. It may therefore be difficult to discern the relative effects of the Alternatives on these resources. To facilitate this comparison and promote understanding of the key impact categories of interest, all impacts in this analysis are summarized at the end of each section in common terms. These "impact categories" include both adverse and beneficial effects and consider three key factors:

- **Length of impact:** Short-term effects generally occur during active mining within the EIS study period of 2020 to 2040; long-term effects extend beyond the study period.[6]
- **Scope of impact:** This factor considers whether the impacts occur within a small, medium, or large geographic area (i.e., whether impacts are expected within or directly adjacent to mining activity or beyond and to what extent). In addition, this factor considers whether impacts occur within the context of small, medium, or large communities or economies.
- **Potential for offsetting the impact:** This factor considers the extent to which the application of best management practices (BMPs), restoration activities, or mitigation may change the net effect.

Based on these factors, Table 4.0-1 describes the impact categories referenced in each section of the analysis. For each impact described in Sections 4.1 through 4.3, the discussion supports the characterization of the impact as minor, moderate, or major by relating it to these definitions. For the purpose of the analysis, a short-term effect to a small geographic area, community or economy within the context of the affected resource would likely not be measureable, and therefore is categorized as negligible. Mitigation also works to decrease length or scope of impact to analyzed resource.

The analysis examines the impacts of the Action Alternatives and the extent to which they would reduce or increase coal mining-related impacts on resources as compared to the No Action Alternative. For example, an Alternative characterized as having a Major Beneficial impact on biology would reduce

---

[6] The EIS study period begins in 2020, approximately three years after OSMRE's anticipated publication of the final SPR. Development of average annual impacts requires forecasts of coal production over an extended time horizon. The study period ends in 2040 was selected to be in line with other existing energy market forecasts; for example, energy use forecasts produced by the EIA currently extend to 2040; beyond this point, reliable coal forecasts are assumed to be not be feasible due to volatility in the industry.

mining impacts in a way that would provide major benefits to biological resources as compared to the No Action Alternative. This finding is not equivalent to saying that mining activity itself would benefit biological resources. Rather, the incremental effects of the Action Alternative, compared with the No Action Alternative, are beneficial.

Table 4.0-1 General Impact Category Definitions[1]

Impact Characterization	Definition
Negligible	• Minimal measurable impacts (adverse or beneficial) are expected; or • Short term effects to a small geographic area, community or economy within the context of the affected resource.
Minor Adverse	• Short-term effect to a medium geographic area, community or economy within the context of the affected resource; or • Long-term effect to a small geographic area, community or economy within the context of the affected resource; or • Short-term effect and the resource would recover completely without any offsetting activities (e.g., restoration activities) once the action is completed.
Moderate Adverse	• Short-term effect to a large geographic area, community or economy within the context of the affected resource; or • Long-term effect to a medium geographic area, community, or economy within the context of the affected resource; or • Effect occurs to a large geographic area, community, or economy within the context of the affected resource, but the resource likely recovers substantially through mitigation.
Major Adverse	• Long-term effect to a large geographic area, community, or economy within the context of the affected resource; and • Effects are irreversible, even if BMPs, restoration, or mitigation activities are undertaken.
Minor Beneficial	• Short-term benefit to a medium geographic area, community or economy within the context of the affected resource; or • Long-term benefit to a small geographic area, community or economy within the context of the affected resource.
Moderate Beneficial	• Short term benefit to a large geographic area, community or economy within the context of the affected resource; or • Long-term benefit to a medium geographic area, community, or economy within the context of the affected resource.
Major Beneficial	• Long-term benefit to a large geographic area, community, or economy within the context of the affected resource.

[1] Determinations were made using criteria developed for each affected resource. These criteria are presented in section 4.0.3 as well as in resource-specific sections.

4.0.3 Summary of Results

This section summarizes the results of the resource-specific analyses presented in this chapter. Results are organized in two ways. The first set of tables (Tables 4.0-2 through 4.0-8) presents comparisons of impacts for each coal region under each Alternative and resource. The second set of tables (Tables 4.0-9 through 4.0-16) describes the impacts for each Alternative across all coal regions and resources. The determinations in these exhibits are detailed in the individual resource sections of this document (Section 4.3 and 4.4). Table 4.0-17 summarizes overall impacts of the Alternatives on all resources.

Mining under the No Action Alternative (i.e., continuation of existing regulations) has known effects on physical, biological, and human resources, and these effects vary by region. Impacts of the No Action Alternative (Alternative 1) are detailed in the resource-specific sections of this chapter. When assessing the Action Alternatives, all the impacts characterized throughout this chapter represent incremental effects relative to conditions realized under the No Action Alternative.

Finally, Table 4.0-17 summarizes overall impacts of the Action Alternatives by resource. In order to create summary determinations, analysts considered the variation in impacts across all the regions and reasoned that a major adverse impact at a regional scale would also apply at the national scale. As shown, Alternative 2 has the most intensely adverse impacts, which are anticipated for socioeconomic conditions, as well as the most intensely beneficial impacts, which occur for most other resources, when compared to impacts of the No Action Alternative. Alternative 9 shows Negligible impacts when compared to impacts of the No Action Alternative. The remaining Alternatives exhibit the same pattern of impacts as Alternative 2, but with varying degrees of adverse effects on socioeconomic conditions and benefits to natural resources. The following sections present the determination criteria and results of the analysis by resource in more detail.

4.0.3.1 Water Resources

Consistent with the purpose of the proposed action, the Action Alternatives (except Alternative 9) would result in benefits to water resources relative to the No Action Alternative at the national scale. Because impacts would be expected to extend beyond the period of active mining, these beneficial impacts are considered long-term. To evaluate the intensity of these beneficial impacts on water resources, OSMRE considered the results of the quantitative analysis of the impacts of the Action Alternatives on: (1) miles of streams filled, (2) increased restoration of ephemeral streams that are mined through, (3) stream miles downstream of mine sites experiencing improved water quality, and (4) stream miles that are preserved from adverse effects of mining, as well as qualitative assessments of the impacts on water quality associated with improvements to streamside habitat conditions. Specifically, determinations were made using the following analytical categories:

- Negligible: Minimal impacts (adverse or beneficial) anticipated, e.g. short-term effects to a small geographic area, community, or economy, or no effects.
- Minor Beneficial: Impacts expected to be small and localized were considered to result in minor benefits.
- Moderate Beneficial: Impacts expected to affect local and adjacent areas. The benefits could permanently improve the area’s hydrology, including surface and ground water flows and water quality.
- Major Beneficial: Impacts to water quality anticipated to be widespread; permanent improvements to regional hydrologic patterns, water flows, wetlands, could occur.

In particular, the analysis finds that Action Alternatives would result in Major Beneficial impacts to water resources under Alternatives 2, 3, 4, and 8 (Preferred) at the national scale. Moderate Beneficial impacts to water resources would be expected under Alternatives 6 and 7, with Minor Beneficial impacts under Alternative 5 at the national scale. Alternative 9 is anticipated to be functionally similar to the No Action Alternative and is anticipated to result in Negligible effects on water resources.

On a regional scale, Major Beneficial impacts are anticipated in the Appalachian Basin under Alternatives 2, 3, 4, 7 and 8 (Preferred) and in the Illinois Basin under Alternatives 2, 3, 4, and 8 (Preferred). Moderate Beneficial impacts are anticipated in the Appalachian Basin for Alternatives 5 and 6, in the Illinois Basin for Alternatives 6 and 7, and in the Colorado Plateau, Gulf Coast, and Northern Rocky Mountains and Great Plains regions for Alternatives 2, 3, 4, 6, 7, and 8 (Preferred). Other effects on water resources are anticipated to be Negligible at the regional scale when compared to the No Action Alternative.

4.0.3.2 Biological Resources

To evaluate the impacts of Alternatives on biological resources, OSMRE considers potential changes to the quality and quantity of terrestrial and aquatic habitats occurring in coal-producing areas, vegetative cover for terrestrial systems, and features of flowing and ponded aquatic systems. Impacts on these habitats in turn affect the wildlife communities they support. Coal mining affects: (1) the biological composition, which is the number and proportion of habitat types (e.g., the amount of forest, length of stream habitat); (2) the biological structure, which is the geographical arrangement of the habitat types; and (3) the biological function, which is how these arranged habitat types interact with their respective plant and animal species. Thus, the extent to which the Action Alternatives would impact biological resources is in part dependent upon the extent to which the Action Alternatives would affect coal production. Because the Action Alternatives generally result in minor reductions in the volume of coal anticipated to be mined, and also attempt to reduce adverse impacts to habitats, impacts on biological resources are generally anticipated to be beneficial, although the EIS does not quantify these benefits. Impacts are generally likely to extend beyond the period of active mining (long-term). Specifically, determinations were made using the following analytical categories:

- Negligible: Minimal impacts (adverse or beneficial) anticipated, e.g. short-term effects to a small geographic area, community, or economy, or no effects.
- Minor Beneficial: Benefits to native forest, streamside, and stream habitat could be detectable, but would likely be limited to localized areas. A reduction in infrequent or insignificant disturbances to locally suitable habitat could occur.
- Moderate Beneficial: Benefits to native forest, streamside, and stream habitat could be measureable but limited to local and adjacent areas. A reduction in occasional disturbances to local and adjacent areas could be expected. These reductions in disturbances could benefit the local habitat but would not be expected to affect regional stability. Some beneficial impacts could occur in key habitats, which would help local habitat retain function and maintain viability both locally and in adjacent areas.
- Major Beneficial: Benefits to native forest, streamside, and stream habitat could be measurable and widespread. Reduced frequency of disturbances to habitat could be expected, with benefits to both local and regional systems. These benefits could positively affect rangewide habitat stability. Some impacts could occur in key habitats, and impacts could positively affect the viability of the habitat both locally and throughout its range.

Action Alternatives are generally anticipated to benefit biological resources at the national scale when compared to the No Action Alternative, with Alternatives 2, 3, 4, 7, and 8 (Preferred) providing Moderate Beneficial impacts, and Alternatives 5 and 6 providing Minor Beneficial impacts at a national scale.

Alternative 9 is anticipated to be functionally similar to the No Action Alternative and is anticipated to result in Negligible effects on biological resources.

On a regional scale, and similar to water resources, Major Beneficial impacts are anticipated in the Appalachian Basin and the Illinois Basin under Alternatives 2, 3, 4, and 8 (Preferred). Major Beneficial impacts are also anticipated in the Appalachian Basin under Alternative 5. Moderate Beneficial impacts are anticipated in the Colorado Plateau, Gulf Coast, and Northern Rocky Mountains and Great Plains regions under Alternatives 2, 3, 4, 7, and 8 (Preferred). Moderate Beneficial impacts are also anticipated in the Appalachian Basin and the Illinois Basin under Alternative 7. Other effects on biological resources are anticipated to be Minor Beneficial or Negligible at the regional scale when compared to the No Action Alternative.

4.0.3.3 Air Quality, Greenhouse Gas Emissions, and Climate Change

While, none of the Action Alternatives explicitly targets air quality resources, implementation of the elements of the Action Alternatives (excluding Alternative 9) may have both beneficial and adverse effects on air quality and greenhouse gas emissions. The predominant effect of the rule on air quality and greenhouse gas emissions that is quantified in this EIS is the reduction in carbon dioxide (CO_2) emissions associated with the overall reduction in coal activity due to increased costs of coal production.

Even accounting for increased energy generation from substitute sources (primarily natural gas), the Action Alternatives would generate a net reduction in greenhouse gas emissions over the timeframe of the analysis. The monetary value of this benefit reflects the anticipated effect of marginal reductions in emissions on a wide range of climate-related impacts, such as agricultural productivity, human health, and property damage from flooding. Additionally, the Action Alternatives may increase the terrestrial carbon sequestration potential of the landscape during and post-mining activities due to the reforestation and streamside vegetative corridor requirements of the Action Alternatives (except for Alternative 9), further generating reductions in climate-related damages. On the other hand, the Action Alternatives may also increase the use of equipment and vehicles to haul materials and therefore increase greenhouse gas emissions from these sources.

In contrast to the other categories of environmental and economic impacts evaluated in this analysis, the benefits of reduced greenhouse gas emissions represent worldwide climate-related damages, independent of the geographic source of the emissions. This analysis accordingly considers the magnitude of these benefits, finding that the effects are beneficial across all Action Alternatives (excluding Alternative 9).

4.0.3.4 Topography, Geology, and Soils

The extent to which the Action Alternatives would impact topography, geology, and soils is in part dependent upon the extent to which the Action Alternatives would affect coal production because the process of coal mining necessarily disturbs the topography, geology, and soils of the mine site. Although the EIS does not quantify these benefits, OSMRE anticipates the impacts of the Action Alternatives on topography, geology, and soils to be beneficial because the Action Alternatives generally result in minor reductions in the volume of coal anticipated to be mined, and would indirectly reduce adverse impacts on soils such as erosion and runoff. Impacts are generally likely to extend beyond the period of active mining (long-term). Specifically, determinations were made using the following analytical categories:

- Negligible: Minimal impacts (adverse or beneficial) anticipated, e.g. short-term effects to a small geographic area, community, or economy, or no effects.
- Minor Beneficial: Benefits to soil or geologic features could be detectable, but would be small and localized. Reduced erosion and/or subsidence could occur in localized areas.
- Moderate Beneficial: Benefits to geologic features or soils could be readily apparent and result in improvements to the soil character or local geologic characteristics in local and adjacent areas. Erosion and subsidence impacts could be reduced in local and adjacent areas.
- Major Beneficial: Benefits to geologic features or soils could be readily apparent and result in improvements over a widespread area. Erosion and subsidence impacts could be reduced over a widespread area. Improvements to geologic features or soils could be permanent.

The Action Alternatives are generally anticipated to benefit topography, geology, and soils when compared to the No Action Alternative, with Minor Beneficial impacts anticipated for Alternatives 2, 3, 4, 5, 7, and 8 (Preferred). Alternatives 6 and 9 are anticipated to result in Negligible effects on topography, geology, and soils at a national scale.

On a regional scale, Moderate Beneficial impacts are anticipated in the Appalachian Basin under Alternatives 2, 4, 5, 7, and 8 (Preferred). Impacts in other regions to topography, geology, and soils resources are anticipated to be Minor Beneficial or Negligible at the regional scale when compared to the No Action Alternative.

4.0.3.5 Land Use, Utilities, Infrastructure, Visual Resources, and Noise

Section 4.3.2 considers the potential effects of the Alternatives on land use, utilities, infrastructure, visual resources, and noise. Some impacts of the Alternatives on these resources would be confined to the mining period (short-term), and other impacts would be expected to extend beyond the period of active mining (long-term). A number of impacts on these resources are anticipated to be beneficial (e.g., a reduction in the amount of surface coal mined may decrease the total area of affected land use and reduce adverse impacts on visual resources, infrastructure, and noise). Other impacts are anticipated to be neutral or negligible (e.g., because increased utility prices are expected to be passed through to consumers, impacts to utilities for all Action Alternatives are classified as negligible.) The impact determinations also considered the intensity of the potential impacts from each Action Alternative on each resource. Specifically, determinations were made using the following analytical categories:

- Negligible: Minimal impacts (adverse or beneficial) anticipated, e.g. short-term effects to a small geographic area, community, or economy, or no effects.
- Minor Beneficial: The action could reduce land disturbances in localized areas. The impacts could affect decisions to construct residential, commercial, and agricultural developments. The action could improve public services or utilities, but the impact would be localized and within operational capacities. There could be an improvement in the viewshed that is readily apparent. The action could decrease noise, but its benefit to the soundscape would be localized and unlikely to affect current user activities.
- Moderate Beneficial: The action could reduce land disturbances in local and adjacent areas. The impacts could affect decisions to construct residential, commercial, and agricultural developments in surrounding areas. The action could improve public services or utilities in local and adjacent

areas. Short service interruptions to roadway and railroad traffic could be reduced. There could be an improvement in the viewshed that is readily apparent. The changes would not markedly improve the viewshed, but could enhance current user activities or experiences. The action could decrease noise and the benefit could improve the soundscape in local and adjacent areas. User activities could be enhanced.

- Major Beneficial: The action could reduce land disturbances over widespread areas. The impacts could affect decisions to construct residential, commercial, and agricultural developments in the region. The action could improve public services or utilities over a widespread area resulting in an increase of certain services or necessary utilities. Extensive service disruptions to roadways or railroad traffic could be reduced. There could be improvements to characteristic views of the region, which could enhance current user activities or experiences. The action could decrease noise and improve the soundscape over widespread areas. Noise levels could enhance user activities.

Alternative 2 is anticipated to result in Minor Beneficial results to land use, utilities, infrastructure, visual resources, and noise at the national scale when compared to the No Action Alternative. Other alternatives are anticipated to result in Negligible impacts at the national scale.

At a regional scale, Moderate Beneficial impacts to land use, utilities, infrastructure, visual resources, and noise are anticipated in the Appalachian Basin under Alternative 2, 3, 4, 5, 7, and 8 (Preferred). Other effects on land use, utilities, infrastructure, visual resources, and noise are anticipated to be Minor Beneficial or Negligible at the regional scale when compared to the No Action Alternative.

4.0.3.6 Socioeconomic Conditions

For socioeconomic conditions, OSMRE evaluates impacts of the Action Alternatives on employment and income, tax revenues, property values, quality of life, and demographics. Some impacts of the Alternatives would be short-term on a per-mine basis, and others would extend beyond the period of active mining (long-term). Determinations of the intensity of impacts on socioeconomic resources considered the impacts of the Action Alternatives on employment and income, tax revenues, property values, quality of life, and demographics. Indicators of impacts on quality of life and demographics are likely to be linked to impacts on employment and income in each region and, to a lesser degree, impacts on tax revenues. Specifically, determinations were made using the following analytical categories:

- Negligible: Minimal impacts (adverse or beneficial) anticipated, e.g. short-term effects to a small geographic area, community, or economy, or no effects.
- Minor Adverse or Beneficial: A few individuals, groups, businesses, properties, or institutions could be affected. Impacts would be small and localized. The impacts are not expected to alter social and/or economic conditions.
- Moderate Adverse or Beneficial: Many individuals, groups, businesses, properties, or institutions could be affected. Impacts could be readily apparent and detectable in local and adjacent areas and could have a noticeable effect on social and/or economic conditions.
- Major Adverse or Beneficial: A large proportion of individuals, groups, businesses or other institutions would experience a change in economic or social conditions as an obvious result of an action. Impacts could extend over a widespread area. The effect could have a substantial influence on social and/or economic conditions.

At the national scale, Alternative 2 is anticipated to result in Moderate Adverse impacts on socioeconomic conditions including, in particular, employment and severance taxes when compared to the No Action Alternative. Alternatives 3, 4, 5, 6, 7, and 8 (Preferred) are anticipated to result in Minor Adverse impacts socioeconomic conditions including employment and severance taxes at the national scale. Alternative 9 is anticipated to be functionally similar to the No Action Alternative and is anticipated to result in Negligible effects on socioeconomic conditions.

At a regional scale, Major Adverse impacts on socioeconomic conditions including employment are anticipated in the Appalachian Basin under Alternative 2. Moderate Adverse impacts on socioeconomic conditions are anticipated in the Appalachian Basin under Alternatives 3, 4, 5, 7, and 8 (Preferred). Impacts in other regions to socioeconomic conditions are anticipated to be Minor Adverse or Negligible across alternatives at the regional scale when compared to the No Action Alternative.

4.0.3.7 Public Health and Safety

The public health and safety section focuses on understanding how the Alternatives may affect public health and safety. In particular, impacts of the Alternatives may affect water quality and air-quality, which has the potential to result in subsequent effects on public health conditions. Because the Action Alternatives generally result in minor reductions in the volume of coal anticipated to be mined, and therefore reduced effects on water and air resources, impacts on public health conditions are generally anticipated to be beneficial, although the EIS does not attempt to quantify public health benefits. Impacts are generally likely extend beyond the period of active mining (long-term). Intensity determinations were made using the following analytical categories:

- <u>Negligible</u>: Minimal impacts (adverse or beneficial) anticipated, e.g. short-term effects to a small geographic area, community, or economy, or no effects.
- <u>Minor Beneficial</u>: The action could reduce 1) soil, groundwater, and/or surface water contamination; 2) exposure of contaminated media as occupational hazard; and/or 3) mobilization and migration of pollutants currently in the soil, ground water, or surface water in localized areas. These impacts to water quality are anticipated to be good indicators of the intensity of impacts to public health.
- <u>Moderate Beneficial</u>: The action could reduce 1) soil, groundwater, and/or surface water contamination; 2) exposure of contaminated media as occupational hazard; and/or 3) mobilization and migration of pollutants currently in the soil, ground water, or surface water in localized and adjacent areas. These impacts to water quality are anticipated to be good indicators of the intensity of impacts to public health.
- <u>Major Beneficial</u>: The action could reduce 1) soil, groundwater, and/or surface water contamination; 2) exposure of contaminated media as occupational hazard; and/or 3) mobilization and migration of pollutants currently in the soil, ground water, or surface water over widespread areas. These impacts to water quality are anticipated to be good indicators of the intensity of impacts to public health.

At the national scale, Alternatives 2, 3, 4, and 8 (Preferred) are anticipated to result in Major Beneficial impacts to public health and safety when compared to the No Action Alternative. Alternatives 6 and 7 are anticipated to result in Moderate Beneficial impacts to public health and safety. Alternative 5 is anticipated to result in Minor Beneficial impacts to public health and safety at the national scale.

Alternative 9 is anticipated to be functionally similar to the No Action Alternative and is anticipated to result in Negligible effects on public health and safety.

At a regional scale, Major Beneficial impacts are anticipated in the Appalachian Basin and Illinois Basin regions under Alternatives 2, 3, 4, and 8 (Preferred). Major Beneficial impacts are also anticipated in the Appalachian Basin under Alternative 7. Moderate Beneficial impacts are expected in the Colorado Plateau, Gulf Coast, and Northern Rocky Mountains and Great Plains regions under Alternatives 2, 3, 4, 6, 7, and 8 (Preferred). Moderate Beneficial impacts are also anticipated in the Appalachian Basin for Alternatives 5 and 6, and in the Illinois Basin for Alternatives 6 and 7. Impacts in other regions to public health and safety are anticipated to be Minor Beneficial or Negligible at the regional scale when compared to the No Action Alternative.

4.0.3.8 Archaeology, Paleontology, and Cultural Resources

Nationally, all Alternatives are expected to have Negligible impacts on Archaeology, Paleontology, and Cultural Resources. At a regional level, Negligible impacts are expected in all regions under all Alternatives. To the extent that any particular rule element reduces the extent of ground disturbance associated with mining, it would also reduce the disturbance of cultural resources located within that area. Therefore, cultural resources may benefit from some or all of the rule elements.

4.0.3.9 Recreation

The recreation section focuses on understanding potential impacts of the Action Alternatives on land- and water-based recreational opportunities within each of the seven coal regions. These recreational activities include hunting, wildlife viewing, trail use, boating, and fishing, and occur on both public and private lands within the study area. Because the Action Alternatives generally result in minor reductions in the volume of coal anticipated to be mined, impacts are generally anticipated to be beneficial, although the EIS does not attempt to quantify recreational benefits. Impacts are generally likely extend beyond the period of active mining (long-term). Intensity determinations were made by assuming a connection between recreational impacts and the extent of predicted benefits to water resources and terrestrial area vegetation from Action Alternatives using the following analytical categories:

- Negligible: Minimal impacts (adverse or beneficial) anticipated, e.g. short-term effects to a small geographic area, community, or economy, or no effects.
- Minor Beneficial: The action could improve local recreational opportunities but would affect relatively few users.
- Moderate Beneficial: The action could improve many recreational activities locally and in adjacent areas and could affect many users.
- Major Beneficial: The action could improve most recreational activities over a widespread area. Users could choose to pursue additional recreational activities in this area.

At the national scale, Alternative 2 is anticipated to result in Moderate Beneficial impacts to recreational activities when compared to the No Action Alternative. Alternatives 3, 4, 5, 6, 7, and 8 (Preferred) are anticipated to result in Minor Beneficial impacts to recreation. Alternative 9 is anticipated to be functionally similar to the No Action Alternative and is anticipated to result in Negligible effects on recreational activities.

At a regional scale, Major Beneficial impacts are anticipated in the Appalachian Basin under Alternative 2. Moderate Beneficial impacts are anticipated in the Appalachian Basin region under Alternatives 3, 4, 5, 7, and 8 (Preferred) and in the Colorado Plateau region under Alternatives 2, 3, 4, 7, and 8 (Preferred). Impacts in other regions to recreational activities are anticipated to be Minor Beneficial or Negligible at the regional scale when compared to the No Action Alternative.

4.0.3.10 Environmental Justice

Environmental justice communities are those that meet the defined environmental justice criteria for minority, low-income, and American Indian populations. The environmental justice evaluation discusses the potential impacts of the Action Alternatives on these populations, including impacts on socioeconomic resources, public health and safety, biological resources, water resources, air quality, topography, land use, and recreation.

The affected area for this analysis is large and spans a variety of demographic conditions. In total, the affected area intersects with 286 counties in 24 states. The analysis was conducted at a county level to determine if any of the 286 counties contain populations that meet environmental justice criteria. Indian tribes are considered as a distinct category in the minority population environmental justice analysis.

Under the No Action Alternative, no further regulations or corrective measures in addition to those already in place would be implemented. Therefore, ongoing trends in the evaluated resources would continue. The annual quantity of coal demanded and associated production is anticipated to be approximately 10 percent lower in 2040 than in 2020, even without implementation of the Alternatives (i.e., under the No Action Alternative).

Of the 286 counties in the study area, there are 190 counties that have populations that meet the previously specified low income and/or the minority population environmental justice thresholds. Of these 190 counties, 60 percent of them are in the Appalachian Basin. Of those counties in the Appalachian Basin, four have been identified as minority communities, 103 as low income communities, and nine as both low income and minority environmental justice communities.

Mining occurs in close proximity to or on a number of tribal reservations. The Northern Cheyenne Indian Reservation is situated in both Big Horn and Rosebud Counties in Montana where five active surface mines exist. In addition, the Crow Indian Reservation covers nearly 65 percent of Big Horn County. San Juan County overlaps both the Navajo Nation Reservation and the Ute Mountain Reservation where one active surface mine and one active underground mine exist. The Zuni Reservation is located primarily in McKinley County where two active surface mines exist. McKinley County also overlaps with the Navajo Nation Reservation. Navajo County in Arizona is comprised of the Navajo Nation Reservation, the Fort Apache Reservation, and the Hopi Reservation where one active surface mine exists.

Of particular note are mines located on (not just near) tribal land. For example, the Navajo Mine and the Kayenta Mine are operated on the Navajo Nation lands and produce about 15 million tons of coal annually (U.S. EIA, 2012c). An additional coal mine, the Absaloka Mine, is located on the Crow Reservation in Montana.

Table 4.0-2. Summary of Impacts in the Appalachian Basin Region by Alternative, Relative to the No Action Alternative

Resources	Alternative 2	Alternative 3	Alternative 4	Alternative 5	Alternative 6	Alternative 7	Alternative 8 (Preferred)	Alternative 9
Air Quality, Greenhouse Gas Emissions, and Climate Change[1]	Beneficial	Beneficial	Beneficial	Beneficial	Beneficial	Beneficial	Beneficial	Negligible
Biological Resources	Major Beneficial	Major Beneficial	Major Beneficial	Major Beneficial	Minor Beneficial	Moderate Beneficial	Major Beneficial	Negligible

[1] The benefits of reduced greenhouse gas emissions represent worldwide climate-related damages, independent of the geographic source of the emissions. Alternative 9 is not anticipated to have measurable impacts over and above the No Action Alternative and is considered Negligible.

Tables 4.0-9 through 4.0-16 compare the impacts of each Action Alternative across coal regions. Under Alternatives 2 through 9, for seven of the eight resource categories considered, every coal region experiences a Beneficial or Negligible impact. Adverse impacts are anticipated only for socioeconomic resources, where production decreases may trigger job losses. This effect is most pronounced in the Appalachian Basin under Alternative 2, where production decreases are predicted to be the greatest.

[1] The benefits of reduced greenhouse gas emissions represent worldwide climate-related damages, independent of the geographic source of the emissions. Refer to Section 4.2.4 for monetized estimates of GHG impacts by Alternative.

4.0.4 Limitations and Uncertainties

Two primary limitations and uncertainties are present in this analysis. First, this FEIS relies on five inter-related models to evaluate the impacts of the Action Alternatives on coal demand, supply, and prices. Employing detailed information on a multitude of factors that affect coal production and consumption, these models simulate how changes in market conditions may cascade through different parts of the coal market, affecting both coal supply and quantity of coal demanded. Detailed assumptions and findings are presented in the RIA for the proposed action. Second, the study uses a model mine approach to determine the regional effects of the Action Alternatives. The fidelity of these model mines to the average regional mine characteristics determines the accuracy of the analysis. These key uncertainties and limitations and how they are addressed in this analysis are presented in Table 4.0-18. Resource-specific limitations and uncertainties are addressed in the appropriate resource-specific sections. Despite efforts to address heterogeneity in the effects of the SPR on various mine types, multiple baselines, and sensitivity analyses, significant sources of uncertainty remain given the numerous input assumptions in the engineering, market, and water quality analyses conducted for this FEIS.

Table 4.0-18. Summary of Key Uncertainties and Limitations

Limitation and Uncertainty	Explanation
Forecasts of Coal Supply and Coal Demand	Future coal supply and demand are not known with certainty. Numerous factors affect coal supply and demand, including electricity demand growth; installed generating capacity; relative prices of alternative fuel sources; U.S. coal exports; other coal demand from the domestic metallurgical and industrial markets; and existing and proposed environmental rules. The coal market has been volatile in the most recent years, and several major environmental regulations are being developed simultaneously with these Alternatives. The coal market modeling conducted for this analysis takes these factors into consideration, documents key assumptions, and compares OSMRE's coal market forecast to other market forecasts. The coal market modeling has been updated to reflect 2016 conditions wherever possible from the 2015 DEIS.
Model Mine Approach	OSMRE developed a detailed description of each element of the rule, and conducted an engineering analysis of the expected impacts of the rule on mine operations. To capture the heterogeneity of the coal industry, the analysis employs 13 model mines across the U.S. Throughout the analysis, qualified mining engineers used their best judgment to develop the most appropriate cost assumptions for each model mine. Recognizing that assumptions in the engineering analysis are important to the overall results of the FEIS, a number of sensitivity analyses were conducted related to specific assumptions. These sensitivity analyses are described in RIA Appendix B, Part 6. Tested assumptions included assumptions related to hourly equipment costs for haulage costs, spoil handling percentage of overburden in haulage costs, per acre costs of reforestation in streamside vegetation corridors, production levels and stripping ratios. This approach strives to capture the overall scope and scale of potential changes under each Alternative, but is not likely to be accurate for any specific mining operation.

4.1 Mineral Resources and Mining

Chapter 3 describes general characteristics of mineral resources and mining. This section of Chapter 4 analyzes how mineral resources and mining are affected by the No Action Alternative and by the Action Alternatives under consideration for the SPR.

This section:

- Provides an overview of the current and forecasted coal industry, which forms the baseline for analysis of the No Action Alternative in the study period from 2020 to 2040;
- Presents the model mines approach used to analyze effects of Alternatives 2 through 9 relative to the No Action Alternative; and
- Presents forecasted changes in the distribution of industry compliance costs and overall coal production during the study period.

Subsequent sections present impacts of each Alternative on natural resources and socioeconomic conditions.

4.1.1 Effects of the Current Regulatory Environment (the No Action Alternative)

This section summarizes the conditions of the coal mining industry and market under the No action Alternative, including regional distribution of coal production, the quantity of coal produced by method of coal mining, and the coal industry market structure.

In 2015, 25 states reported coal mine production to MSHA (MSHA, 2015). OSMRE classifies coal-producing areas into regions, seven of which produced coal in 2015.

These regions are described below, and organized from largest volume of production to least production in 2015:

- **Northern Rocky Mountain and Great Plains** (including the Powder River Basin): Wyoming, Montana, Eastern Colorado, North Dakota, South Dakota[7]
- **Appalachian Basin**: West Virginia, Eastern Kentucky, Pennsylvania, Ohio, Virginia, Alabama, Tennessee, Maryland
- **Illinois Basin**: Illinois, Indiana, Western Kentucky
- **Colorado Plateau**: Western Colorado, New Mexico, Utah, Arizona
- **Gulf Coast**: Texas, Mississippi, Louisiana
- **Northwest**: Alaska, Washington[8]
- **Western Interior**: Oklahoma, Missouri, Kansas, Arkansas.

4.1.1.1 Overview of Current Coal Market Conditions

This section provides an overview of current coal market conditions. Additional information historical and current coal market conditions are provided in Chapter 3. Total U.S. coal production has fluctuated somewhat over time, with production from particular regions varying to a greater degree. Total U.S. coal production was 893 million tons in 2015, which was 17.5 percent less than production in 2010 (MSHA, 2015). Since the late 1990's, the two largest coal production regions in the U.S. have been the Northern Rocky Mountain and Great Plains, and the Appalachian Basin regions. In 2015, these two regions together accounted for approximately 75 percent of domestic coal production.

As shown in Figure 4.1-1, coal production tonnage and production tonnage by mine type varies across the regions. All regions have surface mining operations, but not all regions have underground mines. The Gulf Coast and the Northwest have no underground mines. Over the past 14 years, coincident with full development of the Powder River Basin, the mining industry has become dominated by surface mining. The Powder River Basin, which is part of the Northern Rocky Mountain and Great Plains Region, produces coal primarily from surface mines. Overall, surface coal mining comprised 66 percent of U.S.

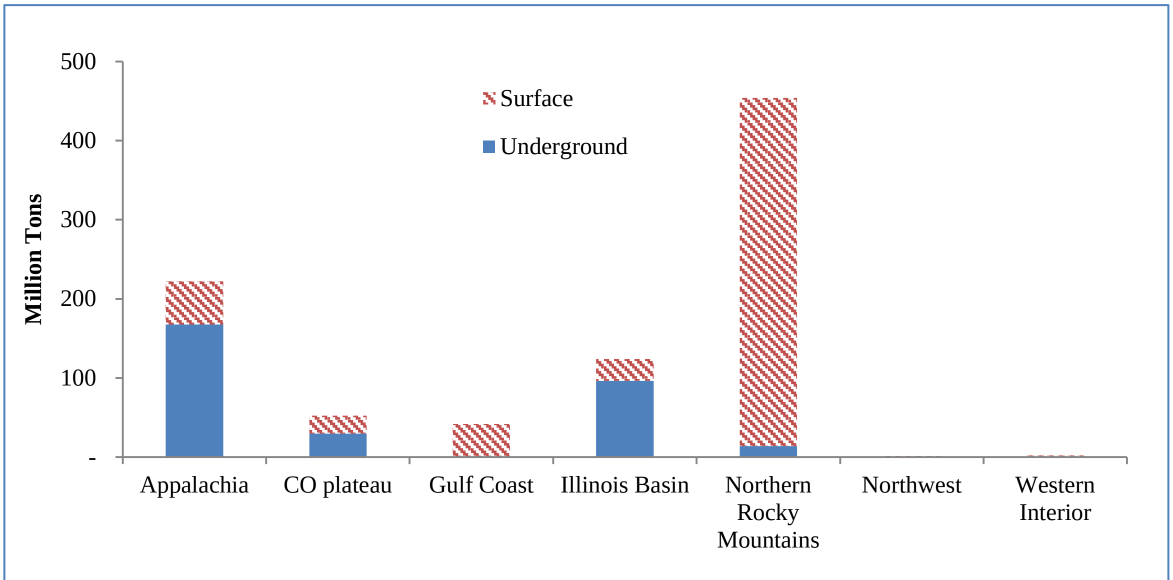
---

[7] South Dakota is included in the Northern Rocky Mountain and Great Plains region but did not produce any coal in 2015.

[8] Washington is included in the Northwest region but did not produce any coal in 2015.

coal production by volume in 2015 (MSHA, 2015). As presented in Figure 4.1-1, coal production volume and production volume by mine type varies across the regions.

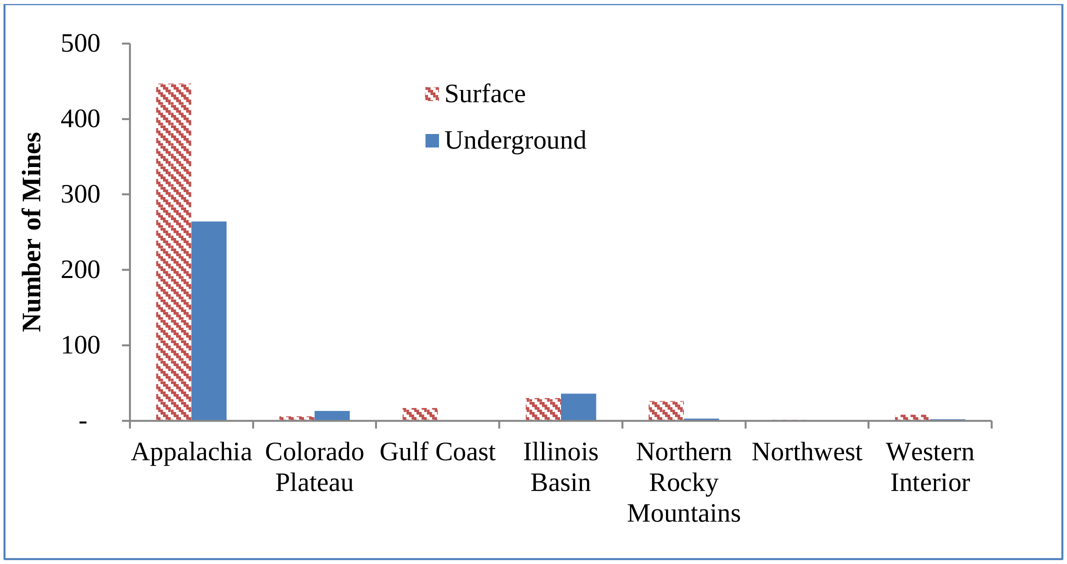
Figure 4.1-1. Coal Production by Mine Type by Region, Million Tons (2015)



Source: MSHA. 2015. MSHA Annual Coal Production Data 2015. Provided by OSMRE April 12, 2016.

In 2015, over 850 mines reported coal production to the Mine Safety and Health Administration (MSHA, 2015). Although the mines in Appalachia have relatively small average production levels compared to mines in other regions, the largest number of mines are found in that region, as shown in Figure 4.1-2 (MSHA, 2015). In fact, of the 853 producing surface mines and underground mines operating in 2015, over 700 were located in Appalachia. In contrast, the Northwest Region had only one producing mine in 2015.

Figure 4.1-2. Number of Coal Mines by Region, 2015



Source: MSHA. 2015. MSHA Annual Coal Production Data 2015.

4.1.1.1.1 Natural Gas

The supply of natural gas in the U.S. has increased significantly in the past five years due to production of shale gas. The growth in supply exceeded the growth in demand. As a result, the price of gas fell during this period as the only market that could absorb the additional supply was the power market, which had under-utilized capacity. The price for natural gas fell to the levels necessary for gas-fired combined cycle generating capacity to dispatch ahead of coal-fired generation. Natural gas accounted for 23 percent of power generation in 2010 and 32 percent in 2015.

4.1.1.1.2 Renewables, Energy Efficiency, Distributed Generation and Electricity Demand Growth

Electricity demand growth in the U.S. historically was driven by economic and industrial activity, and weather. This has changed. There has effectively been no growth in electricity demand since 2007. This is due to a number of factors including a decline in industrial electricity demand, which was largely offset by growth in demand from the residential and commercial sectors. Also significant is lower demand due to energy efficiency and distributed generation. Energy efficiency means using less energy to provide the same service. The most often used examples are fluorescent lighting instead of traditional incandescent bulbs. Distributed generation is small-scale technologies that produce electricity close to the end users of power. The technologies including modular and renewable-energy generators, such as roof-top solar, that are often behind the meter meaning they are not counted as retail sales. In addition, in many states the excess behind the meter power is sold into the grid.

In addition, there has been substantial growth in renewables, particularly wind in the western U.S. Between 2010 and 2015, 33 GWs of wind have been added to capacity. Electricity generation from wind increased from 94,654 GWH in 2010 to 190,926 GWH in 2015. The Production Tax Credits (PTC) incentivize wind producers to generate around the clock (when wind is available). As a result, wind power contributes to lower power prices as well. The PTC was extended in December 2015 until 2019 along with the Business Energy Tax Credit (ITC), which applies to construction and development of renewable technologies (U.S. Energy Department 2016a; U.S. Energy Department 2016b).

The net effect of low electricity demand growth is a diminished market for coal as hydropower, nuclear, and renewables regularly dispatch ahead of coal. The price of natural gas determines whether it dispatches ahead of coal. With a pie the same size, there is less left over for coal.

4.1.1.1.3 Demand for U.S. Coal

The largest market for U.S. coal has been the power sector, typically accounting for 80 to 90 percent of total production in recent years (U.S. EIA 2016f; U.S. EIA 2016g). The increase in gas and renewable generation directly reduced coal generation and the resulting demand for coal. Coal consumed in the power sector was 955 million tons in 2010 and 769 million tons in 2015 (U.S. EIA, 2016h). Estimates for coal consumed in the power sector for 2016 range between 650 and 700 million tons (U.S. EIA, 2016h). In addition, during the period 2010 through 2015, 45.5 GW of coal-fired capacity was retired (EVA, 2016).

The second largest market for U.S. coal has been exports. The export market has been cyclical, depending upon both the global supply and demand for coal and the relative strength of the U.S. dollar. During the 2011 to 2013 period, there was a substantial increase with U.S. coal exports exceeding 100 million tons in each of those years. The strong demand reflected growth in seaborne coal trade combined with a weak U.S. dollar which made U.S. coals competitive in the U.S. dollar-denominated global coal market. The positive outlook for exports of U.S. coals in 2011 and 2012 has faded due to several factors including supply growth from other countries to the global market, a relatively strong U.S. dollar which has reduced global coal prices, a weaker global market due to a slowdown in the Chinese economy, and the lack of progress in the development of west coast export terminals which would be required to increase in a meaningful way exports of western coal to Asian markets. The positive outlook could be restored if the U.S. dollar weakens relative to other currencies or there is reduced supply and/or increased demand in the global seaborne market for coal. The range in potential export levels is handled through the scenario analysis.

4.1.1.1.4 Coal Supply

As a result of the decline in demand for U.S. coals, the coal industry has reduced production. Production fell from 1.1 billion tons in 2010 to 0.9 billion tons in 2015 (Table 4.1-1). Based upon H1 2016 actual production to date, production in 2016 appears likely to be less than 0.8 billion tons.

With supply exceeding demand in most regions, prices fell through mid-2016, as shown in Exhibit 2-16. Prices strengthened over the summer of 2016 as a result of a warm summer which increased gas prices and coal burn. The increase also reflects curtailments in production (either through schedule changes or idling) were greater than underlying demand changes. The coal prices used in this analysis are based upon equilibrium coal prices consistent with the demand forecast.

During the difficult periods in 2015 and 2016, a significant portion of the industry filed for bankruptcy. All but one of the larger companies in bankruptcy has emerged from bankruptcy. Two of the five major supply regions (i.e., Central Appalachia and the Powder River Basin) have been affected the most as a result of declining demand.

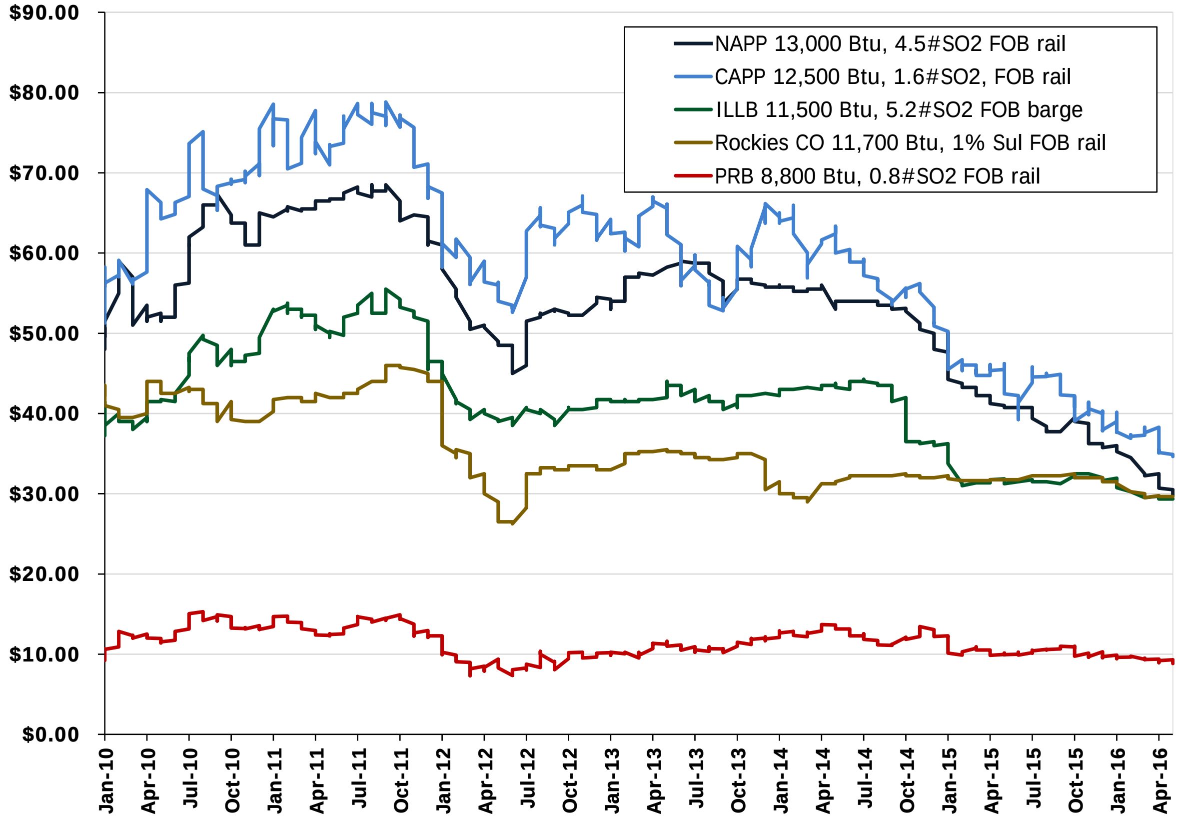
Table 4.1-1. Coal Production by Supply Region, 2010 and 2015

Region	Production (Million Tons) 2010	Production (Million Tons) 2015	Change from 2010 to 2015 MM Tons	Change from 2010 to 2015 Percent
Central Appalachia	129	116	(13)	-10%
Northern Appalachia	184	89	(95)	-52%
Southern Appalachia	20	15	(5)	-25%
Appalachia Total	333	220	(114)	-34%
Illinois Basin	105	131	26	25%
East Total	483	351	(133)	-27%
Powder River Basin	468	392	(76)	-16%
Rockies	71	62	(9)	-13%
Lignite	79	66	(13)	-16%
Southwest	21	19	(1)	-6%
Interior	2	2	(0)	-6%
West Total	640	540	(100)	-16%
U.S. Total	**1083**	**893**	**(190)**	**-18%**

Source: MSHA 2015 and Energy Ventures Analysis (EVA), 2016.

Coal production in Central Appalachia, which consists of coal production from Southern West Virginia, East Kentucky, Virginia and Tennessee, has fallen the most. Production was 184 million tons in 2010 and 88 million tons in 2015. Based upon first half 2016 production levels, 2016 production is expected to be well under 80 million tons. The reasons for the disproportionate bankruptcy impact are as follows. First, this region has been mined long and hard for decades. The geology of the remaining reserves has deteriorated from a mining perspective (i.e., higher ratios for surface mines and thinner, below-drainage seams for underground mines) resulting in higher costs compared to other coal supply regions. Second, the demand for lower sulfur steam coals has declined disproportionately with (1) the retrofit of scrubbers on power plants historically supplied by these coals and (2) plant retirements. Third, a significant amount of Central Appalachia coal production capacity was purchased at inflated prices due to the coal market spikes in 2009 and 2011. The buyers were burdened with high debt service significantly adding to their costs of production. The reorganizations allowed for a financial restructuring of their obligations.

Figure 4.1-3. Historical Coal Prices (Nominal $/ton)



Source: EVA Analysis, 2016.

4.1.1.2 Overview of the Forecasted Coal Market Conditions

The demand for coal from a given region will be influenced by numerous exogenous factors (i.e., factors unrelated to this rulemaking), including:

- Electricity demand growth;
- Installed generating capacity;
- Relative prices of alternative fuel sources;
- U.S. coal exports;
- Other coal demand from the domestic metallurgical and industrial markets; and
- Existing and proposed environmental rules.

Each factor is discussed below.

4.1.1.3 Electricity Demand Growth

According to U.S. Energy Information Administration's (EIA) *Annual Energy Outlook (AEO) 2016*, U.S. electricity energy demand is expected to grow at a 0.9 percent annual rate from 2015 to 2040 (U.S. EIA, 2016e). In 2015, coal was the source of approximately 33 percent of all electricity produced in the U.S. (U.S. EIA, 2016d). The first time in over a half century that coal's market share fell below 40 percent was in 2012, where it has held since. The primary reasons for the low level of coal-fired power generation has been the dramatic decline in natural gas prices during this period, giving natural gas-fired combined cycle power plants a cost advantage over coal-fired power plants in many parts of the country, along with environmental requirements and other market factors, as discussed below.

Because domestic power plants typically account for between 80 and 90 percent of the coal consumed in the U.S. (U.S. EIA 2016f; U.S. EIA 2016g), even small changes in the electricity market can influence both short and long-term demand for domestic coal. Thus, an accurate forecast of coal-fired electricity generation is critical to specification of baseline coal demand. The forecast of coal-fired electricity generation used in this EIS under the No Action Alternative is a function of electricity demand growth, the coal-fired generating capacity available to meet demand, environmental regulations that affect the dispatch of coal-fired power plants, natural gas prices, and generation from nuclear and renewables. The electricity demand growth forecast is derived from expectations for economic growth combined with the outlook for each sector. The forecast assumes continued but slower growth in demand in the residential and commercial sectors as a result of new lighting standards and improvements to energy efficiency in consumer electronics. After a modest rebound in industrial electricity demand, the forecast assumes slow growth for the remainder of the forecast period. The forecast electricity growth is anticipated to vary annually, with average changes ranging from an increase of 0.46 in 2021-2025 to 0.72 in 2036-2040 under the No Action Alternative.

4.1.1.4 Natural Gas Supply

The supply of natural gas in the U.S. has increased significantly due to production of shale gas. The growth in supply exceeded the growth in demand. As a result, the price of gas fell (Table 4.1-2) during this period as the only market which could absorb the additional supply was the power market which had under-utilized capacity. The price for natural gas fell to the levels necessary for gas-fired combined cycle generating capacity to dispatch ahead of coal-fired generation. Natural gas accounted for 23 percent of power generation in 2010 and 32 percent in 2015.

Table 4.1-2. Natural Gas Prices at Henry Hub Reference Case ($2016/MMBTU)

2016	2020	2025	2030	2035	2040
$2.16	$4.05	$4.56	$5.06	$5.72	$6.43

Source: EVA Analysis, 2016.

4.1.1.5 U.S. Coal Exports

In 2015, international demand for U.S. coal, primarily metallurgical coal, represents approximately ten percent of total U.S. production (EVA, 2016). The U.S. has the potential to significantly increase its coal exports. Across the industry, the export market shows some signs of expansion, as detailed in *AEO 2012, 2013,* and *2016*. A number of coal terminals have been proposed for the Pacific Northwest. These terminals are in the process of obtaining the necessary permits, which may or may not be granted. In 2015, total exports of coal exceeded 75 million tons, with projections for further growth to 94 million tons by 2040 (U.S. EIA, 2016e). Potential growth in exports is possible with a weaker U.S. dollar and additional terminal capacity.

The two largest determinants of U.S. coal exports are the global supply/demand balance for the seaborne market and the relative strength of the U.S. dollar, particularly against the Australian dollar. The base long-term forecast, which is based upon a moderation of the exchange rate differences between the U.S. and Australian dollars, assumes U.S. coal exports regain some strength through the forecast period. Exports in the reference base case, however, are not expected to move back to the levels achieved earlier in this decade. Therefore, an unexpected event, such as flooding in Queensland or a material weakening of the U.S. dollar, could change this outlook. Additional detail regarding modeling assumptions are provided in Chapter 5 and Appendix F of the Final RIA for the SPR.

4.1.1.6 Other Domestic Markets for Coal

Industries, such as steel, iron, and cement manufacture, rely on coal for energy. Thus, fluctuations in these markets can also cause changes in coal demand. Steel and iron production relies on metallurgical coal, which is relatively high-energy, low-sulfur, and low-ash coal and is primarily mined in the Appalachian and Illinois Basins. This coal is used for coking purposes or in direct coal injection into blast furnaces.

Although much smaller than the utility market, the domestic metallurgical and industrial/other coal markets are significant sources of U.S. coal demand. Domestic metallurgical coal demand is tied to coke oven capacity which is expected to decline over the forecast period as retirements of existing ovens exceed additions of new ones. The industrial/other market is expected to decline over the forecast period due to fuel switching and lost demand. The industrial/other and domestic metallurgical coal forecasts are assumed to be fixed in this analysis.

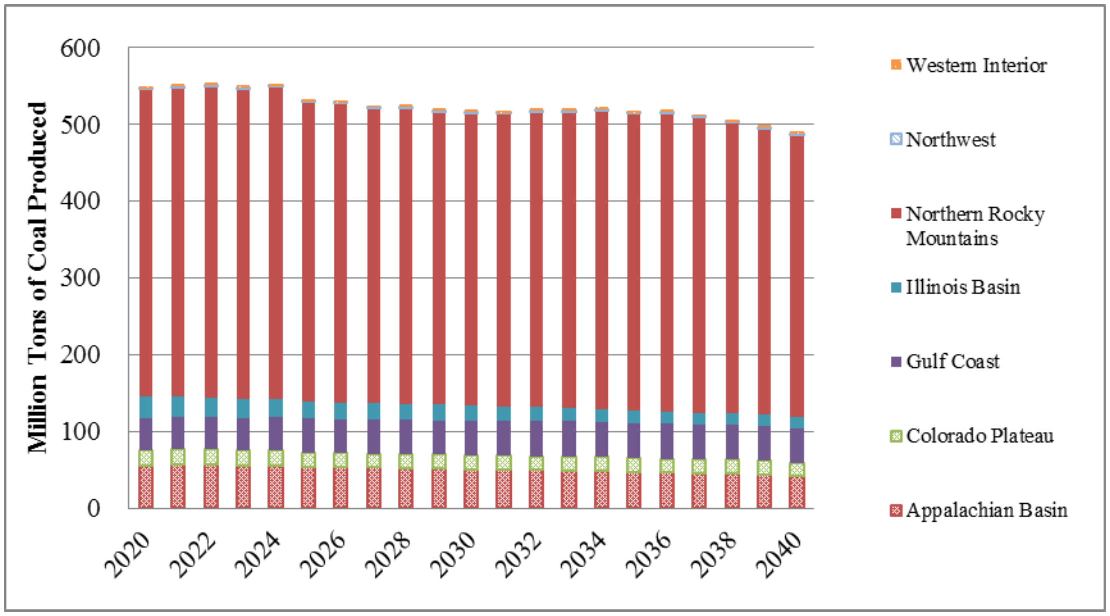
4.1.1.7 Existing and Proposed Environmental Regulations

Environmental regulations can also affect coal demand. Important to this discussion are regulations that affect water discharges under the clean water act, as well as regulations that affect coal combustion at coal fired power plants.

4.1.1.8 Forecasted Coal Production Under the No Action Alternative

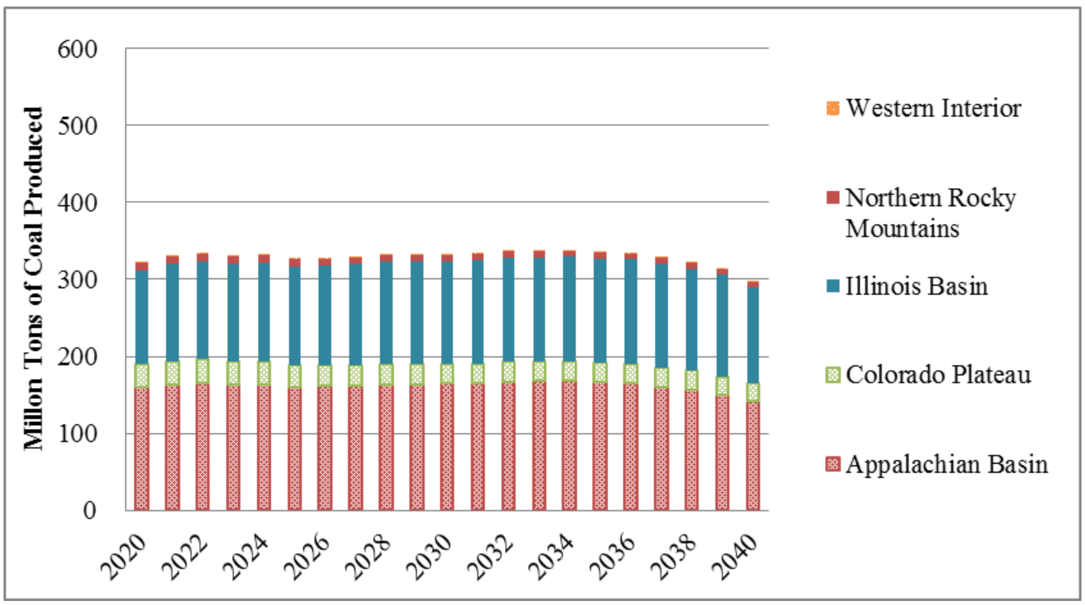
The coal mining industry is expected to continue to change, even under the No Action Alternative (i.e., absent the SPR). These changes will be driven by market conditions and the characteristics of remaining coal reserves. Over the study period of 2020 to 2040, the No Action Alternative as reflected by the baseline analysis conducted as part of the RIA anticipates a general decline in annual total surface and underground production of approximately 10 percent (84 million tons). Figures 4.1-4 and 4.1-5 summarize the projected changes in production for surface and underground mining by region.

Figure 4.1-4. Forecasted Surface Coal Production by Region under the No Action Alternative, Millions of Tons Produced, 2020 to 2040



Source: Energy Ventures Analysis (EVA) analysis, Primary Base Case 2016.

Figure 4.1-4. Forecasted Underground Coal Production under the No Action Alternative by Region, 2020 to 2040



Source: EVA analysis, Primary Base Case, 2016.

Under the No Action Alternative, declines in surface coal production are anticipated in nearly all coal regions between 2020 and 2040, with annual production falling from 550 million tons to 491 million tons over the time period. Most of the drop in total surface production (54 percent) is anticipated in the

Northern Rocky Mountains and Great Plains region where a decline of over 30 million tons in annual production between 2020 and 2040 is expected. The steepest declines in terms of the percent of regional production are expected in the Illinois Basin and Appalachian Basin regions, where declines of 52 percent and 23 percent of regional production, respectively, are anticipated between 2020 and 2040.

As with surface mining, declines in underground production are expected in nearly all coal regions between 2020 and 2040, with annual production falling from 323 million tons to 298 million tons over the study period (a reduction of 25 million tons in annual production). In the near term, however, underground production is expected to grow temporarily because of the addition of several new longwall mines, peaking in 2024. Most of the drop in total underground production (73 percent) is anticipated in the Appalachian Basin region, where a decline of approximately 18 million tons between 2020 and 2040 is expected. The steepest declines in terms of the percent of regional production are expected in the Northern Rocky Mountains and Great Plains and Colorado Plateau regions, where declines of 24 and 23 percent of regional production, respectively, are anticipated between 2020 and 2040.

4.1.2 Model Mine Approach to Understanding Coal Industry Impacts

This section provides an overview of the model mines approach used to analyze industry and environmental conditions under the various Alternatives. Coal mining operations vary substantially from region to region, within a region, and even within a mining type in a given region. Thus, OSMRE employs a model mines analysis to determine the likely changes that would be made by mine operators in response to the Action Alternatives.

The analysis in this FEIS uses a model mine approach to examine the impacts of elements under each Action Alternative. The goal of the analysis is to design mines representative of the operations located in each region and to identify and quantify the effects of each Action Alternative on mining operations. This analysis is not an evaluation of individual mining operations, which vary in practice due to factors such as topography, geology, and hydrology. Instead, the analysis approximates changes expected to occur in a region as a result of each of the Action Alternatives.

The model mines were created after evaluating the overall distribution of coal production by location, mine type, and controlling company. Each of the seven major coal-producing regions is evaluated to determine the type and size of mining operations that are representative of those providing the majority of production for the region.[9] Using this information, specific model mines that capture the regional characteristics were developed.[10] Future production trends were taken into account, most notably in the Illinois Basin, where increases in longwall mining production are anticipated. Overall, 13 model mines

[9] Because the Western Interior region shares features with the Illinois Basin, the Illinois Basin surface model mine was applied to the Western Interior region. Similarly, the model developed for Colorado Plateau underground longwall mines was also used to evaluate impacts to the Northern Rocky Mountains and Great Plains underground mining activities. The analysis did not define a model mine specific to address anthracite mines due to its small contribution of this industry to the current level of U.S. coal production, the small average size of the anthracite mines, and the very site specific/proprietary mining methods used in anthracite mining, which make doing a model mine analysis problematic. However, we recognize that the impacts of the SPR on these mines may result in somewhat different impacts to these operations than other mining operations in the Northern Appalachian region.

[10] Alaska's only operating mine is taken to be representative of coal production in Alaska.

were developed, which together represent over 90 percent of coal mining production nationwide. Table 4.1-3 shows the location, mining type, and typical annual production for each model mine.

After considering the locations, sizes, and mining methods for the 13 model mines, permit data on topography, geology, and stream characteristics are used to establish a realistic physical setting for each model mine. Surface topography from the USGS Seamless Server, GIS analysis, and AutoCAD software are used to develop contours, delineate watersheds and streams, and insert coal seams. Based upon the geology, topography, and mine size, a mineral removal boundary is created for each model mine. For more details on this analysis, please refer to Appendix B of the SPR RIA.

Recognizing that assumptions in the engineering analysis are important to the overall projected impact results, a number of sensitivity analyses were conducted related to specific assumptions. These sensitivity analyses are described in SPR RIA Appendix B, Part 6. Tested assumptions included assumptions related to hourly equipment costs for haulage costs, spoil handling percentage of overburden in haulage costs, per acre costs of reforestation in riparian zones, production levels and stripping ratios.

After designing the location and characteristics of each model mine, the effects of each Action Alternative relative to the No Action Alternative were assessed. This analysis is referred to throughout this document as the "model mines" or "engineering" analysis.

Table 4.1-3. Model Mine Analysis, Type and Estimated Annual Production

Region	Mine Type	Annual Production (Million tons)	Life of mine (years)	Total production over life of mine (million tons)	Disturbed Area (acres)
Appalachian Basin	CAPP Surface - Area	2.3	16.1	37	1,260
	CAPP Surface - Contour	0.5	10.0	5.0	448
	CAPP Underground (Room and Pillar)[1]	0.3	8.0	1.6	205
	NAPP Surface – Contour	0.2	12.0	3.0	12
	NAPP Underground (Longwall) [1]	4.6	15.1	69	145
Colorado Plateau	Surface – Area	3.3	27.9	92	3,311
	Underground (Longwall)[1]	3.0	6.8	20	44
Gulf Coast	Surface – Area	3.3	12.3	41	1,988
Illinois Basin	Surface – Area	1.0	12.4	12.4	1,067
	Underground (Room and Pillar) [1]	2.1	9.1	19.1	45
	Underground (Longwall) [1]	6.0	17.7	110	134
Northern Rocky Mountain and Great Plains[2]	Surface – Area	27.2	38.8	1,100	6,049
	Underground (Longwall)[1]	3.0	6.8	20	44
Northwest	Surface – Area	2.0	18.5	37	497
Western Interior[3]	Surface – Area	1.0	12.4	12	1,067
	Underground (Room and Pillar)	2.1	9.1	19	45

Notes: CAPP = Central Appalachia. NAPP = Northern Appalachia. A detailed description of each model mine is presented in Appendix B. Maps of each model mine are presented in Appendix C for the baseline as well as evaluated Alternatives. Appendix D describes potential impacts of the SPR on longwall mines in particular. The analysis did not define a model mine

Region	Mine Type	Annual Production (Million tons)	Life of mine (years)	Total production over life of mine (million tons)	Disturbed Area (acres)

specific to address anthracite mines due to its small contribution of this industry to the current level of U.S. coal production, the small average size of the anthracite mines, and the very site specific/proprietary mining methods used in anthracite mining, which make doing a model mine analysis problematic.
[1] The analysis also designed coal refuse facilities associated with these underground mining operations. Please refer to Appendix E for additional details. The results of that analysis are incorporated into the costs for model mines described in Appendix B.
[2] The model developed for Colorado Plateau underground longwall mines was also used to evaluate impacts to the Northern Rocky Mountains and Great Plains underground mining activities.
[3] The models developed for Illinois Basin underground surface and room and pillar mines were also used to evaluate impacts to the Western Interior mining activities (Oklahoma, Missouri, Kansas, Arkansas).
Source: Model mines analysis.

4.1.3 Total Compliance Costs

The compliance cost analysis estimates the incremental industry operational, industry administrative and regulatory authority costs anticipated to result from each Action Alternative (i.e., the changes in industry operational, industry administrative and regulatory authority costs expected as a result of each Action Alternative over and above costs that would be incurred under the No Action Alternative). To estimate the total compliance costs of an Action Alternative, the analysis first estimates the expected increase in industry operational costs for each of the thirteen model mines. The analysis then converts them to costs per ton of coal produced. These increases in per-ton costs of operations are then combined with estimates of industry administrative and regulatory authority costs and modeled to anticipated production impacts in each region.

Estimated increased industry operational costs related to the Action Alternatives are derived from the model mine analysis described above. The primary industry operational cost components include the following:

- Haulage costs – haulage costs are associated with moving mine spoils; these costs vary based on the requirements of each alternative, and only apply where valley fills occur;
- Stream restoration costs – the costs of returning to form and/or function streams disturbed due to mining;
- Reforestation/PMLU costs – costs associated with reforesting or return to premining land use (PMLU) requirements; and
- Bonding costs – costs associated with getting and maintaining a bond for reclamation efforts.

For purposes of this analysis, industry administrative costs are defined as the industry costs associated with time spent on permitting activities and requirements as well as related material costs (e.g. baseline data collection and monitoring, digital elevation modeling software). OSMRE estimated industry administrative efforts expected to result from compliance with Alternative 8 (Preferred) for purposes of meeting the requirements of the Paperwork Reduction Act (PRA). These efforts were calculated on an annual basis, per permit, for mine operators, based on experience and collaboration with the state regulators. OSMRE estimates of these costs, which were informed by public comments, are the basis for the administrative costs calculated below. For more detailed information on OSMRE's effort calculations, please see the PRA analysis prepared by OSMRE.

In order to comply with the PRA, OSMRE estimated the aggregate administrative burden (in hours) for information collection for Alternative 8 (Preferred), along with associated industry wage rates. Specifically, OSMRE calculated the number of hours needed to comply with each element of the rule by 30 CFR sections. Wage costs were then applied to obtain an estimate of wage costs associated with administrative efforts. Non-wage costs due to Alternative 8 (Preferred) were then added to estimate the total industry administrative burden for each region. These costs were then divided by 2015 regional production to get industry administrative costs per ton. These costs were then adjusted by element to approximate differential administrative burdens for each Action Alternative.

Regulatory authority costs are additional costs that would be incurred by state regulatory authorities to review, administer, and enforce permits that would not otherwise be incurred absent the rule. Annual regulatory costs are influenced by a host of factors other than market factors. Because state regulatory authority costs have no direct bearing on the coal market, state regulatory authority costs would not drive market outcomes or the price of coal.

OSMRE assessed the expected additional regulatory burden of Alternative 8 (Preferred) for state regulatory authorities on a per permit basis. These cost estimates were then used to estimate the regulatory authority cost burden for the rest of the Action Alternatives. Although future coal production is expected to decrease during the time period for this analysis, regulatory costs incurred by state regulatory authorities are not expected to closely mirror this trend. As such, the analysis estimates an estimated average annual increase in these costs.

All of the Action Alternatives would result in increased compliance costs over the No Action Alternative, except for Alternative 9. The operational requirements of Alternative 9 were determined to be either the same as the No Action Alternative or achievable at comparable costs to baseline practices.

After calculating the revised coal production forecast that takes into consideration the implementation of the Action Alternatives, the total compliance costs are calculated. Tables 4.1-4a through present the regional annualized increased compliance costs by Action Alternative. Additional details about this analysis are presented in the Chapter 4 of the SPR RIA. Results are summarized as follows:

- Annualized compliance costs are highest in Alternative 2 at $150 million. Compliance costs under Alternative 2 are greater than costs under the other Alternatives because of the stringency and broad applicability of the requirements. Appalachian Basin mines, especially surface mines, contribute most to the high costs under this Alternative. These costs are driven by requirements (limiting mining near streams, spoil management, approximate original contour (AOC) restoration) that increase haulage costs.
- Annualized compliance costs for Alternatives 3 and 4 are anticipated to be $110 million. Like Alternative 2, these Alternatives apply nationally with varying requirements. Under Alternatives 3 and 4 the majority of costs are seen in the Appalachian Basin and the Illinois Basin.
- Annualized compliance costs for Alternative 5 are anticipated to be $44 million. Under Alternative 5, costs accrue primarily in the Appalachian Basin because the requirements are limited to areas where mining operations place excess spoil outside of the mined area or where

coal mine refuse disposal occurs in in perennial or intermittent streams. These practices are largely restricted to the Appalachian Basin.

- Annualized compliance costs for Alternative 6 are anticipated to be $61 million. Under Alternative 6, the mix of costs among regions is different. Specifically, surface mines in Illinois incur a proportionally larger share of costs (roughly 50 percent). Although the Alternative prohibits mining activities within 100 feet of intermittent or perennial streams, it allows regulatory authorities to approve placement of excess spoil or coal mine waste in an intermittent or perennial stream under certain conditions. These conditions are prevalent in the Appalachian Basin, lowering costs in this region.
- Annualized compliance costs for Alternative 7 are anticipated to be $59 million. Although Alternative 7 applies only where enhanced permitting conditions exist, costs are still moderately high because these conditions exist throughout much of the Appalachian Basin.
- Annualized compliance costs for Alternative 8 (Preferred) are anticipated to be $82 million. Alternative 8 (Preferred) costs are similar, but somewhat lower than those anticipated for Alternative 4 primarily because enhanced permitting conditions and land forming requirements do not apply under Alternative 8 (Preferred).
- As discussed previously, Alternative 9 is not anticipated to result in additional compliance costs over and above the No Action Alternative.

For context, EIA reports 2014 coal production of approximately one billion short tons and an average sales price of $34.83 per short ton for approximate revenues of $34.8 billion (U.S. EIA, 2016a). Annualized compliance costs as share of 2014 industry revenue would have ranged from approximately 0.13 percent (Alternative 5) to 0.43 percent (Alternative 2).

Table 4.1-4a. Regional and U.S. Compliance Costs under Alternative 2, Annualized at a 7 Percent Real Discount Rate (2014 Dollars)

Region	Mine Type	Industry Operational Cost (Annualized)	Industry Administrative Cost (Annualized)	Total Cost (Annualized)
Appalachia	Surface	$62,000,000	$14,000,000	$76,000,000
	Underground	$1,500,000	$5,100,000	$6,600,000
Colorado Plateau	Surface	$3,500,000	$38,000	$3,500,000
	Underground	$120,000	$81,000	$200,000
Gulf Coast	Surface	$12,000,000	$1,500,000	$14,000,000
Illinois Basin	Surface	$30,000,000	$750,000	$31,000,000
	Underground	$0	$3,400,000	$3,400,000
Northern Rocky Mountains and Great Plains	Surface	$8,600,000	$800,000	$9,400,000
	Underground	$55,000	$37,000	$92,000
Northwest	Surface	$140,000	$1,100	$140,000
Western Interior	Surface	$4,400,000	$6,100	$4,400,000
	Underground	$0	$1,600	$1,600
Total U.S. Compliance Cost Impacts	Surface	$120,000,000	$17,000,000	$140,000,000
	Underground	$1,700,000	$8,600,000	$10,000,000
	Regulatory Authority	NA	NA	$510,000
	TOTAL	$120,000,000	$26,000,000	$150,000,000

Note: Totals may not sum due to rounding. Includes industry operational, industry administrative, and regulatory authority costs.

Table 4.1-4b. Regional and U.S. Compliance Costs under Alternative 3, Annualized at a 7 Percent Real Discount Rate (2014 Dollars)

Region	Mine Type	Industry Operational Cost (Annualized)	Industry Administrative Cost (Annualized)	Total Cost (Annualized)
Appalachia	Surface	$33,000,000	$14,000,000	$48,000,000

4.1.4 Effects of Action Alternatives on Coal Production

The difference in compliance costs for each Action Alternative yields changes relative to the No Action Alternative's projected coal production presented in Section 4.1.1. Table 4.1-5 presents the forecasted annual changes in coal production across the different Action Alternatives and regions; these are average annual production changes across the 21-year study period, relative to the forecasted baseline included within the No Action Alternative. Increased coal prices are expected to influence the demand for coal, the regional distribution of coal production, and the total tonnage of coal produced by various mine types.

For this analysis, compliance costs associated with implementation of the Action Alternatives are entered into a coal market model to examine industry-level effects of the Action Alternatives. The market model of forecast coal production is then used to calculate total compliance costs to industry. The detailed assumptions and results of this forecast are described in SPR RIA Appendix F.

All of the Action Alternatives, except Alternative 9, are expected to result in some net decrease in total national production, resulting from the anticipated decrease in surface production primarily from the Appalachian Basin. As discussed, the analysis found negligible incremental compliance costs for Alternative 9. Consequently, Alternative 9 would lead to the same level of coal production as in the No Action Alternative. This finding is consistent with the requirements of Alternative 9, which contains no absolute prohibitions on mining in or within streams. Therefore, Alternative 9 would not change coal production any more than the No Action Alternative.

As Alternative 9 forecasts no change in national production from the No Action Alternative, it will be excluded from the following discussion of Table 4.1-5. The average annual decreases range from a low 0.7 million tons (0.08 percent of baseline production) under Alternative 8, to a high of 1.3 million tons (0.16 percent of baseline production) under Alternative 2. Net production decreases are forecasted for all coal regions, with all Action Alternatives expected to experience similar changes. For context, annual coal production in the U.S. in 2014 was 1 billion short tons and Appalachia production was 267 million short tons (U.S. EIA, 2016a).

Table 4.1-5. Regional Forecast Changes in Average Annual Coal Production under the Action Alternatives Compared to the No Action Alternative (Millions of Tons)

Alternative	Mine Type	Appalachia	Colorado Plateau	Gulf Coast	Illinois Basin	Northern Rocky Mountains	Northwest	Western Interior	Total

4.2 Natural Resources

4.2.1 Water Resources

As described in Chapter 1, the primary purpose of the proposed action is to anticipate and prevent adverse impacts to streams and related resources as a result of coal mining activities while balancing the Nation's need for an adequate coal supply. To achieve this objective, meaningful protection of water resources is essential. Therefore, this section of Chapter 4 analyzes how water resources are currently impacted by the No Action Alternative and what is expected to occur if no changes are made as a result of this rulemaking effort. Following a synopsis of the No Action Alternative relative to water resources, the various effects of the Action Alternatives on water resources are analyzed. This analysis considers impacts upon both surface water and groundwater. The remaining subsections are structured as follows:

- Section 4.2.1.1 provides an overview of SMCRA and the Clean Water Act (CWA) to describe how implementing regulations under these laws interact to regulate water quality impacts related to coal mining. This subsection then describes mining-related effects on water quality that are occurring under these existing regulations, i.e., under the No Action Alternative;
- Section 4.2.1.2 describes how particular elements of the proposed action would likely affect water resources;
- Section 4.2.1.3 describes the analytic methods employed to evaluate potential effects to water resources;
- Section 4.2.1.4 presents results of the quantitative analysis of surface water impacts; and
- Section 4.2.1.5 presents a summary of the results that would be achieved from the Action Alternatives.

4.2.1.1 Effects of the Current Regulatory Environment (the No Action Alternative)

This subsection provides an overview of the existing regulatory environment governing water resources related to coal mining. The subsection begins with a discussion of important sections of the CWA as there is a high degree of interaction between the requirements of SMCRA and the requirements of the CWA. While a SMCRA permit addresses all parts of the mining activity, those activities affecting waters subject to jurisdiction under the CWA will also require a CWA permit. For example, a proposed surface coal mining operation requires a SMCRA permit to authorize the mining activity itself, a permit under section 404 of the CWA, and a state water quality certification under section 401 if the mining activity requires the discharge of fill material into the waters subject to jurisdiction under the CWA.

Each relevant CWA section is discussed below, followed by a water quality focused discussion of existing requirements under SMCRA.

4.2.1.1.1 Existing Regulatory Environment

4.2.1.1.1.1 Clean Water Act

Congress established the CWA with the goal of "restor[ing] and maintain[ing] the chemical, physical, and biological integrity of the Nation's waters" (33 U.S.C. § 1251(a)). To achieve that objective, the CWA prohibits the discharge of pollutants from point sources into navigable waters unless consistent with the requirements of that act (*Id.* § 1311(a)). The CWA allows for the discharge of pollutants into navigable waters under two permitting programs. Section 402 governs the discharge of pollutants other than dredged or fill material; section 404 governs the discharge of dredged or fill material. Congress charged EPA with oversight authority of state-authorized permit programs (*Id.* §§ 1342(b)-(e); 1344(g)(l), (n)) and provided EPA with other authorities in connection with section 404 permits issued by the U.S. Army Corps of Engineers (USACE) (*Id.* § 1344(b)-(c), (q), (n)). On July 29, 2015, the EPA and USACE finalized a rule to increase the clarity of waterway definitions under the Clean Water Act waters of the U.S. definition related to tributaries, adjacent wetlands/waters, "other" waters, and exclusions. This rule was stayed on October 9, 2015 by the U.S. Court of Appeals for the Sixth Circuit and is awaiting further action.

The CWA defines "navigable waters" to mean "waters of the United States, including the territorial seas" (*Id.* § 1362(7)). On June 29, 2015, following years of litigation over the term, the EPA and USACE issued a rule to clarify the scope of the definition of "waters of the United States" (80 FR 37053). The revised definition would narrow the scope of CWA jurisdiction such that fewer waters would be jurisdictional and would provide bright-line tests to reduce the number of instances where permitting authorities would need to make case-specific jurisdictional determinations (80 FR 37053). Multiple industry and environmental groups challenged the rule, and the Sixth Circuit issued an order staying the rule nationwide. The Sixth Circuit has set a briefing schedule that will conclude on February 17, 2017, and oral arguments will be scheduled as soon as practicable after briefing is complete (*OH, et al v. U.S. Army Corps of Engineers, et al*, Case No. 15-3799 (6th Cir 2015)). In response to the Sixth Circuit's stay, the EPA and USACE resumed nationwide use of the agencies' prior regulations (U.S. EPA, 2015). Thus, the agencies' prior regulations form part of the existing regulatory environment for purposes of this EIS.

4.2.1.1.1.2 CWA Section 303 Water Quality Standards

Section 303 of the CWA requires states to adopt water quality standards applicable to their intrastate and interstate waters (33 U.S.C. § 1313). Water quality standards assist in maintaining the physical, chemical, and biological integrity of a waterbody by designating uses, setting criteria to protect those uses, and establishing provisions to protect water quality from degradation. Water quality standards established by states[11] are subject to EPA review (40 CFR 131.5; 33 § U.S.C. 1313(c)). EPA may object to state-adopted water quality standards and may require changes to the state-adopted water quality standards and, if the state does not respond to EPA's objections, EPA may promulgate federal standards (33 U.S.C. § 1313(c)(3)-(4); 40 CFR 131.5, 131.21).

Water quality criteria may be expressed numerically and implemented in permits through specific numeric limitations on the concentration of a specific pollutant in the water (e.g., 0.1 milligrams of chromium per liter) or by more general narrative standards applicable to a wide set of pollutants. To assist states in adopting water quality standards that will meet with EPA's approval, Congress authorized EPA to develop and publish recommended criteria for water quality that accurately reflect "the latest scientific knowledge" (33 U.S.C. § 1314(a)). Water quality standards are not self-implementing; they are implemented through permits, such as the section 402 permit or the section 404 permit (33 U.S.C. § 1311(b)(1)(C); 40 CFR 122.44(d), 230.10(b)).

---

[11] EPA may treat an eligible federally recognized Indian tribe in the same manner as a state for implementing and managing certain environmental programs, including under the Clean Water Act.

4.2.1.1.1.3 CWA Section 401 Water Quality Certification

State water quality standards are incorporated into all federal CWA permits through section 401, which requires each applicant to submit a certification from the affected state that the discharge will be consistent with state water quality requirements (33 U.S.C. § 1341(a)(1)). Thus, section 401 provides states with a veto over federal CWA permits that may allow exceedances of state water quality standards, and empowers states to impose and enforce water quality standards that are more stringent than those required by federal law (33 U.S.C. § 1370).

4.2.1.1.1.4 CWA Section 402 Permits

Section 402 of the CWA, 33 U.S.C. § 1342, governs discharges of pollutants other than dredged or fill material. Permits issued under the authority of section 402 are known as National Pollutant Discharge Elimination System (NPDES) permits, and typically contain numerical limits called "effluent limitations" that restrict the amounts of specified pollutants that may be discharged. NPDES permits must contain technology-based effluent limits, and any more stringent water quality-based effluent limits necessary to meet applicable state water quality standards (33 U.S.C. §§ 1311(b)(1)(A),(C), 1342(a); 40 CFR 122.44(a)(1), (d)(1)). Water quality-based effluent limitations are required for all pollutants that the permitting authority determines "are or may be discharged at a level [that] will cause, have the reasonable potential to cause, or contribute an excursion above any [applicable] water quality standard, including State narrative criteria for water quality" (40 CFR 122.44(d)(1)(i)). The procedure for determining the need for water quality-based effluent limits is called a reasonable potential analysis, or "RPA."

Section 402 permits are issued by EPA, unless the state has an approved program whereby the state issues the permits, subject to EPA oversight (33 U.S.C. § 1342(b)(e); *Nat'l Ass'n of Home Builders v. Defenders of Wildlife*, 551 U.S. 644, 650-651 (2007)). The state must submit draft permits to EPA for review, and EPA may object to a proposed permit that is not consistent with the CWA and federal regulations (33 U.S.C. § 1342(d); 40 CFR 123.43 and 123.44). If the state does not adequately address EPA's objections, EPA may assume the authority to issue the permit (33 U.S.C. § 1342(d)(4)). EPA's procedures for the review of state-issued permits are set forth in regulations at 40 CFR 123.44 and in memoranda of agreement with the states.

Sediment control ponds and other sediment control structures, connected by various diversion channels and other conveyances, often form an integral part of the wastewater effluent treatment systems on coal mine sites. Section 402 authorizations (NPDES permits) consider the effectiveness of these systems on the mine site in ensuring that discharges leaving coal mining permit areas meet applicable water quality standards.

4.2.1.1.1.5 CWA Section 404 Permits

Section 404(a) of the CWA, 33 U.S.C. § 1344(a), authorizes the Secretary of the Army, acting through the USACE, to "issue permits ... for the discharge of dredged or fill material into the navigable waters at specified disposal sites" (33 U.S.C. § 1344(a)). By this authority, the USACE regulates discharges of dredged and fill material into waters of the United States in connection with surface coal mining activities. The USACE's regulations governing section 404 permit procedures are set forth at 33 CFR Part 325.

Although the USACE is the permitting authority under section 404, EPA has an important role in the permitting process. Section 404(b) of the CWA requires that USACE's permit decisions comply with guidelines developed by EPA in conjunction with the USACE, referred to as the "404(b)(1) Guidelines" (33 U.S.C. § 1344(b)(1)). Among other things, the 404(b)(1) Guidelines prohibit the discharge of fill if it would cause or contribute to a violation of a water quality standard or cause or contribute to significant degradation of the waters of the U.S. (40 CFR 230.10(b), (c)(1)-(3)). The 404(b)(1) Guidelines require the USACE to analyze more than 15 different factors that could be impacted by the proposed action, including substrate, suspended particulates, turbidity, water quality, water circulation, water level fluctuations, salinity gradients, threatened and endangered species, aquatic organisms in the food web, other wildlife special aquatic sites, water supplies, fisheries, recreation, aesthetics, and parks (40 CFR 230 (c)-(f)). The 404(b)(1) Guidelines provide that the USACE must ensure that the proposed discharges would not cause or contribute to significant adverse effects on human health or welfare, aquatic life, or aquatic ecosystems (40 CFR 230.10(c)(1)-(3)).

Before the USACE may issue a section 404 permit, it must provide notice to the public, EPA, and other resource agencies, which may all provide comments to the USACE for consideration (33 CFR 325.3(d)). In addition, the USACE and EPA have entered into a Memorandum of Agreement (MOA) as directed by section 404(q) of the CWA, 33 U.S.C. § 1344(q), that expressly recognizes that "the EPA has an important role in the Department of the Army Regulatory Program under the Clean Water Act[.]" The MOA provides that "[p]ursuant to its authority under section 404(b)(1) of the Clean Water Act, the EPA may provide comments to the Corps identifying its views regarding compliance with the section 404(b)(1) Guidelines" and USACE "will fully consider EPA's comments when determining [compliance] with the National Environmental Policy Act, and other relevant statutes, regulations, and policies" (*Id*).

In addition, and in recognition of "EPA's expertise and concentrated concern with environmental matters," (*James City County v. EPA*,12 F.3d 1330, 1336 (4th Cir. 1993)), Congress gave EPA the authority in section 404(c) to prohibit, withdraw, deny, or restrict the specification of disposal sites that would otherwise be authorized by a section 404 permit--often referred to as EPA's "veto" authority.

The USACE reviews "individual" permit applications on a case-by-case basis under section 404(a) (33 U.S.C. § 1344(a)). Individual permits may be issued or denied after a review involving, among other things, site specific documentation and analysis, opportunity for public hearing, public interest review, and a formal determination that the permit is lawful and warranted (33 CFR Parts 320, 323, 325).

Not every discharge is of such significance that an individual evaluation of the discharge's environmental effects is necessary. Instead, section 404(e)(1) authorizes the Secretary of the Army to issue general permits for categories of activities involving discharges of dredged or fill material that, as a group, have only minimal impacts on the waters of the U.S. The USACE can issue these general permits (as well as individual permits) on a state, regional, or nationwide basis. The USACE refers to general permits issued on a nationwide basis as "Nationwide permits" (NWP). Current NWPs related to coal mining include NWP 21 related to surface mining, NWP 49 related to surface remining, and NWP 50 related to underground mining.

These NWPs provides USACE authorization for the discharge of dredged or fill material into waters of the U.S. associated with coal mining activities. The USACE review under these permits is focused on the individual and cumulative adverse effects to the aquatic environment, and on determining appropriate mitigation should mitigation become necessary. The USACE review does not extend to the mining operation as a whole, unlike the SMCRA permit.

To qualify for NWP 21, for example, an activity must meet all of the following criteria:

(1) The activities are already authorized or are currently being processed by a SMCRA-approved state program or an integrated permit processing procedure by the Department of the Interior;

(2) The discharge will not cause the loss of more than ½ acre of non-tidal waters of the United States, including the loss of no more than 300 linear feet of stream bed, unless for intermittent and ephemeral stream beds the district engineer waives the 300 linear foot limit by making a written determination concluding that the discharge will result in minimal individual and cumulative adverse effects; and

(3) The discharge is not associated with the construction of valley fills which are fill structures associated with surface coal mining activities that are typically constructed within valleys associated with steep, mountainous terrain.

Coal mining activities that impact waters of the U. S., and that do not meet the respective requirements of NWP 21 (surface coal mining), NWP 49 (surface coal remining), or NWP 50 (underground coal mining) would require an individual section 404 permit to proceed. Consideration of resources occurs under either an individual permit or a NWP, as required by the 404(b)(1) guidelines. The primary differences between the two processes are the extent of public review opportunities, the degree of administrative burden, and the amount of time involved in processing the permit.

4.2.1.1.1.6 CWA Compensatory Mitigation Requirements

In 2008, EPA and the U.S. Army Corps of Engineers issued a joint rulemaking expanding the CWA 404(b)(1) Guidelines regarding standards for compensatory mitigation for loss of aquatic resources. Compensatory mitigation refers to the restoration, establishment, enhancement, and/or preservation of wetlands, streams, or other aquatic resources conducted specifically for the purpose of offsetting authorized impacts to these resources. With respect to intermittent and perennial streams that are mined through during the course of mining operations, the CWA mitigation rule requires restoration. Compliance with these existing restoration standards will be required under the No Action Alternative.

4.2.1.1.1.7 Surface Mining Control and Reclamation Act

Congress enacted SMCRA for the purpose of, among other things, striking a balance between protecting the environment from the adverse effects of surface coal mining operations and meeting the Nation's energy requirements (30 U.S.C. § 1202(a), (d), (f)). SMCRA expressly provides that "[n]othing in this chapter shall be construed as superseding, amending, modifying, or repealing" the CWA or "any rule or regulation promulgated thereunder" (*Id*. § 1292(a)(3)). In addition, SMCRA requires that "[t]o the greatest extent practicable each federal agency shall cooperate with the Secretary and the States in carrying out" its provisions, and it directs the coordination of regulatory activities among departments and agencies responsible for implementation of identified statutes, including the CWA (*Id*. §§ 1292(c), 1303(a)).

As discussed previously in Chapter 1 of this FEIS, a state may assume primary jurisdiction (primacy) over the regulation of surface coal mining and reclamation operations within its borders by submitting a program proposal to the Secretary for approval (*Id*. § 1253). Regardless of whether OSMRE is the regulatory authority or whether the state has an approved program, consideration and protection of surface and groundwater resources are required throughout the permitting, mining, and reclamation phases.

The regulations implementing SMCRA include extensive permitting requirements and performance standards intended to protect the hydrologic balance (see, e.g., 30 CFR Parts 780, 784, 785, 815, 816, and 817). For example, the regulatory authority may authorize mining activities in or adjacent to perennial or intermittent streams only when the permit applicant has successfully demonstrated that the "activities will not cause or contribute to the violation of State or Federal water quality standards, and will not adversely affect the water quantity or other environmental resources of the stream" (30 CFR 816.57(a)(1); 30 CFR 817.57(a)(1)).

Each SMCRA permit application must include an assessment of the probable hydrologic consequences of the proposed mining and reclamation operations (30 U.S.C. § 1257(b)(11) and 30 CFR 780.21(f) and 784.14(e)). The assessment must include a review of groundwater and surface-water quantity and quality, both on and off the mine site. Each permit application must include specific, detailed information concerning the hydrology and geology of the proposed permit and adjacent areas. Subsection 2.4.1 of Chapter 2 describes baseline data collection and analysis requirements under existing regulations.

The regulatory authority uses this assessment of the probable hydrologic consequences and other available information to prepare the cumulative hydrologic impact assessment and to determine if the permittee has designed the proposed operation appropriately to prevent material damage to the hydrologic balance (30 CFR 780.21 and 784.14). The regulatory authority cannot approve the permit application unless the applicant successfully shows that the proposed operation has been designed to prevent material damage to the hydrologic balance outside the permit area (30 U.S.C. § 1260(b)(3); 30 CFR 773.15(e)).

However, there are shortcomings in the current regulations implementing SMCRA. Insufficient baseline data can make it difficult or impossible for the regulatory authority to determine whether problems detected during and after mining are a result of the mining operation or are instead related to other sources. Although the regulations require baseline characterization they do not establish standard protocols for determining the placement and number of water sampling points. The regulations at 30 CFR 780.21(b) require water quality descriptions for pH, total iron, total manganese, and total dissolved solids or specific conductance, but they do not require monitoring of other constituents, such as selenium, that have also been scientifically linked to some coal mining activities. The existing SMCRA implementing regulations also do not expressly require baseline assessment of biological conditions in streams.

Although the statute and the regulations clearly prohibit material damage to the hydrologic balance outside the permit area, neither SMCRA nor the implementing regulations provide a definition of "material damage to the hydrologic balance outside the permit area." Without a clear definition of this term, it is difficult for applicants to show that they have adequately designed their proposed mining operation to avoid damage, and the regulatory authority may have insufficient information to perform an objective review of the proposed design. The lack of a federal definition also contributes to variability among states, and even among permits, in what the regulatory authority might require of the applicant.

The lack of a federal definition for material damage to the hydrologic balance outside the permit area also complicates enforcement of permit conditions. SMCRA regulatory authorities have historically relied upon a qualitative approach when defining material damage to the hydrologic balance outside the permit area and have not specifically assigned numerical values to the point at which material damage to the hydrologic balance outside the permit area would occur. Absent a clearly defined threshold, it is difficult for operators to identify an impending problem and address it before damage occurs. It is also difficult for the regulatory authority to demonstrate that material damage to the hydrologic balance outside the permit area has occurred, or conversely that the operation is in fact in compliance or has been brought into compliance through the application of corrective measures.

Determining whether damage is occurring requires monitoring. Whereas baseline data provides a snapshot of conditions before mining, monitoring of conditions throughout the activity provides data on conditions resulting from the activity itself. There are gaps in OSMRE's current regulations regarding how the operator is to conduct the monitoring. As with the baseline data requirements, OSMRE's current regulations do not establish standard protocols for the number of water sampling points and they are not inclusive of all mining-related water quality concerns (see the list of analytes required above in the discussion of baseline data). For example, monitoring of selenium is not currently required (30 CFR 780.21(b)).

Vegetated buffer zones can slow overland water flow and allow sediment particles to settle out before they reach surface waters. SMCRA's implementing regulations at 30 CFR 816.57 and 817.57 require a 100-foot buffer along perennial and intermittent streams. However, the regulations allow the regulatory authority to grant an exception to this requirement, which they routinely do. The exception review and decision process is inconsistent among regulatory authorities.

4.2.1.2 Impacts of the No Action Alternative on Water Resources: Surface Water and Groundwater Effects

As explained in detail below, despite existing regulations, both surface and underground mining operations continue to produce adverse effects on the quality and quantity of surface water and groundwater outside the permit area. These effects are occurring for a variety of reasons related to the nature of the mining activity, the sensitivity of the resources, and the efficacy of current regulations.

4.2.1.2.1 Surface Water Effects

Both surface and underground mining operations have the potential to adversely affect surface water quantity and quality. These effects can be chemical (e.g., changes to the water chemistry and characteristics) or they can be physical (e.g., changes to the size, location, and flow characteristics). The effects are generally more pronounced in areas with a long history of mining, such as sites disturbed prior to the enactment of SMCRA in 1977, as compared to more current operations, as mining practices have improved over time.

However, as described in the studies presented below, mining under current regulations is continuing to result in physical and chemical effects on surface waters. Some effects of mining activities are unavoidable. For example, during the duration of the mining activity, vegetation is removed and surfaces remain exposed, topography is altered and surfaces are compacted, infiltration of rainwater and uptake of water into vegetation is reduced and consequently overland runoff of water is increased. The local geology has a profound influence on the quantity and quality of surface water and groundwater. Mining activities break rock into smaller fragments, exposing previously unexposed minerals and increasing the amount of surface area available for weathering. As weathering commences, chemical constituents contained within the rock are released to the environment. In the mining environment, these constituents would be released into waters on the site, which would then make their way to water treatment structures, such as sedimentation ponds, before being discharged from the permit area. Despite treatment, discharge from sedimentation ponds can demonstrate elevated levels of total dissolved solids. Constituents also make their way into groundwater and then are discharged as groundwater baseflow into receiving streams.

4.2.1.2.1.1 Chemical Effects on Surface Waters

Under existing regulations, mining continues to affect downstream water chemistry. Studies have shown that mining-impacted waterways often contain elevated levels of arsenic, selenium, iron, aluminum, manganese, and sulfate. These waters typically have lower alkalinity concentrations and lower pH, while specific conductivity and total suspended solids are typically higher, as compared to streams unimpacted by mining (Wangsness et al., 1981; Zuehls et al., 1984; Herlihy et al., 1990; Howard et al., 2001; Stauffer and Ferreri, 2002; Bryant et al., 2002; Hartman et al., 2005; Pond et al., 2008; Petty et al., 2010; U.S. EPA, 2011g; Presser, 2013; Skogerboe et al 1979).[12]

Acid mine drainage has historically been a primary concern associated with coal mining due to the effects of low pH on the viability of the system for aquatic life and human health (Dills and Rogers, 1974; Powell, 1988; Sams and Beer, 2000). The concern is relevant to mining nationwide, although contamination from acid mine drainage is more difficult to observe in western coal fields (e.g., Colorado Plateau, Northern Rocky Mountains and Great Plains), where the geology, soils and hydrology provide high buffering capacity (alkalinity), which neutralizes mine spoil and waste (Powell, 1988; Lowry et al., 1983).

Excess spoil fills constructed during large-scale mining operations in steep-slope areas may impact aquatic ecosystems by, among other things, increasing ion concentrations in receiving waters. These impacts may occur both during the mining activity and after reclamation. Palmer and Bernhardt (2009) found that streams impacted by valley fills often have 30- to 40-fold increases in sulfate concentrations and that sulfate concentrations in receiving waters continued to increase after mining activities ended. In addition, streams and rivers below valley fills receive elevated concentrations of calcium, magnesium,

[12] Despite more limited information on surface mining impacts in western streams than in eastern streams, some studies have shown evidence, as early as in the 1970's, that increased periods of flow in a stream adjacent to a mine site may be accompanied by a disproportionate increase in concentration of total dissolved solids. For example, Skogerboe et al 1979 found an increase in total dissolved solids that was attributed to weathering of exposed strata, which mobilizes calcium, magnesium, sodium, sulfate, and alkalinity constituents. At this site, spatial variations in the dissolved solids, specific conductivity, hardness, calcium, magnesium, sodium, potassium, sulfate, and chloride exhibit the same pattern as the stream progresses past the mine. Specifically, levels of these constituents are lowest at sites above the mine, increase to maxima at sites of maximum inflow from the mine, and decline at sites downstream of the mine. Seasonally, the highest impacts on the water quality occur during the spring snowmelt. Increases in manganese and selenium concentrations were detected in the recipient stream, however, remained below levels sufficient to impact biota. Surface water concentrations of other trace metals such as aluminum, arsenic, cadmium, copper, iron, lead, and zinc were not observed to be impacted by mining operations at this site (Skogerboe et al. 1979).

bicarbonate ions, and often trace metals, leading to elevated conductivity levels in these waterways. Conductivity levels in receiving streams below valley fills contribute to biological impairment of aquatic ecosystems (Palmer and Bernhardt, 2009). Biological impairment has been shown to occur in the form of, for example, shifts in the species diversity and reduced abundance and richness of *Ephemeroptera* taxa (Pond et al., 2008).

Direct impacts to streams from mining and reclamation activities also occur in association with the practice of mining through ephemeral, intermittent, and perennial streams. The impacts of large-scale mining operations upon the water quality of ephemeral, intermittent, and perennial streams in Central Appalachia are highlighted in Bernhardt and Palmer (2011). Research compiled in Bernhardt and Palmer (2011) demonstrated that multiple surface mines and valley fill activity within large watersheds resulted in increases in concentrations of sulfate, bicarbonate, calcium, and magnesium ions further downstream.

4.2.1.2.1.2 Physical Effects on Surface Waters

Physical effects on surface waters include all those effects that would change the size (width and or depth) and location of the surface water. These effects occur from mining activities that include mining through surface waters, placement of fill in surface waters to cross them with mining roads, and placement of spoil or refuse in surface waters. Each of these activities has difference consequences as discussed below.

Excess spoil placement into streams is allowable under longstanding interpretations of our current regulations and substantial effects of excess spoil generation on streams continue to occur, particularly in Appalachia. For example, a 2007, *Times West Virginian* article reported that surface mining permits issued between October 2001 and June 2005 affected approximately 535 miles of streams, including 367 miles of streams in the Appalachian coal fields. More specifically, the West Virginia Department of Environmental Protection completed a report titled; *Trends in Mining Fills and Associated Stream Loss in West Virginia 1984-2012*, in 2013 (Shank and Gebrelibanos, 2013). The authors of the report calculated stream loss due to spoil and refuse fill construction between 1984 and 2012. The analysis indicated the following:

- Completed or under construction fills included 1,932 spoil fills and 392 refuse fills;
- Fill acreage totaled 62,471 acres or approximately 97 square miles;
- Direct stream loss (under the fills) totaled 764.3 miles (297.5 miles of intermittent and 466.8 miles of perennial streams); and
- Indirect stream impacts above fills, including change in ecologic function, totaled 279.5 miles.

Activities that involve land disturbance, such as mining and reclamation, increase the risk of erosion and, therefore have the potential to affect the quantity of sediment that reaches waterways. Sediments are fragmented materials originating from the weathering and erosion of rocks or unconsolidated deposits, which are transported or deposited by or suspended in water. Sediments are a pollutant of waters because sediment particles can carry attached pollutants with them. They can also affect biological processes directly by burying or smothering aquatic organisms or their habitats, and reducing the amount of light available for photosynthesis or activities requiring visibility. Excessive sediment reduces stream depth, which increases water temperatures and reduces the dissolved oxygen content (Slagle et al., 1986).

An unintended consequence of the storage function provided by sediment ponds is that the impoundment of the waters affects the timing and volume of water received downstream from the pond; peaks and lows in the hydrograph are smoothed out due to the impoundment and controlled release of the water. This, in turn, affects the physical and biological characteristics downstream. Captured runoff released from impounding structures such as sediment ponds can be a source of downstream channel instability. The energy potential of the water that was once used to transport sediment is now available to erode the receiving channel (Leopold and Maddock, 1953; Smith et al, 2002). Limiting the frequency of flow and sediment delivered to streams below mined areas may initiate changes in channel form due to deposition of eroded sediment and mass wasting processes, altering the channel's capacity to convey flow and causing subsequent channel incision or widening.

When streams are filled for any reason, the water that once made its way to that stream will find a new pathway. Flooding or, conversely, water deprivation, scouring, and gullies are all possible consequences of poor water management. Additionally, changes in drainage divides, contributing area, and drainage density may affect how much runoff is contributed to the receiving stream system.

The quantity and rate of water flow are important hydrologic characteristics that help to determine the water that will be available to support aquatic life and other stream benefits. Mining activities have had documented impacts on hydrologic characteristics. Higher infiltration rates on mined areas increased stream baseflow. Further, increased storage capacity in replaced mine spoils reduced peak flow in streams receiving drainage from mine sites (Corbett and Agnew, 1968). Conversely, negative effects on streamflows have also been documented, particularly in the Appalachian Basin region. For example, there are documented cases of subsidence-induced stream dewatering caused by longwall mining operations in Pennsylvania and West Virginia (Wade, 2008; Rauch et al., 1984; Hobba, 1993; Stout, 2004). In some cases, the streamflow rebounded within months while other cases have shown the dewatering to persist for years.

Interpretation of the incremental impacts of the rule and Alternatives on stream fill, miles of mined through streams, and downstream stream degradation, would benefit from contextual information that describes impacts on streams from coal mining under the No Action Alternative. For instance, estimates of the total number of stream miles that are mined through, filled, and impaired annually by coal mining under current regulatory conditions would be helpful. While comprehensive contextual information is not generally available, the following studies and analytic observations provide some context:

- **Stream fills.** With respect to stream miles not filled (Table 4.2-10), five studies provide some context:
    - Shank (2010) and Shank and Gebrelibanos (2013) use GIS analysis to compile data on refuse fill in West Virginia between 1984 and 2012, and estimate linear stream loss due to fill construction over time. The more recent study estimated that 1,932 spoil fills and 392 refuse fills totaling 62,471 acres (97 square miles) were completed or under construction in West Virginia at the time. The fills resulted in a direct loss of 764.3 miles of perennial (466.8 miles) and intermittent (297.5 miles) streams from 1984 to 2012, which is an average fill rate of 28 miles per year. The study also documented a marked decrease in fill construction starting in approximately 2003. In 2012, stream miles filled decreased to approximately 18 miles in West Virginia for that year.

- The 2005 Mountaintop Mining EIS (U.S. EPA, 2005) included two studies that estimate the effect of mountaintop mining and valley fills in West Virginia, Kentucky, Tennessee, and Virginia. This first study estimated that between 1985 and 2001, 724 stream miles (1.2 percent of streams) were covered by valley fills (equating to 45 miles per year). This study, known as the fill inventory, includes a variety of information regarding valley fills constructed from 1985 to 2001, including the feet of stream under valley fill footprints. This study measured streams based on a synthetic stream network defined on a 30-acre watershed accumulation threshold over the National Elevation Dataset (NED). The NED for each state was processed to enforce hydrologic integrity. A flow accumulation grid was prepared and queried to define a drainage network over the entire region. The synthetic stream network represents all drainage for watersheds greater than 30 acres.
- The 2005 Mountaintop Mining EIS (U.S. EPA, 2005) also included a study that estimated impacts of mountaintop mining and valley fills between 1992 and 2002 of 1,200 stream miles (equating to approximately 110 per year), out of 58,998 streams in the study area. As with the previous study, this study also used GIS modeling of "synthetic streams" (in that they were not generated from existing maps, but instead were created by assuming that 30-acre areas generate a stream,) to estimate potential impacts. This estimate of filled or mined through streams represents 2.05 percent of the stream miles in the study area.
- In a 1998 study, U.S. FWS evaluated stream miles permitted or filled with excess spoil and other coal mining wastes in Kentucky, Pennsylvania, Virginia, and West Virginia between 1986 and 1998. This study found that at least 900 stream miles were permitted for filling in this time period (about 75 stream miles per year). The study did not evaluate actual stream miles filled, which are believed to be less than the number of miles permitted to be filled. Other uncertainties relating to the accuracy of this estimate are presented in study. Most notably, the study evaluated fills only for streams marked by USGS topographic maps as blueline streams.

Additional information on surface water impacts is available from permit data provided by the U.S. Army Corps of Engineers (USACE). USACE issues nationwide permits (NWPs) and individual permits (IPs) to authorize certain activities under Section 404 of the Clean Water Act and Section 10 of the Rivers and Harbors Act. All IPs require application to USACE. In most cases, permittees may proceed with activities authorized by NWPs without notifying USACE. However, the three NWPs that pertain to coal mining activities, including number 21 for surface coal mining activities, number 49 for coal remining activities, and number 50 for underground coal mining activities, all require USACE to approve any impacts under the permits. As a result, USACE data on the permitting programs for these activities provide insight into the extent of planned and authorized impacts to wetlands and streams from coal mining activity.

USACE provided three years of data from the permitting program, covering the timeframe from the beginning of 2012 to the end of 2014 and showing authorized impacts for coal mining related activities under both NWPs and IPs in coal counties across the United States. Figures 4.2-1 and 4.2-2 below provide summarized information from this dataset. As the Exhibits demonstrate, the majority of permitted wetland and stream impacts occur within the Appalachian Basin, Illinois

Basin, and Gulf Coast regions. Without exception the data presented below are the impacts authorized through the permitting process, and are not a measurement of the actual extent of impacts that resulted from these operations. The actual extent of impacts may be less than the amount authorized for a number of reasons including the following: the operation may not have progressed to the phase of the operation where the impact will occur, the operation may have changed, or the extent of actual impacts may be less than originally predicted.

- **Mined through streams**. Few studies characterize the extent to which ephemeral streams are mined through currently, or under the No Action Alternative. Inputs used in the model mines analysis provide partial context to the estimated incremental impacts. For instance, a typical surface mine in the Illinois Basin is estimated to mine through and fill about nine miles of ephemeral stream. Likewise, a surface mine in the Northern Rocky Mountains and Great Plains region is estimated to fill nearly 35 miles of ephemeral streams (these assumptions are described in sections 4 and 5 in Appendix B of the RIA).
- **Streams degraded downstream of mining operations**. It is especially difficult to provide context to estimates of miles where water quality would be improved as a result of implementing rule Alternatives given the general nature of this indicator. Chapter 3 (Section 3.5) presents an overview of water resources in each of the coal-producing regions, including an analysis of the total miles of intermittent and perennial streams in each region. These figures suggest that the incremental downstream miles improved by the Action Alternatives represent a relatively small share of the overall water resources in affected regions. For instance, while several of the Alternatives could contribute to water quality improvements in roughly 171 stream miles in the Appalachian Basin, this can be compared to approximately 126,000 total stream miles in the region. A more focused point of comparison would be to examine the total stream miles degraded by coal mining activities. While state CWA section 303(d) water quality reports routinely identify coal mining as a pollution source, these data are not compiled at the regional level.

4.2.1.2.2 Groundwater Effects

4.2.1.2.2.1 Chemical Effects on Groundwater

Mining can also affect groundwater. A USGS study (Eberle and Razem, 1985) investigating the effects of surface mining in small watersheds of the Allegheny Plateau in Ohio identified a change in upper aquifers associated with surface coal mining from calcium bicarbonate to calcium sulfate predominated water. Following reclamation dissolved sulfate, iron, and manganese in the upper aquifers generally exceeded U.S. and Ohio EPA drinking water standards. These water sources generally did not demonstrate these exceedances prior to reclamation. Middle and lower aquifers were generally not affected by surface mining. Another USGS study (Paybins et al., 2000) investigating groundwater water quality downgradient of reclaimed surface coal mines showed lowered pH and increased sulfate concentrations at sampling locations affected by mining. Paybins et al. (2000) showed higher sulfate concentrations in groundwater in shallow wells within 1,000 feet of reclaimed surface mines. This study also documented higher iron, manganese, and aluminum concentrations (1,800, 640, and 11 µg/L, respectively) within about 2,000 feet of reclaimed surface mines (Paybins et al., 2000). An additional USGS study focusing on groundwater resources in the Allegheny and Monongahela River Basins found groundwater in shallow private domestic wells near reclaimed surface coal mines had higher concentrations of sulfate, iron, and manganese compared to unmined areas, even after all mining and reclamation had been completed (Anderson et al., 2000).

4.2.1.2.2.2 Physical Effects on Groundwater

Mining activities can affect both the quantity and direction of groundwater flow. Water infiltration contributes to groundwater, and coal mining and reclamation activities can change overland flow and the amount of water that infiltrates the surface to ultimately recharge the groundwater system. Subsidence due to underground mining impacts the direction of groundwater flow as well because it changes the contour and infiltration capacity of the overlying surface (discussed in greater detail in the next section). According to the USGS Groundwater Atlas of the United States, HA 730-L (Trapp and Horn, 1997):

Underground mining of coal disturbs the natural groundwater flow system when the mines are active because artificial drains are constructed to dispose of unwanted water and mining activities can create new fractures and thus increase permeability. The regional water table can be lowered when the drains are effective and groundwater flow directions can be changed in some cases until flow moves across former groundwater divides into adjoining basins. Groundwater tends to flow toward mines, which are usually dewatered by pumping. Adverse effects of mine drainage on well yields are greatest where the mines are not much deeper than the bottoms of the wells and where vertical fractures connect the aquifers and the mines.

Overburden removal and coal excavation during surface coal mining results in a new groundwater static water level within the disturbance boundary. This consequently affects the hydraulic gradients surrounding the mined area, resulting in changes to direction of the groundwater flow. Although intact portions of the aquifer(s) may still exist beyond the extent of the coal removal area, water availability from within these aquifers will generally be reduced as the water flows towards the active pit in response to a lowering of hydraulic head values. As a result, water levels in existing wells installed in these aquifers may be lowered, potentially reducing the amount of water available for use (e.g., as drinking water) and the amount of water discharged downstream as baseflow.

Mines and preparation facilities may also need to use groundwater resources for their operations. Some mines must continuously pump water either from open pits or underground mine workings to facilitate mining operations. The interception of groundwater and continuous mine pumping lowers the surrounding groundwater table. The lowered groundwater table may affect springs, streams, or users of groundwater resources. In doing so, water levels in affected aquifers may be significantly lowered over long periods of time (OSMRE, 2007). These levels may recover over time once surface mining and reclamation activities are complete and the mine pits fill, saturating the backfilled spoil material.

Groundwater can also be affected when surface water is diverted underground through new fractures in underlying strata. Surface-water that flows into underground mine voids form mine pools, which are an underground accumulation of water where the water fills a void left after coal has been removed. Flooded mines can then induce artesian conditions where water from the flooded mine is higher (but still subsurface) than the surrounding materials that wells are drawing water from, creating a pressure situation where the water will be forced vertically upward in the well. This effect was seen at Spruce Laurel Fork, a perennial stream in Boone County, WV, which was adversely affected by both pre- and post-SMCRA underground mining operations, resulting in the formation of a mine pool. Downstream artesian effects on residential wells then occurred when pumping did not control the mine pool level (Galya, 2008).

4.2.1.2.3 Subsidence and Effects on Surface Water and Groundwater

Underground mining can have significant impacts upon surface waters and groundwater due to subsidence (downward vertical movement of the overlying land surface from the removal of underlying strata). With respect to surface hydrology, the major concern associated with subsidence is that it changes the shape of the overlying surface with commensurate impacts on surface-water flow and drainage. With respect to groundwater, the most common problem is dewatering aquifers above the mined-out coal seam, which most often affects the hydrologic balance outside the permit boundary by adversely impacting baseflow to intermittent and perennial streams. In addition, subsidence within the permit boundary can impact water-quality of the groundwater providing baseflow to the streams outside the permit boundary.

Several studies have documented subsidence-related impacts to hydrologic systems that continue to occur under our existing regulations. These studies are summarized below.

Subsidence from longwall mining continues to affect base flow in affected streams, despite the requirements contained in the current regulations. Carver and Rauch (1994) reported the following findings from a study looking at West Virginia streams affected by subsidence associated with longwall mining:

Subsidence from longwall mining typically reduced stream discharge for two to three years. Panels positioned beneath upland catchment areas and not under streams caused no apparent stream dewatering. … Monitored stream reaches within the angle of draw zone of an adjacent panel did not normally become dewatered for panels older than 2.3 years. However, stream reaches in basins less than 200 acres in size often experienced dewatering for up to 3.1 years after undermining. … After two to three years since mine subsidence occurred recovered streams displayed lower high base flow and higher low base flow discharge, or more uniform base-flow discharge, compared to unsubsided streams.

Subsidence impacts to hydrology are continuing to occur in other regions as well. The USGS conducted several studies describing the effects of longwall mining in Carbon and Emery Counties, Utah. The initial study reported that subsidence had impacted the hydrologic system by loss of flow in reaches of perennial streams, and had increased dissolved solids content in streams and dewatering of the aquifer above the mine workings (Slaughter et al., 1995). The initial study also reported that there was not a clear relationship between mining subsidence and spring discharge. The follow-up study reported on hydrologic and water quality conditions thirteen years after longwall mining (Wilkowske et al., 2007). This study concluded that some of the previously reported impacts still remain, while others appear to have lessened. The persistent effects include increases in the dissolved solids and sulfate content in water samples, increased base flow, and a significant increase in spring discharge.

4.2.1.3 Action Alternatives and Potential Effects on Water Resources

As described in Chapter 2, the SPR Action Alternatives address multiple components of coal mining operations. Table 4.2-1 summarizes how specific SPR elements affect water resources relative to the No Action Alternative (Alternative 1). The comparison of each Action Alternative to the No Action Alternative determines whether and to what extent the Action Alternative creates beneficial or adverse effects on water resources. In general, the Action Alternatives have the potential to benefit water resources in one or more of the following ways:

- Reduce the miles of streams filled by coal mining activities or avoid impacts to streams;
- Increase the number of mined-through ephemeral streams that are restored.
- Improve surface- water quality downstream of coal mining activities; including improving the quality of interconnected surface waters within the watershed (i.e., lakes, ponds, wetlands).
- Preserve surface-water flow that would have been affected by mining activities;
- Increase restoration of streams; and
- Improve the quality and quantity of groundwater that may be affected by coal mining.

For each SPR element, Table 4.2-1 describes: how the requirements for that element vary by Alternative; the anticipated effect on water resources; and the explanation for the anticipated water resource impacts. We note that while the Action Alternatives include restoration to hydrologic form and function of intermittent and perennial streams, OSMRE was not able to identify a meaningful difference between how the Action Alternatives describe these activities and how they are currently being implemented under the No Action Alternative due to existing regulatory requirements, including requirements under the Clean Water Act. Thus, the "primary effects on water resources," column of the table summarizes the impacts of the Action Alternatives with respect to water resources only where meaningful differences from the No Action Alternative are anticipated.

Alternative 9 considers a scenario in which the 2008 Stream Buffer Zone rule is repromulgated and fully implemented across the timeframe of this analysis. Engineering analysis of current coal industry practices finds that, during the period that the 2008 Stream Buffer Zone rule was in place, the permits issued in Appalachia changed in response to USACE, EPA, and state policies that are similar to the No Action Alternative. As a result, Alternative 9 is anticipated to have Negligible effects on water resources.

Table 4.2-1. Action Alternative Elements and Projected Effects on Water Resources

Action Alternative Element	Treatment in Action Alternatives[1]	Primary Effects on Water Resources in Comparison to the No Action Alternative	Explanation
Baseline Data Collection and Analysis	Alternatives 2, 3, 4, 5, and 8 (Preferred) require expanded data collection and analysis. Alternative 2 requires greater monitoring frequency of stream flow, groundwater levels, and rainfall using continuous recording devices. Alternatives 6 and 7 are similar to Alternative 2 with respect to baseline data collection. Alternatives 5, 6, and 7 are limited to specific scenarios. Alternative 9 is the same as the No Action Alternative.	Improve surface-water and groundwater quality Preserve surface-water flow and groundwater quantity Improve characterization of potential impacts to water resources	Enhanced baseline characterization of surface water and groundwater provide a better understanding of the premining hydrologic regime by 1) improving the probable hydrologic consequences determination and the cumulative hydrologic impact assessment; 2) extending the scope of water monitoring parameters to ensure impacts are consistently documented in SMCRA water quality monitoring programs Enhanced baseline monitoring results in a better understanding of the premining hydrology which allows the regulatory authority to ensure that the mining operations are designed to minimize or prevent impacts to water resources
Monitoring During Mining and Reclamation	Alternatives 2, 3, 4, 5, and 8 (Preferred) require expanded data collection and analysis. Alternative 2 requires greater monitoring frequency of stream flow, groundwater levels, and rainfall using continuous recording devices. Alternatives 6 and 7 are similar to Alternative 2 with respect to monitoring. Alternatives 5, 6, and 7 are limited to specific scenarios. Alternative 9 is the same as the No Action Alternative.	Improve surface-water and groundwater quality Preserve surface-water flow and groundwater quantity Improve documentation of impacts to water resources	Enhanced monitoring of surface water and groundwater quantity and quality during mining and reclamation operations allows operators to detect adverse impacts more readily before they cause material damage to the hydrologic balance outside the permit area. Enhanced monitoring extends the scope of water monitoring parameters to ensure impacts which occurred but were not documented under the No Action Alternative SMCRA water monitoring programs do not occur in the future.
Definition of Material Damage to the Hydrologic Balance	Alternatives 2, 3, 4, and 8 (Preferred) include a definition of material damage to the hydrologic balance outside the permit area. Alternatives 5, 6, 7, and 9 are the same as the No Action Alternative. Alternative 7 requires the regulatory authority to determine material damage to the hydrologic balance outside the permit area under enhanced permitting conditions.	Avoid impacts to surface-water and groundwater quality outside the permit areas of coal mines Avoid impacts to surface-water flow and groundwater quantity outside the permit areas of the coal mines	Establishing a definition for material damage to the hydrologic balance outside the permit area should improve protection of perennial and intermittent streams and groundwater outside the permit area and provide an early warning system to prevent adverse impacts from developing to the point that they cause material damage to the hydrologic balance outside the permit area.
Evaluation Thresholds	Alternatives 2, 3, 4, 7 and 8 (Preferred) require evaluation thresholds. Alternatives 5, 6 and 9 are same as the No Action Alternative. Alternative 7 is limited to specific scenarios.	Improve surface - water and groundwater quality Preserve surface-water flow and groundwater quantity	Establishing evaluation thresholds should improve protection of surface water and groundwater outside the permit area, by providing an objective early warning system that could prevent adverse impacts from developing to the point that they cause material damage to the hydrologic balance outside the permit area.
Activities In or Near Streams, Including Excess Spoil	All Action Alternatives require changes to fill placement and design to varying degrees. Alternative 9 is not expected to	Reduce miles of filled streams Improve surface-water and	Limiting activities in or near intermittent and perennial streams should minimize the number and length of intermittent and perennial stream segments disturbed by mining, minimize

Action Alternative Element	Treatment in Action Alternatives[1]	Primary Effects on Water Resources in Comparison to the No Action Alternative	Explanation
and Coal Refuse	lead to changes in mining operations.	groundwater quality	disturbance and adverse impacts to perennial and intermittent stream segments of high environmental value, protect surface and groundwater quality, and ensure that operations promote enhancement of fish, wildlife, and related environmental values wherever and whenever practicable.
Mining through Streams	All Action Alternatives (excluding Alternative 9) require restoration of hydrologic form and ecological function for intermittent and perennial streams and hydrologic form for ephemeral streams that are mined-through.[2] Alternative 9 is not expected to lead to changes in mining operations.	Restore additional ephemeral streams Improve surface-water and groundwater quality Preserve surface-water flow and groundwater quantity	Potential for increase in miles of intermittent and perennial streams with restored hydrologic form and ecological function (not generally anticipated due to change activities anticipated under the No Action Alternative); increase in miles of ephemeral streams restored to hydrologic form after being mined through.
Approximate Original Contour (AOC) Variances	Alternative 2 prohibits AOC variances Alternatives 3, 4, and 5 , require that the permittee demonstrate that watershed would be improved by the mining when compared with the condition of the watershed before mining *and* with its condition if the AOC were to be restored. Alternative 8 (Preferred) requires the permittee to demonstrate one or the other of these two conditions. Alternatives 3, 4, 5, and 8 (Preferred) prohibit approval of an AOC variance if it would result in placement of excess spoil in intermittent and perennial streams. Alternatives 6, 7, and 9 are unchanged from the No Action Alternative.	Reduce streams filled Improve surface-water and groundwater quality Preserve surface-water flow and groundwater quantity	Specific requirements for AOC restoration should result in a surface configuration that more closely resembles and functions like the premining landforms, with convex and concave patterns, and ephemeral channels. Reduce the number and length of intermittent and perennial streams reaches filled with excess spoil.
Surface Configuration and Fills	All Alternatives except Alternatives 6 and 9 require changes to surface configuration and fills to varying degrees. Alternatives 6 and 9 are unchanged from the No Action Alternative.	Reduce streams filled Improve surface-water and groundwater quality	These specific requirements should more completely implement the statutory requirement that the surface configuration of the reclaimed area closely resemble the general surface configuration of the land prior to mining, so that the reclaimed land functions as it did before mining and does not discharge substances that cause material damage to the hydrologic balance outside the permit area. Changes in fill practices are designed to reduce the miles of filled streams.
Revegetation, Topsoil Management, and Reforestation	All Action Alternatives except Alternatives 6 and 9 require changes to revegetation, topsoil management, and reforestation. Alternatives 6 and 9 are unchanged from the No Action Alternative.	Improve surface-water and groundwater quality	Improved revegetation and increased reforestation requirements improve the ability of the postmining landscape to filter pollutants from runoff as water travels across the landscape to receiving surface waters.

Action Alternative Element	Treatment in Action Alternatives[1]	Primary Effects on Water Resources in Comparison to the No Action Alternative	Explanation
Fish and Wildlife Protection and Enhancement	All Action Alternatives, except Alternative 9, require varying protections of streamside vegetative corridors and fish and wildlife.	Improve surface-water quality	Improved ability of the postmining landscape to filter pollutants from runoff as water travels across the landscape to receiving streams because of the enhanced streamside vegetative corridors. Improved surface-water quality and more abundant streamside areas would improve habitat and contribute to survival and abundance of fish and wildlife.

Notes: In addition to the effects discussed above, elements that together or separately have the collective effect of reducing coal mining may also result in the avoidance of adverse downstream impacts of coal mining to streams.
[1] Chapter 2 includes a more complete description of the specific differences in rule elements across the No Action and Action Alternatives. Key points include the following: Alternative 5 applies only to operations that dispose of excess spoil or coal mine waste; Alternative 6 applies only to operations within 100 feet of intermittent or perennial streams; Alternative 7 applies only to operations where conditions warrant enhanced permitting requirements.
[2] While the Action Alternatives additionally specify that mined-through intermittent and perennial streams be restored to form and function, this is also required under the No Action Alternative due to Clean Water Act requirements. This analysis accordingly does not assume restoration of intermittent and perennial streams as a benefit of the Action Alternatives.

Some of the rule elements in Table 4.2-1 would have indirect implications for surface water and groundwater quality that may not be readily measurable or quantifiable. For example, Action Alternatives that require expanded baseline monitoring would help establish a surface water and groundwater baseline that industry and regulatory authorities can use to better assess impacts of mining and the effectiveness of the reclamation. Expanded monitoring programs would also incorporate new pollutants and water quality indicators not previously tracked consistently from mine to mine. This would ensure that impacts from water quality parameters which are not included consistently under SMCRA water monitoring programs throughout the country would be documented in the future. Water quality parameters monitored under approved SMCRA water monitoring programs may be vastly different from mine to mine and state to state due to various reasons. Depending on the quality of the overburden, coal seams, and interburden, different pollutants of concern may be identified for each unique coal mining region or on a mine specific basis. However, some state SMCRA programs have outdated guidance documents dictating the terms of water monitoring programs which do not adequately capture all the possible pollutants resulting from coal mining operations in their areas or at specific mines. In other cases mine operators may submit acid/toxic forming materials testing reports for coal mining permits which do not adequately identify all possible pollutants in the coal seams, overburden, and interburden (between coal seams) which could impact water quality. Expanded water quality monitoring would increase the consistency of SMCRA water monitoring programs and ensure that all impacts occurring or likely to occur are identified and addressed.

Alternative 2 would require more frequent monitoring, which may increase the likelihood that water quality problems are detected early, when more effective and less costly corrective measures are possible. Finally, improved monitoring may enhance the ability to prevent unintended adverse impacts to surface water and groundwater. For example, increased groundwater monitoring may detect changes in groundwater levels, allowing appropriate action to decrease the risk of dewatering the aquifer, and avoiding reduced baseflow to surface waters. Although these types of impacts are indirect and site-specific, they have the potential to provide additional impacts to the more readily quantifiable impacts of elements such as riparian buffers.

The remainder of this section focuses on the expected improvements to water resources described in Table 4.2-1. As described in Table 4.2-1, the effects of the Action Alternatives on water resources fall under five categories: 1) reduce stream fills; 2) improve surface-water quality; 3) preserve surface-water flow; 4) improve groundwater quality and quantity; and 5) increase stream restoration.

4.2.1.3.1 Reduce Miles of Filled Streams

The Action Alternatives have the potential to reduce the miles of filled streams from surface and underground mining activities. Table 4.2-2 identifies the rule elements that relate to stream miles filled relative to the No Action Alternative. In general, the Action Alternatives would restrict fill amounts or the type of fills allowed to varying degrees. All the Action Alternatives require the minimization of excess spoil volume and, except for Alternative 9, the Action Alternatives would prohibit end-dumping techniques in constructing durable rock fills. Alternative 2, 4, 5, 6, 7, and 8 (Preferred) prohibit flat decks on top of excess spoil fills, which are allowed under the No Action Alternative and Alternatives 3 and 9. Alternative 2 would prohibit fills within 100 feet of intermittent and perennial streams. The other Action Alternatives would impose differing restrictions on fills in these areas.

4.2.1.3.2 Improve Surface Water Quality

The Action Alternatives (excluding Alternative 9) are expected to generate improvements to downstream water quality as compared to the No Action Alternative. Improvements to surface water quality are not limited to onsite streams, but persist downstream of the mine sites as the water flows through and off of the mine. The primary rule elements expected to generate improvements in downstream water quality for each Action Alternative are identified in Table 4.2-3. In general, Alternatives 2, 3, 4, and 8 (Preferred) would provide similar protections to downstream water quality by increasing the amount of monitoring required, defining material damage to the hydrologic balance, and establishing evaluation thresholds to determine when preventative actions are required to avoid material damage to the hydrologic balance. Increased monitoring would provide better information for early identification of water quality impacts. Alternative 2 would require more frequent monitoring than the other Action Alternatives, possibly allowing earlier detection of water quality degradation.[13] Defining material damage to the hydrologic balance, and establishing evaluation thresholds to determine when preventative actions are required to avoid material damage to the hydrologic balance, sets protective limits on downstream water quality and creates a mechanism for correcting problems before damage has occurred, which would improve downstream water quality. Alternative 7 includes no standard material damage to the hydrologic balance definition but defines material damage to the hydrologic balance on a permit-specific basis. Alternative 8 (Preferred) includes similar provisions as 2, 3, and 4.

Riparian buffers would also benefit surface water quality as riparian vegetation decreases flow velocity, limiting the mobility of sediment to receiving surface water bodies. One recent study in the Illinois Basin documents the effectiveness of riparian buffers in reducing water quality impacts from coal mining (Willard et al., 2013). The Alternatives differ with respect to the size of the riparian buffers prescribed and the type of streams where streamside vegetative corridors are required. Specifically, Alternatives 2, 5, 6, 7, and 8 (Preferred) specify a 100-foot streamside vegetative corridor for all streams, whereas Alternatives 3 and 4 specify a larger streamside vegetative corridor (300 feet) for a narrower set of streams (only intermittent and perennial, but not ephemeral streams). The wider stream corridor under Alternatives 3 and 4 would provide increased protection against sediment and chemical runoff to streams, but ephemeral streams would have no buffer-based protections.

Additionally, for approximate original contour (AOC) exceptions for mountaintop removal operations, Alternatives 3, 4, and 5 (Alternative 5 only applies to operations that dispose of excess spoil or coal mine waste) would generate improvements to surface-water quality by requiring a demonstration of (1) no damage to natural watercourses within the proposed permit and adjacent areas; (2) no increase in parameters of concern in discharges to surface water or ground water; (3) no change in size or frequency of peak flow as compared to what would occur if the operator returned the site to AOC; and (4) no variance in total flow volume during any season of the year. Similarly, for steep-slope operations, these Alternatives would require demonstration that AOC variances would improve surface water flow and limit aquatic ecological impacts. Alternative 2 would prohibit all variances from the requirements to return the mined area to its AOC. This should ensure that postmine surface configuration resembles and functions more like the premining landforms, reducing stream fills, improving stream-water and groundwater quality, and preserving streamflow and groundwater-flow quantity

Alternatives 5, 6, and 7 would not require all of the elements described above and would apply to fewer mining operations. Alternative 5 applies to limited areas of steep-slope mining with excess spoils and does not contain either a definition of "material damage to the hydrologic balance outside the permit area"

[13] Peer reviewers noted that increased monitoring may not translate directly into better environmental protection if regulatory authorities are not sufficiently staffed to handle the added data review workload. Reviewers noted that some kinds of pollution (e.g., storm-related runoff events) that could be missed by monitoring are better addressed preventatively, i.e., through carefully prepared and implemented reclamation plans. Communication from Jack Nawrot, "OSMRE Proposed Stream Rules: Comments – Water and Biological Resources." Potential additional burden on the regulatory authorities of compliance with Alternatives is discussed in section 4.1.

or evaluation thresholds. Alternative 7 applies only when enhanced permitting conditions exist, as described in Chapter 2, and does not contain either a definition of "material damage to the hydrologic balance outside the permit area" or additional surface-water protections for AOC exceptions. Alternative 6 provisions apply only to activities inside stream buffer zones, does not contain a definition of "material damage to the hydrologic balance outside the permit area," evaluation thresholds or additional surface water protections for AOC exceptions. Consequently, these three Action Alternatives provide a lesser benefit to downstream water quality than Alternatives 2, 3, 4, and 8 (Preferred).

Table 4.2-3. Elements Benefiting Downstream Water Quality

Alternative	Additional Monitoring	Definition of Material Damage to the Hydrologic Balance	Evaluation Thresholds	Streamside vegetative corridor for Ephemeral, intermittent, and perennial Streams (100 feet on either side of streams)	Riparian Buffer for intermittent and perennial Streams (300 feet on either side of streams)	Additional Surface Water Protections in Issuing AOC Variances

7	●		●	●		
8 (Preferred)	●	●	●	●		●
9						

Other rule elements may contribute indirectly to improvements in downstream water quality by reducing negative effects of mining activities on water resources on the mine site. These include reduced stream filling on mine sites and improved postmining reforestation and revegetation practices. For example, Alternatives 2 through 8 (Preferred) would reduce filling of streams from surface mines. In addition, all Action Alternatives, except Alternative 6 and 9, would improve revegetation, topsoil management, and reforestation practices, changes which benefit water quality through reduced sedimentation.

While not attributable to a particular element, the Action Alternatives (excluding Alternative 9) would collectively yield slight changes in the amount of coal produced in particular coal regions, as described in Section 4.1. Decreases in coal production in a given region would reduce the effects of coal mining on downstream water quality.[14] The impacts of reduced mining activity would reduce effects on water

[14] Note that reduced mining impacts resulting from decreased coal production are realized only during the study period of this analysis. Ultimately, market forces will lead to the extraction of all minable coal resources, even if new environmental requirements are imposed.

quality across all relevant mining processes. In addition, some Alternatives could lead to a reduction in the size of the disturbed area in surface mines, further preserving water quality in the relevant regions. The quantitative analysis discussed later in this section estimates the miles of streams where water quality would be preserved (i.e., adverse effects avoided) due to the reduction in intensity of coal mining activity under each Alternative.

Under each Alternative, water quality in receiving water bodies, such as lakes, ponds, and wetlands, is expected to vary in a manner consistent with changes in connected water resources. For instance, if a stream experiences improved water quality, the pond into which it feeds may experience improved water quality (all else equal). The magnitude of the improvement is uncertain as it depends on many other factors, such as the size of the pond, the rate of inflow and outflow, and other factors.

4.2.1.3.3 Preserve Stream Flow

Multiple rule elements contribute to the Action Alternatives' focus on preserving stream flow, as described in Table 4.2-4, which in turn should protect regional groundwater levels due to the hydrologic connectivity between surface and groundwater. Additional monitoring related to surface water flow and groundwater levels is required under Alternatives 2, 4, 6, and 8 (Preferred) and also to 7 (when enhanced permitting requirements apply); this monitoring enables early identification of impacts of the mining activity on hydrologic conditions. Documentation of stream hydrologic form and function is not required under the No Action Alternative, but it is required under all Action Alternatives (with the exception of Alternative 9). This reflects the additional focus of the Action Alternatives on addressing effects of mining on stream flow and hydrology.

Alternatives 2, 3, 4, and 8 (Preferred) additionally require defining material damage to the hydrologic balance outside the permit area. By directing regulatory authorities to demonstrate that the operation has prevented material damage to the hydrologic balance outside the permit area would enhance efforts to preserve stream flow. Alternatives 2, 3, 4, 7, and 8 (Preferred) additionally require that regulatory authorities develop evaluation thresholds that are less than the thresholds the regulatory authority developed for material damage to the hydrologic balance outside the permit area. This would help to ensure that mining operations avoid material damage to the hydrologic balance outside the permit area and further serves to preserve stream flow.

The Action Alternatives would additionally serve to protect stream flow by imposing new requirements for restoration to form of mined-through ephemeral streams (as described below). In addition, Alternatives 2, 3, 4, 5, and 8 (Preferred) would all limit the extent with which AOC variances will be approved. Alternative 2 would prohibit AOC variances altogether, whereas Alternatives 3, 4, 5, and 8 (Preferred) would require a permit applicant to demonstrate improvement in the condition of the watershed given restoration of the AOC. The purpose of these requirements would be to minimize effects of mining on surface water flows.

In summary, Alternative 2 is the most protective of surface water flows as it is associated with the greatest levels of additional monitoring and documentation, establishment of evaluation thresholds, restoration to hydrologic form of mined through ephemeral streams, and prohibitions on AOC variances. Alternative 4 is similarly protective while allowing the possibility of some AOC variances. Alternative 3 is similar to Alternative 4 without the additional monitoring requirements for stream flow and groundwater levels. Next most protective is Alternative 8 (Preferred). Alternatives 5, 6, and 7 are less protective of stream flow and Alternative 9 does not include additional protections beyond the No Action Alternative.

Table 4.2-4. Elements Benefiting Surface Water Flows

9						

4.2.1.3.4 Increase Stream Restoration

The No Action Alternative requires restoration of intermittent and perennial streams that are mined through, predominantly as a result of existing CWA requirements. In general, mining is allowed through intermittent and perennial streams upon demonstration by the applicant that the reclamation plan would achieve restoration in accordance with standards established by the CWA permitting authority. As such, this analysis finds that the Action Alternatives would not generally affect the manner in which restoration would have occurred under the No Action Alternative for these intermittent and perennial streams.

The Action Alternatives do, however, all include requirements for restoration of the hydrologic form of mined-through ephemeral streams, which would not be expected to be universally practiced under the No Action Alternative. Specifically, Alternatives 2 and 4 would require restoration of all mined-through ephemeral streams in form. Alternatives 3, 5, and 6 would require restoration of mined-through ephemeral streams to form as well, but with the added stipulation that this applies only to the extent required by geomorphic reclamation. Alternative 8 (Preferred) would also require restoration of mined-through ephemeral streams to form but not using geomorphic reclamation.

4.2.1.3.5 Improve Groundwater Quality and Quantity

The Action Alternatives (excluding Alternative 9) would generate improvements to groundwater quality and/or quantity as compared to the No Action Alternative. The relevant rule elements of each Action Alternative are identified in Table 4.2-5.

In general, Alternatives 2, 3, 4, and 8 (Preferred) would provide similar protections to groundwater quality and quantity by: (1) increasing monitoring requirements in order to detect material damage to the hydrologic balance outside the permit area; (2) requiring a definition of when material damage to the hydrologic balance outside the permit area occurs; and (3) establishing evaluation thresholds to determine when an evaluation would be undertaken to determine if action is needed to avoid material damage to the hydrologic balance outside the permit area. Alternative 7 defines material damage to the hydrologic balance outside the permit area on a case-by-case basis whenever enhanced permitting conditions (e.g., the presence of unique hydrologic environments) exist. Alternatives 5 and 6 require additional monitoring but do not require a definition of material damage to the hydrologic balance or establish evaluation thresholds. As a result, Alternatives 5, 6, and 7 present less potential for alerting regulators to groundwater quality and quantity issues and contain less clear standards for restoring groundwater quality.

Additionally, Alternatives 3, 4, 5, and 8 (Preferred) would improve groundwater quality through AOC variance conditions. Specifically, for AOC variances for mountaintop removal operations, Alternatives 3, 4, 5, and 8 (Preferred) would require a demonstration of no increase in parameters of concern in discharges to groundwater. Alternative 2 disallows AOC variances altogether. As a result of more frequent monitoring and the ban on AOC variances, Alternative 2 is anticipated to generate the greatest improvements to groundwater quantity and quality.

Alternatives 5, 6, and 7 would not include blanket provisions for material damage to the hydrologic balance outside the permit area definition and evaluation thresholds, but would pertain to a more specialized segment of mining activity: Alternative 5 applies only to operations that dispose of excess spoil or coal mine waste; Alternative 6 applies only to operations within 100 feet of intermittent or perennial streams; Alternative 7 applies only to operations where conditions warrant enhanced permitting requirements (e.g., steep slope areas, and riparian areas). These Action Alternatives, therefore, would provide a lesser benefit to groundwater than Alternatives 2, 3, 4 and 8 (Preferred) because of more limited application and fewer concrete standards against which to judge compliance with permit conditions. Alternative 9 has provisions similar to the No Action Alternative, so it would likely provide no incremental benefit to groundwater.

Table 4.2-5. Elements Benefitting Groundwater Quality or Quantity

Alternative	Additional Monitoring	Definition of Material Damage to the Hydrologic Balance	Evaluation Thresholds	Additional Groundwater Quality Protections in AOC Variances
2	●	●	●	(prohibits AOC variances)
3	●	●	●	●
4	●	●	●	●
5	●			●
6	●			
7	●		●	
8 (Preferred)	●	●	●	●
9				

Other rule elements may also contribute indirectly to improvements in or preservation of groundwater quality or quantity by reducing negative effects of mining activities on water resources on the mine site. These include elements that reduce filling of streams on the mine site and improve postmining reforestation and revegetation practices.

4.2.1.4 Analytic Methods for Surface Water Resources

This section describes the methods used to characterize the impact of the Action Alternatives on surface water resources. Overall, the approach involves quantifying the linear extent of streams (measured in stream miles) affected within each region under each Action Alternative. The quantified factors include:

- **Reduction in streams filled**. These are streams that would have been filled under the No Action Alternative, but are not filled due to the implementation of the Action Alternative.
- **Increased restoration of ephemeral streams that are mined through**. These are streams that would have been mined through and not restored under the No Action Alternative, but are restored due to the implementation of the Action Alternative. Because intermittent and perennial streams are generally already restored under the No Action Alternative, this metric applies to ephemeral streams.
- **Stream miles downstream of mine sites experiencing improved water quality**. These are streams that would have been impaired due to mining activities under the No Action Alternative, but would have less impairment due to implementation of the Action Alternative.
- **Stream miles that are preserved from adverse effects of mining**. These are streams that would have been impaired due to mining activities, but does not experience water quality impacts due to reduced mining activity associated with the Action Alternative.

Table 4.2-6 describes the steps involved in estimating the impacts of the Alternatives on each of these quantified factors. The subsequent text describes the methods in greater detail.

4.2.1.4.1 Reduction in Miles of Streams Filled and Increased Restoration of Ephemeral Streams

As described in Table 4.2-6, the method to quantify the reduction in stream miles filled and in ephemeral stream miles restored is a direct extrapolation from the model mine analysis described in Section 4.1. That is, the model mine analysis determines how mines in each coal region would implement the Action Alternatives, and how these practices would affect stream fill and stream restoration. As such, for each model mine and for each Alternative, engineers altered the design in order to take into consideration each Alternative requirement. In most cases, the revised mine designs did not show changes in the lengths of intermittent or perennial streams filled as a result of existing baseline requirements. However, the Action Alternatives resulted in a reduction in the number of ephemeral streams filled in many areas compared to the No Action Alternative because existing requirements were found to be generally less protective of ephemeral streams.

To quantify the broader benefits of the Action Alternatives, the analysis translates the reduction in streams filled and the increase in stream miles restored into an average change in impacts per ton of coal that would be produced for each modeled mines in each region. Then the analysis applies this multiplier (streams filled per ton of coal produced) to the estimated production (tons of coal produced) in each region under each Alternative.

Table 4.2-6. Methods for Quantification of Benefits to Water Resources

Step	Reductions in Miles of Perennial, Intermittent, and Ephemeral Streams Filled	Additional Miles of Ephemeral Streams Restored	Perennial and Intermittent Stream Miles Downstream of Mine Sites Experiencing Improved Water Quality	Perennial and Intermittent Stream Miles Downstream of Mine Sites that are Preserved from Adverse Effects of Mining
1	For each Alternative, including No Action, determine number of stream miles filled by region based on conditions at the "typical mine"	For each Alternative, including No Action, determine number of ephemeral stream miles restored by region based on conditions at the "typical mine"	Based on scientific literature, determine how far downstream of a mine site negative effects of coal mining persist. Limited data require use of a national average rather than mine-specific figures.	Analyze, by region and mine type (i.e., surface versus underground), the number of streams that flow off of a mine site, on average
2	For each Alternative, convert to impact per million tons of coal produced by region/mine type, i.e., divide "typical mine" miles of streams filled by total "typical mine" coal production	For each Alternative, convert to impact per million tons of coal produced by region/mine type, i.e., divide "typical mine" miles of ephemeral streams restored by total "typical mine" coal production. 4.2.1.4.2 Stream Miles Downstream of Mine Sites Experiencing Water Quality Improvements

The analysis uses the following method to estimate the number of improved stream miles downstream of mine sites. First, the analysis incorporates findings from the scientific literature to estimate how far downstream of a mine site negative effects of coal mining persist. The scientific literature addressing effects of coal mining on water resources primarily focuses on how coal mining affects surface water quality, as summarized in Table 4.2-7. As described below, the studies find evidence of elevated levels of arsenic, selenium, iron, aluminum, sulfate, and manganese, as well as increased acidity and elevated conductivity in downstream waters from coal mining sites, and demonstrate the need for additional regulation focused on reducing these impairments.

The history and extent of mining in the Appalachian Basin makes it the subject in the majority of the water quality studies (e.g., Lindberg et al., 2011, Merriam et al., 2011, Petty et al., 2010, Pond et al., 2008, Fulk et al., 2003). In addition, authors have also noted that due to the arid climate and high mineralization of surface water, analyses of this type are more difficult in western regions (Powell, 1988). In general, these studies describe coal mining's effects on stream quality but do not specify the particular management practices at mine operations (e.g., blasting, spoil movement, coal stockpiling, reclamation practices, etc.) that generate the adverse effects. As such, the studies do not support an explicit analysis of the Action Alternative elements' impact on downstream water quality as the effects are significantly variable and site-specific. Data are also currently insufficient to develop a model that forecasts a specific level of water quality improvement expected from the Action Alternatives (e.g., a specific reduction in the presence of a particular pollutant or improvement in stream health metrics, such as EPT richness) downstream of each future mine site. In other words, no scientific studies or data allow us to forecast the beneficial effects of the SPR on water quality with certainty. In light of current data limitations and in order to provide perspective on the level of downstream water quality benefit generated by the rule alternatives, this analysis estimates the downstream stream distance over which adverse effects of mining may occur absent Action Alternatives, and which may benefit from implementation of these Alternatives.

Environmental Geology and Water Sciences	Streams in or near eastern and western coal fields	Degraded water quality in streams associated with coal mining is readily detectable in the eastern U.S. because of the low mineralization of natural water. Effects of coal mining in western U.S. streams are more difficult to detect due to the arid climate and high mineralization in the waterways.
1. Study not published in the peer reviewed literature.			

Specifically, this analysis relies on the scientific literature and GIS data on locations of existing and historical coal mines and USGS data on stream locations in order to estimate the linear extent of the waters downstream of mines in each region that are expected to benefit (i.e., experienced reduced levels of impairments) from the protection measures described in the Alternatives. These adversely affected streams are expected to benefit from improved management practices as part of the Action Alternatives. The region-specific multipliers estimating the downstream distance of impairments applied in the analysis integrate information on: the average size of mine sites in each region; the number of intermittent and perennial streams that have crossed mine sites on average in each region (ephemeral streams were not included in the analysis of downstream water quality benefits); and the distance over which the negative water quality effects persist. The steps of this analysis are described below.

4.2.1.4.3 Step 1: Analyze, by region and mine type (i.e., surface mining versus underground mining), the number of streams that flow off of a mine site, on average

This analysis employs GIS data identifying locations of historical mines in each region by mine type.[15] As the GIS data are only points identifying locations of historical mines, the analysis estimates the size of each mine site relying on the size of the "disturbed area" for typical mines, as estimated in the model mines analysis described in Section 4.1. After mapping the location and size of historical surface and underground mines in each region, the analysis references the U.S. Geological Survey's high resolution National Hydrography Dataset to estimate the average number of intermittent and perennial streams flowing off of surface and underground mines in each region.[16]

For these historical surface mines, between one and seven streams cross each mine site, and the average varies by region. An average of one stream flows through the surface portion of underground mines (consistent with the structure of coal preparation facilities at underground mines). Exhibit 4.2-8 presents the results of the GIS analysis quantifying number of streams crossing mine sites. Of note, while the Northern Rocky Mountains region surface mines are associated with the greatest number of intermittent and perennial crossings, this is due to the relatively large disturbed area covered by these mines. In fact, the stream density in the Northern Rocky Mountains region is significantly less than in Appalachia.

[16] To estimate the average number of streams flowing off of the mine site, this analysis counts the number of times perennial and intermittent streams intersect the mine site and divides this by two. This method assumes that each stream crosses the mine site once upstream of the mine and once downstream of the mine. Due to data limitations related to the streams data available ephemeral streams are not included in these calculations. As a result, these estimates could underestimate stream lengths that may benefit from rule alternatives, to the extent that ephemeral streams are present downstream of mine sites. The analysis uses USGS classifications to differentiate streams.

Table 4.2-8. Number of Stream Crossings at Mine Sites

Region/Mine Type	Average Number of Streams Crossing Mine Site
Central Appalachia -- Contour and Surface Area	3.1 streams[a]
Northern Appalachia -- Surface	1.3 streams
Colorado Plateau -- Surface	3 streams[b]
Gulf Coast -- Surface	4.3 streams
Illinois Basin -- Surface	3.4 streams
Northern Rocky Mountains -- Surface	7.2 streams
Western Interior -- Surface	3.3 streams
Northwest -- Surface	5 streams[c]

Notes:
The analysis of downstream benefits to water quality is assumed to be associated with improvements to mining practices at surface mines, which is where the majority of anticipated changes to mining practices are anticipated. To the extent that underground mines also change practices that would improve water quality, benefits could be underestimated.
This exhibit provides the estimated number of intermittent and perennial streams that cross mine sites in each of the regions, on average. These averages were generated by conducting a USGS analysis of data on intermittent and perennial stream locations to the locations and extents of current and historical mines in each region. Due to data limitations related to the streams data available ephemeral streams are not included in these calculations. As a result, these estimates could underestimate stream lengths that may benefit from rule alternatives, to the extent that ephemeral streams are present downstream of mine sites.
[a] The number of stream crossings for all mines does not change across alternatives, with the exception of Alternative 2, where the Central Appalachian surface mine is anticipated to disturb a smaller area and therefore intersects fewer intermittent and perennial streams. For this mine under Alternative 2, the number of stream crossings is 2.7.
[b] The Colorado Plateau surface mine figure is the average of the number of streams leaving the mine site from the one surface mine site in the GIS database for the Colorado Plateau and the Colorado Plateau surface mine site in the engineering analysis.
[c] The Northwest surface mine figure is the number of streams leaving the Northwest surface mine site in the engineering analysis as there are no sites that meet the criteria for the GIS analysis.

4.2.1.4.4 Step 2: Determine how far downstream of a mine site negative effects of coal mining persist, on average

Limited literature exists evaluating how far downstream of coal mines negative water quality impacts persist. One study, Petty, et al. (2010), indicates that the downstream effects of mining may extend approximately 6.2 miles from the mine site on average in Appalachia. The Petty, et al. (2010) research includes stream sampling from both underground and surface mining and includes both pre- and post-SMCRA mining activities in the Appalachian coal region. While this study is focused on Appalachia, absent comparable studies in other regions, this finding is applied across the coal regions for the purposes of this analysis and to compare projected impacts of each action alternative. OSMRE recognizes that transferring this study to other regions generates uncertainty for the downstream water quality improvements results outside of Appalachia. However, because this analysis finds that the vast majority of downstream water quality impacts occur in Appalachia due to the combination of the geologic and hydrologic environments associated with the coal mines, OSMRE feels that using the 6.2 miles determined in the 2010 Petty et al., study was acceptable as a standardized assumption metric to bring forward into the mine model.

The adversely affected downstream reaches (6.2 miles for intermittent and perennial streams downstream of coal mines) are expected to benefit from improved management practices as part of the Action Alternatives, as described above.

4.2.1.4.5 Step 3: Multiply the number of streams crossing the mines (Step 2) by the average extent of downstream water quality effects (Step 1) to estimate the "typical mine" downstream miles affected

The third step of the analysis multiplies the average number of streams crossing the mines by the average spatial extent of downstream water quality effects (6.2 miles) to estimate the total number of downstream stream miles affected by coal mining for each region/mine type under the baseline for this analysis.

Note that the estimate of total downstream stream miles affected at a given mine implicitly assumes no downstream convergence. This assumption allows for a comparison across regions that reflects the stream density of different regions. However, it is likely that, streams crossing the mine sites ultimately converge. In such cases, the total number of stream miles experiencing improved water quality may be overestimated. On the other hand, the level of the water quality improvement may be greater downstream of the convergence of two improved streams.

4.2.1.4.6 Step 4: Estimate downstream impact per million tons of coal produced by region/mine type

To estimate region-specific multipliers for linear downstream extent affected per unit of coal production, OSMRE divides the total downstream miles affected by coal mining activity (Step 3) by the forecasted total volume of coal production at each typical mine site over the life of the mine. This calculation yields an estimate of average miles of surface water quality affected per million tons of coal produced.

After factoring in the region-specific information on average mine size, number of streams affected, and coal production levels, the multipliers are larger for Appalachia than for other regions. Specifically, the analysis finds that on the order of 0.5 to 4.8 stream miles are impaired per million tons of coal produced in Appalachia, compared to 0.04 stream miles impaired per million tons of coal produced in the Northern Rocky Mountains and Great Plains region. The difference is due to the greater production levels and larger aerial extent of mines in the Northern Rocky Mountains and Great Plains region, and to the greater density of intermittent and perennial streams in Appalachia (see Table 4.2-9).

4.2.1.4.7 Step 5: Multiply the downstream miles affected per million tons by the expected coal production for the relevant mine type/region over the study period (Table 4.2-9, Column G); and Step 6: Sum downstream miles affected across the study period

In this step, the estimated coal production forecast over the study period for each region is multiplied by the multiplier calculated in Step 4 (impacts per-million-ton downstream effects). Because there are three surface mines types designed in Appalachia, the forecast regional coal production was weighted by the volume of coal production for each of these mine types as follows: CAPP Area mine= 20 percent; CAPP Contour mine=54 percent; NAPP Contour=26 percent.

4.2.1.4.8 Step 7: Estimate average annual downstream miles affected by dividing total downstream miles affected over the entire study period (Step 6) by the number of years in study period (21 years)

Dividing the total miles of downstream water quality affected over the study period by the number of years of analysis (21) yields an average annual downstream water quality impact in miles.

4.2.1.4.9 Step 8: Estimate benefit of the Action Alternatives by subtracting anticipated annual average miles from No Action Alternative annual average miles

The analysis calculates these results for each region and mine type, for the No Action Alternative and each of the Action Alternatives. As the Action Alternatives improve the management of mining operations to mitigate effects on water quality (as described above), the stream reaches downstream of the mine sites would experience some amount of improvement in water quality as compared to the No Action Alternative. Improvement in water quality does not mean that an impaired stream is returned to premining conditions; rather, improvement is considered an incremental betterment of water quality.

These analytic steps and results are provided in Table 4.2-9 for Alternative 8 (Preferred) in order to illustrate the methods used to calculate the downstream improved intermittent and perennial stream miles. Downstream improved intermittent and perennial stream miles for other Action Alternatives are calculated in the same manner.

Table 4.2-9. Calculations for Downstream Improved Intermittent and Perennial Stream Miles under Alternative 8 (Preferred)

Region and Surface Mining Type (Model Mine) [1]	Average number of I&P streams crossing mine site[2] (Step 1)	Downstream reach over which negative effects of mining persist[3] (Step 2)	Total length of stream adversely affected by mining per mine site (Step 3)	Recoverable coal per mine site (over life of mine, million tons (MT))[4]	Downstream reach over which negative effects of mining persist per million tons (MT) of coal produced (Step 4)	Average annual production in region for this mining method/type[5]	Average annual stream miles experiencing water quality improvements in region (over 21 years, Steps 5-8)
Central App. Surface Area	3.1 streams	6.2 miles	19.2 miles	37 MT	0.5 miles/MT	10.3 MT	5 miles
Central App. Contour	3.1 streams	6.2 miles	19.2 miles	5 MT	3.8 miles/MT	27.5 MT	104 miles
Northern App. Surface Contour	1.0 miles	6.2 miles	7.8 miles	1.6 MT	4.8 miles/MT	13.4 MT	65 miles
Colorado Plateau Area Surface	3.0 streams	6.2 miles	18.6 miles	92.2 MT	0.2 miles/MT	18.2 MT	4 miles
Gulf Coast Area Surface	4.3 streams	6.2 miles	26.6 miles	40.7 MT	0.7 miles/MT	44.7 MT	29 miles
Illinois Basin Area Surface	3.4 streams	6.2 miles	20.9 miles	12.4 MT	1.7 miles/MT	19.7 MT	33 miles
Northern Rocky Mountains Area Surface	7.2 streams	6.2 miles	44.5 miles	1,056 MT	0.04 miles/MT	388 MT	16 miles
Northwest Area Surface	5 streams	6.2 miles	31.0 miles	37 MT	0.8 miles/MT	1.0 MT	1 mile
Western Interior Area Surface	3.3 streams	6.2 miles	20.2 miles	12.4 MT	1.6 miles/MT	2.8 MT	4 miles

1 The analysis of downstream benefits to water quality is assumed to be associated with improvements to mining practices at surface mines, which is where the majority of anticipated changes to mining practices are anticipated. To the extent that underground mines also change practices that would improve water quality, benefits could be underestimated.

2. Analysis includes only estimated number of intermittent and perennial streams that cross mine sites in each of the regions, on average. These averages were generated by comparing USGS data on intermittent and perennial stream locations to the locations and extents of mines in each region. Due to data limitations related to the streams data available ephemeral streams are not included in these calculations. As a result, these estimates could underestimate stream lengths that may benefit from rule alternatives, to the extent that ephemeral streams are present downstream of mine sites. Please refer to Exhibit 4.2-8 for additional details.

3. Limited literature exists evaluating how far downstream of coal mines negative water quality impacts persist. One study, Petty, et al. (2010), indicates that the downstream effects of mining may extend approximately 6.2 miles from the mine site on average in Appalachia. The Petty, et al. (2010) research includes stream sampling from both underground and surface mining and includes both pre- and post-SMCRA mining activities in the Appalachian coal region. While this study is focused on Appalachia, absent comparable studies in other regions, this finding is applied across the coal regions for the purposes of this analysis and to compare projected impacts of each action alternative. OSMRE recognizes that transferring this study to other regions generates uncertainty for the downstream water quality improvements results outside of Appalachia. However, because ultimately this analysis finds that the vast majority of downstream water quality impacts occur in Appalachia are due to the combination of the geologic and hydrologic environments associated with the coal mines, which are also found in the other coal regions, OSMRE feels that using the 6.2 miles determined in the 2010 Petty et al., study was

Region and Surface Mining Type (Model Mine) [1]	Average number of I&P streams crossing mine site[2] (Step 1)	Downstream reach over which negative effects of mining persist[3] (Step 2)	Total length of stream adversely affected by mining per mine site (Step 3)	Recoverable coal per mine site (over life of mine, million tons (MT))[4]	Downstream reach over which negative effects of mining persist per million tons (MT) of coal produced (Step 4)	Average annual production in region for this mining method/type[5]	Average annual stream miles experiencing water quality improvements in region (over 21 years, Steps 5-8)

acceptable as a standardized assumption metric to bring forward into the mine model.
4. From the model mines analysis, each model mine is assigned a volume of annual coal production and total volume of recoverable coal based on local geological conditions.
5. While production varies from year to year over the 21 year study period, this column reflects average annual production for each mine type across the study period. Because there are three surface mines types designed in Appalachia, the forecast regional coal production was weighted by the volume of coal production for each of these mine types as follows: CAPP Area mine= 20 percent; CAPP Contour mine=54 percent; NAPP Contour=26 percent.

4.2.1.4.10 Stream Miles Downstream of Mine Sites Preserved from Adverse Effects of Mining

This analysis estimates the downstream miles for which adverse effects are avoided. This change in stream miles affected would derive from changes in the volume of coal that is mined from surface mines, and assumes that reducing coal production would reduce the extent of downstream impacts on streams that would have occurred under the No Action Alternative. For each Action Alternative, the difference between the length of downstream affected stream miles in the No Action Alternative minus the length of downstream affected stream miles estimated for the Action Alternative represents the length of miles preserved for that Alternative. The No Action Alternative calculation follows the same steps as the Action Alternatives, except the results are for stream miles *affected by coal mining (i.e., avoided),* rather than stream miles *improved.* In cases where production increases for a particular region and mine type, the downstream stream miles preserved can be negative, reflecting an increase in downstream stream miles affected by mining in a given year.

4.2.1.5 Results of Quantitative Analysis of Surface Water Impacts

4.2.1.5.1 Streams

The results of the quantitative analysis are presented in Tables 4.2-10 through 4.2-13. Discussion of the results follows.

- **Reductions in streams filled:** The quantified reduction in the miles of filled streams varies across regions and Action Alternatives (Table 4.2-10). The Appalachian Basin is the only region where excess spoil fills are common, making it the only region where a change in stream filling practices is anticipated.[17] Reduced fill benefits of the Action Alternatives (other than Alternative 9, which does not have these benefits) on surface mining are accordingly limited to this region.
- **Increase in ephemeral stream restoration:** Ephemeral stream restoration also varies by region and Action Alternative (Table 4.2-11). Under the No Action Alternative, ephemeral stream restoration practices are limited; specifically occurring only in the Colorado Plateau and Northern Rocky Mountains regions. Review of existing permits in these regions identified that the actual number of ephemeral streams that were restored was small (approximately 10 to 20 percent). Elsewhere, ephemeral stream restoration is generally not expected to occur under the No Action Alternative. As more ephemeral streams occur in the Colorado Plateau, Gulf Coast, Illinois Basin, and Northern Rocky Mountains and Great Plains regions, the benefits of ephemeral stream restoration requirements are concentrated in these regions. Alternative 5 applies specifically to steep slope mining areas (primarily, the Appalachian region), where there are generally fewer ephemeral streams than in the more westerly regions, thus benefits of additional stream restoration for this Alternative are limited.
- **Downstream miles experiencing improved water quality:** The majority of improved stream miles occur in Appalachia, as small mine size and high stream density leads to high per-ton effects on downstream stream miles (Table 4.2-12). The level of improvement would vary across the Action Alternatives in a manner that would be consistent with the stringency of the

[17] Illinois Basin ephemeral streams are sometimes used in the construction of sediment basins or slurry impoundments.

requirements. As detailed in Table 4.2-1, rule elements related to monitoring and the definition of material damage to the hydrologic balance have the potential to improve water quality at and downstream of surface mine sites. Changes in mine site practices related to stream restoration and fills are intended to benefit downstream water quality. The engineering analysis (model mines analysis) found that direct stream impacts from underground mines were temporary; therefore, downstream improved miles from underground mines are not quantified. However, rule elements related to monitoring and the definition of material damage to the hydrologic balance may improve water quality at underground mine sites.

- **Downstream miles preserved:** The length of downstream miles preserved varies across Action Alternatives primarily due to changes in coal production (see Section 4.1) expected as a result of the Action Alternatives (Table 4.2-13). The production changes generally influence between one and two percent of total affected downstream miles. Only in Alternative 2 does a production change result in a significant change in preserved miles. The vast majority of preserved stream miles occur in Appalachia, the region anticipated to experience the greatest reduction in surface coal mining activity under the Action Alternatives.

4.2.1.5.2 Characterization of Impacts of Rule Alternatives on Other Water Resources

4.2.1.5.2.1 Groundwater and Drinking Water

The Action Alternatives (excluding Alternative 9) require, to varying degrees, additional monitoring of groundwater quality and quantity before, during, and after mining activities; in addition, some of these Alternatives require groundwater protections when considering AOC variances. In addition to benefits to groundwater, improvements in water quality may benefit public drinking water suppliers by reducing pollutant levels and therefore costs of water treatment. Overall, Alternatives 2, 3, 4, 7, and 8 (Preferred) are more protective of groundwater. Of these, Alternative 2 is the most protective due to more frequent monitoring, which may allow earlier detection of emerging water quality issues. Alternatives 3, 4, and 8 (Preferred) have similar elements (e.g., groundwater protection in material damage to the hydrologic balance definitions) and therefore may affect groundwater to a roughly equal degree. Ultimately, Alternatives 4 and 8 (Preferred) may be more protective due to increased monitoring of groundwater. Alternatives 5, 6, and 7 are less protective of groundwater because they lack a definition of material damage to the hydrologic balance and because of their limited geographic applicability.[18] Alternative 9 is expected to have a negligible effect on groundwater resources as it is found to be functionally similar to current practices.

To characterize the relative effect of the Alternatives on groundwater by region, this analysis identified regions where groundwater is most often used for private water supplies.[19] Groundwater usage for public and private water supplies by coal region is presented in Table 4.2-14. Groundwater supplies are also used for agriculture and commercial/industrial purposes among other uses. Groundwater usage for private supplies is susceptible to changes in water quality and quantity because wells may not be monitored consistently and treated accordingly. The Appalachian Basin has the greatest percentage of withdrawn groundwater used for private supply. Given the limited level of coal mining activity on private land in the Western Interior region, this analysis suggests that the benefits of the Action Alternatives on groundwater are most likely concentrated in the Appalachian Basin.

---

[18] Alternative 5 applies only to operations that dispose of excess spoil or coal mine waste; Alternative 6 applies only to operations within 100 feet of intermittent or perennial streams; Alternative 7 applies only to operations where conditions warrant enhanced permitting requirements (e.g., steep slope areas, riparian areas).

[19] Private water supplies receive less detailed and frequent monitoring than municipal supplies, and therefore represent a more significant pathway for potential exposure to groundwater pollution. Municipal and other public water suppliers may also benefit from reduced pollution in their water sources.

Table 4.2-14. Percent of Regional Groundwater Withdrawals used for Public Supply Utilities and Private Supply for Domestic Use

Coal Region	Public Supply Utilities	Private Supply for Domestic Use	Supply for Agricultural Use
Appalachian Basin	45%	20%	13%
Colorado Plateau	19%	2%	75%
Gulf Coast	13%[1]	3%	74%
Illinois Basin	46%	0.1%	23%
Northern Rocky Mountains and Great Plains	11%	3%	81%
Northwest	None	None	None
Western Interior	42%	5%	42%

Sources: USGS, 2010b; Maupin et al., 2014
Notes: [1] The percent reported for public supply utilities in the Gulf Coast region comes from the USGS, 2010 report; all other numbers in this table are from Maupin et al., 2014.

4.2.1.5.2.2 Wetlands, Lakes, and Ponds

While the elements of the Action Alternatives do not specifically target wetlands, lakes, and ponds, these water resources would be influenced by the changes in the quality and quantity of surface water and groundwater within watersheds. Improved surface-water quality downstream of mine sites may improve inflow to lakes, ponds, wetlands, and the overall hydrologic balance.[20]

4.2.1.6 Summary of Effects

Consistent with the purpose of the proposed action, the Action Alternatives (except Alternative 9) are anticipated to result in benefits to water resources relative to the No Action Alternative. Table 4.2-15 summarizes the anticipated effects of the Action Alternatives on water resources compared to the No Action Alternative for each region. In applying the criteria used to define major, moderate, and minor effects (see discussion in Section 4.0) this analysis considers: (1) the length of the impact (i.e., during mining activity or beyond the life of the mine); and (2) the geographic scope of impact (to what extent impacts are expected to be limited to the mine site or extend beyond it). Beneficial effects associated with reductions in filled streams, downstream and groundwater quality improvements, and ephemeral stream restoration, are all considered long-term as they are anticipated to extend beyond the period of active mining. Determinations of the intensity of these beneficial impacts on water resources were made considering the quantified results of the analysis of the impacts of the Action Alternatives on miles of streams filled, increased restoration of ephemeral streams that are mined through, stream miles downstream of mine sites experiencing improved water quality, and stream miles that are preserved from adverse effects of mining, as well as qualitative assessments of the impacts on water quality associated with improvements to riparian habitat conditions. Specifically, determinations were made using the following analytical categories:

[20] Hydrologic Balance is defined at 30 CFR 701.5 as follows: "Hydrologic Balance means the relationship between the quality and quantity of water inflow to, water outflow from, and the water storage in a hydrologic unit such as a drainage basin, aquifer, soil zone, lake, or reservoir. It encompasses the dynamic relationships among precipitation, runoff, evaporation, and changes in ground and surface water storage."

- **Negligible**: Minimal measurable impacts (adverse or beneficial) are expected; or short term effects to a small geographic area, community or economy.
- **Minor Beneficial**: Impacts expected to be small and localized were considered to result in minor benefits.
- **Moderate Beneficial**: Impacts expected to affect local and adjacent areas. The benefits could permanently improve the area's hydrology, including surface and ground water flows and water quality.
- **Major Beneficial**: Impacts to water quality anticipated to be widespread; permanent improvements to regional hydrologic patterns, water flows, wetlands, could occur.

Consistent with the intent of the regulations to reduce adverse impacts of mining activities on perennial and intermittent streams, the Action Alternatives (except Alternative 9) would result in benefits to water resources relative to the No Action Alternative at the national scale. In particular, the analysis finds that Action Alternatives would result in Major Beneficial impacts to water resources under Alternatives 2, 3, 4, and 8 (Preferred) at the national scale. Moderate Beneficial impacts to water resources would be expected under Alternatives 6 and 7, with Minor Beneficial impacts under Alternative 5 at the national scale. Alternative 9 is anticipated to be functionally similar to the No Action Alternative and is anticipated to result in Negligible effects on water resources.

On a regional scale, Major Beneficial impacts are anticipated in the Appalachian Basin and Illinois Basin under Alternatives 2, 3, 4, and 8 (Preferred). Moderate Beneficial impacts are anticipated in the Appalachian Basin for Alternatives 5, 6, and 7, in the Illinois Basin for Alternatives 6 and 7, and in the Colorado Plateau, Gulf Coast, and Northern Rocky Mountains and Great Plains regions for Alternatives 2, 3, 4, 6, 7, and 8 (Preferred). Other effects on water resources are anticipated to be Negligible at the regional scale when compared to the No Action Alternative.

For all Action Alternatives, the benefits to water resources in the Western Interior and Northwest coal regions are Negligible due to the limited coal mining activity expected in these regions. For all other regions, specific findings are discussed below.

4.2.1.6.1 Alternative 1 (No Action Alternative)

Under the No Action Alternative, mining practices would remain unchanged and no further regulations or corrective measures in addition to those already in place would be implemented. As such, the impact of surface and underground mining operations would continue to produce adverse effects on water resources outside the permit area. Some examples of the impacts of mining include, but are not limited to, reduced stream and groundwater pH from acid mine drainage; elevated concentrations of iron, aluminum, manganese, and sulfate in surface water; increased sedimentation in the water column; flow alteration and stream elimination as a result of mining through streams and spoil management practices; drawdown of groundwater levels; and degradation of groundwater through increased concentrations of sulfate, iron, and other pollutants (see Subsection 4.2.1.1).

Ideally, this analysis would describe the impacts on water resources under the No Action Alternative using estimates of the total number of stream miles that are mined through, filled, and impaired annually by coal mining under current regulatory conditions. While such comprehensive baseline data are not readily available, there are some data and studies that can provide some context on the baseline impact of coal mining activities on water resources. For example, and as noted in Subsection 4.2.1.1, the 2005 Mountaintop Mining EIS estimated that approximately 45 stream miles were filled per year between 1985 and 2001 in West Virginia, Kentucky, Tennessee, and Virginia. Another study estimated that approximately 18 stream miles were filled in West Virginia from mining activities in 2012, which was down from approximately 28 miles per year from 1984 to 2012 (Shank and Gebrelibanos, 2013).[21] These studies provide some information to suggest that the rate of stream filling is declining under the No Action Alternative.

Additional information on surface water impacts of mining activities is available by examining USACE permitting activities under Section 404 of the CWA. Between 2012 and 2014, USACE permitted coal mining impacts to between 257 and 115 stream miles across four coal regions (Illinois Basin, Gulf Coast, Appalachian Basin and Northern Rocky Mountains and Great Plains). Of these stream miles, the majority (between 39 and 50 percent during the same timeframe) occurred in Illinois Basin.

As discussed in Section 4.1, the annual quantity of coal demanded and associated production is anticipated to be approximately 10 percent lower in 2040 than in 2020, even without implementation of the Alternatives (i.e., under the No Action Alternative). This reduction in production would reduce adverse impacts of ongoing coal mining activities on water resources under the No Action Alternative. The number of valley fills in the Appalachian region seems to be declining; this trend is expected to also continue under the No Action Alternative.

Water resources may also be affected by cumulative impacts under the No Action Alternative. Population growth is a primary driver of water quality changes associated with land clearing and development, as well as overall resource use. The socioeconomic section of Chapter 3 describes demographic trends in the coal-producing regions. In the period from 2000 to 2010, the coal regions seeing the greatest growth tended to be those in western states. The Northern Rocky Mountains and Great Plains region showed a 21 percent growth in population during this period, making it the fastest growing coal region. Other rapidly growing regions include the Colorado Plateau and the Gulf Coast regions. In terms of 2010 population, the most populous coal regions are the Appalachian Basin and the Illinois Basin. These population growth pressures are likely to increase adverse impacts to water resources under the No Action Alternative.

Trends in forestry under the No Action Alternative would also affect water resources. Approximately 60 percent of land in the Appalachian Basin is deciduous forest and several large National Forests exist in the region. While trends vary by sub-region, some portions of the Appalachian Basin have seen increased timber harvests in recent years. For instance, West Virginia production of industrial roundwood roughly doubled from 1979 to 2007, totaling nearly 190 million cubic feet (Piva and Cook, 2011). In the Gulf Coast region, Mississippi and Louisiana have extensive commercial forestry operations. Forest products were the highest value crop harvested in Louisiana in 2010, worth over three billion dollars (Louisiana Forestry Association, 2011). In Mississippi, the timber harvest was valued at $1.1 billion in 2013 (Mississippi State University, 2014). In addition, the Texas timber industry is concentrated almost

[21] Subsection 4.2.1.1 also presents some additional studies estimating the numbers of stream miles filled due to mining activities. These data do provide some context for understanding the history of stream filling from coal mining and is relevant when considering the cumulative effects of streams filled by mining activities.

exclusively in the northeast portion of the state (near Louisiana), meaning that it is almost fully contained in the Gulf Coast coal region (Texas Almanac, 2014). The delivered value of Texas timber was roughly $500 million in 2011. State forestry programs may promote best management practices (BMPs) that are intended to protect water resources, among other resources. For example, Tennessee's BMP guide recommends practices such as establishment of streamside buffer zones, soil stabilization through reforestation, and use of sediment control structures (Tennessee Department of Agriculture, 2003). In conjunction with the proposed action, these BMPs could reduce forestry impacts such as sedimentation and riparian vegetation removal.

Trends in agriculture also influence water quality within the study area. Relative to the other coal-producing regions, the Illinois Basin has the greatest amount of cultivated cropland. Cropland accounts for over 48 percent of the land use in this coal region. Illinois had approximately 22 million acres of harvested cropland in 2012, roughly unchanged from 2007. The total value of all agricultural products sold in 2012 was about $17.2 billion, up significantly from 2007 when sales totaled $13.3 billion (USDA, 2014). Livestock grazing is common in several coal-producing regions. In the Western Interior region, pasture and grazing operations account for over 38 percent of the land use in Kansas and Oklahoma. Likewise, the Gulf Coast region is over 26 percent pastureland.

In concert with the above, efforts to improve water quality conditions under other OSMRE rules, such as the OSMRE's Abandoned Mine Lands Program, CWA, Wild and Scenic Rivers Act, NRCS water protection program, as well as regional, state, local water quality improvement efforts, may continue to decrease ongoing adverse effects associated with coal mining, agriculture, forestry and residential and other commercial development activities on water resources under the No Action Alternative.

Table 4.2-15. Summary of Effects of the Action Alternatives on Water Resources Compared to the No Action Alternative

Coal Region	Alternative 2	Alternative 3	Alternative 4	Alternative 5	Alternative 6	Alternative 7	Alternative 8 (Preferred)	Alternative 9
Appalachian Basin	Major Beneficial	Major Beneficial	Major Beneficial	Moderate Beneficial	Moderate Beneficial	Major Beneficial	Major Beneficial	Negligible
Colorado Plateau	Moderate Beneficial	Moderate Beneficial	Moderate Beneficial	Negligible	Moderate Beneficial	Moderate Beneficial	Moderate Beneficial	Negligible
Gulf Coast	Moderate Beneficial	Moderate Beneficial	Moderate Beneficial	Negligible	Moderate Beneficial	Moderate Beneficial	Moderate Beneficial	Negligible
Illinois Basin	Major Beneficial	Major Beneficial	Major Beneficial	Negligible	Moderate Beneficial	Moderate Beneficial	Major Beneficial	Negligible
Northern Rocky Mountains / Great Plains	Moderate Beneficial	Moderate Beneficial	Moderate Beneficial	Negligible	Moderate Beneficial	Moderate Beneficial	Moderate Beneficial	Negligible
Northwest	Negligible	Negligible	Negligible	Negligible	Negligible	Negligible	Negligible	Negligible
Western Interior	Negligible	Negligible	Negligible	Negligible	Negligible	Negligible	Negligible	Negligible
National	Major Beneficial	Major Beneficial	Major Beneficial	Minor Beneficial	Moderate Beneficial	Moderate Beneficial	Major Beneficial	Negligible

Note: See Section 4.0 for a definition of Negligible, Minor, and Moderate effect terms used above. These effect categories consider the length of effect, geographic scope of effect, and potential for offsetting the effect. For a discussion of the impacts of the No Action Alternative (Alternative 1), see Subsection 4.2.1.1 above.

4.2.1.6.2 Alternative 2

Alternative 2 would provide the greatest level of protection and associated benefits to water resources due to the stringency of the requirements, its broad applicability and long-term effects. In the Appalachian Basin, rule elements prohibiting mining operations in or through perennial streams as well as the placement of excess spoil in intermittent or perennial streams, would avoid the filling of nine streams annually, more than any other Action Alternative. The Appalachian Basin is the only region where excess spoil fills are common; making Appalachian Basin the only region where a change in stream filling practices is anticipated. When compared to the 18 stream miles filled in 2012 in West Virginia, the incremental stream miles not filled in the Appalachian Basin due to Alternative 2 appear to represent a potentially substantial share of the overall stream miles filled annually in roughly the same area under current regulations. For this reason, impacts of Alternative 2 on water resources in the Appalachian Basin are considered Major Beneficial.

Alternative 2 also includes a number of rule elements that would improve surface-water quality in addition to limitations on in stream mining activities. In particular, Alternative 2 requires more frequent monitoring than other Action Alternatives, which should improve understanding of the premining hydrology as well as the probable hydrologic consequences of mining activities, possibly allowing earlier detection of water quality degradation during mining operations and mining reclamation activities. In addition to enhanced monitoring, rule elements defining material damage to the hydrologic balance and establishing evaluation thresholds serve as an additional preventative measure designed to increase the likelihood that water quality problems are detected early, when more effective and less costly corrective measures are possible. Collectively these rule elements are expected to generate annual water quality improvements across approximately 249 stream miles of intermittent and perennials streams relative to the No Action Alternative. The majority of improved stream miles occur in Appalachia (161 of 249 stream miles annually), as small mine size and high stream density leads to high per-ton effects on downstream stream miles (Table 4.2-12). Downstream water quality improvements are also expected in a moderate number of stream miles in the other four coal regions of Illinois Basin, Gulf Coast, Northern Rocky Mountain/Great Plains and Colorado Plateau, where Alternative 2 is expected to generate improvements in 33, 29, 16 and 4 stream miles respectively.

While the total number of stream miles currently degraded annually by coal mining activities under the No Action Alternative is not readily available, in one point of comparison, USACE permitted coal mining activities to occur on a range of 257 to 115 stream miles between 2012 and 2014 across four coal regions. The majority (between 69 and 86 percent over the three year timeframe) of these affected stream miles occurred in Illinois Basin followed by Appalachian Basin, with a collective, three-year average in these two coal regions of 146 stream miles per year. These data suggest the water quality improvements generated under Alternative 2 in the Appalachian and Illinois Basins may represent a potentially substantial share of the overall stream miles affected by coal mining activities annually under current regulations. For this reason, impacts of Alternative 2 on downstream intermittent and perennial streams in the Appalachian and Illinois Basin are considered Major Beneficial.

Another rule element unique to Alternative 2 is the prohibition of variances from the requirements to return mined areas to its AOC. As discussed in Section 4.2.1.4, this rule element in combination with the other rule elements is expected to contribute to the restoration of approximately 41 miles of ephemeral streams annually. The majority of the increases in restored ephemeral streams are anticipated in the

Illinois Basin, where 13 ephemeral stream miles would be restored annually. Moderate gains are also expected in three other regions where Alternative 2 is anticipated to improve ephemeral streams, including the Northern Rocky Mountain and Great Plains region with 10 stream miles, the Gulf Coast region with 10 stream miles and the Colorado Plateau with five stream miles.

While not attributable to a particular rule element, as discussed in Section 4.1, Alternative 2 is expected to result in a relatively large reduction in surface coal mining activity in the Appalachian Basin, approximately 0.5 million tons annually, or 0.09 percent of baseline production. As a result of these reductions in the amount of coal produced, Alternative 2 is also expected to result in the preservation of 14 additional downstream miles in the Appalachian Basin annually, substantially greater than any of the other Action Alternatives.

Of the Action Alternatives, Alternative 2 is the most protective of groundwater and drinking water due to more frequent monitoring, which may allow earlier detection of emerging water quality issues. Also contributing to protection of groundwater and drinking water quality is the rule element prohibiting all AOC variances. Groundwater usage for private supplies is susceptible to changes in water quality and quantity because wells may not be monitored consistently and treated accordingly. The Appalachian Basin has the greatest percentage of withdrawn groundwater used for private supply (20 percent), suggesting a relatively high potential for groundwater benefits in this region. Groundwater benefits may be more moderate in the Western Interior where the percent of withdrawn groundwater used for private supply is more modest at five percent annually. The share of groundwater withdrawals used for private supply is even lower in the Northern Rocky Mountains/Great Plains and Gulf Coast (three percent), the Colorado Plateau (two percent) and in the Illinois Basin (0.1 percent of groundwater withdrawals is used for private supply).

In summary, Alternative 2 is expected to provide Major Benefits to water resources over an indefinite period of time, in the large coal regions of the Appalachian and Illinois Basins. As stated above, in these regions, Alternative 2 is expected to avoid the filling of nine stream miles annually and the restoration of 14 ephemeral streams. Water quality improvements are also expected to accrue across a wide geographic area in these two coal regions, a total of 194 stream miles annually. The water resource benefits of Alternative 2 are classified as Moderate in the Colorado Plateau, Gulf Coast and Northern Rocky Mountains/Great Plains regions because the alternative would improve a moderate number of intermittent, perennial and ephemeral streams in these regions relative to the No Action Alternative.

At the national level, Alternative 2 is classified as Major Beneficial because it is expected to generate long-term positive benefits on water resources across an extensive geographic region, specifically Major Benefits in the two large coal-producing regions and Moderate Benefits in an additional three coal regions.

4.2.1.6.3 Alternative 3

Alternative 3 is very similar to Alternative 2 except that Alternative 3 would allow the placement of excess spoil in intermittent streams and lacks a categorical prohibition on mining activities in, near or through perennial streams. As a result of these differences, stream filling practices are expected to remain unchanged under Alternative 3.

Similar to Alternative 2, Alternative 3 includes a number of rule elements that are expected to improve downstream water quality as compared to the No Action Alternative. Improvements to surface water quality are not limited to onsite streams, but are expected to persist downstream of the mine sites as the water flows through and off of the mine. In particular, Alternative 3 requires enhanced monitoring before and during mining activities relative to the No Action Alternative, which should improve understanding of the premining hydrology as well as the probable hydrologic consequences of mining activities, possibly allowing earlier detection of water quality degradation during mining operations and mining reclamation activities. In addition to enhanced monitoring, rule elements defining material damage to the hydrologic balance and establishing evaluation thresholds serve as an additional preventative measure designed to increase the likelihood that water quality problems are detected early, when more effective and less costly corrective measures are possible. Requirements for AOC restoration should further reduce stream filling and improve water quality and preserve water flow by requiring permit applicants to restore the surface configuration to a condition that more closely resembles and functions like the premining landforms, with convex and concave patterns, and ephemeral channels. Alternative 3 would also require a 300-foot streamside vegetative corridor for intermittent and perennials streams; streamside vegetative corridors improve water quality by decreasing flow velocity and capturing sediment, thereby limiting the mobility of sediment to receiving surface water bodies.

Collectively these rule elements are expected to generate annual water quality improvements across approximately 263 stream miles of intermittent and perennials streams relative to the No Action Alternative. The majority of improved stream miles are expected to occur in Appalachia (174 of 263 stream miles annually), as small mine size and high stream density leads to high per-ton effects on downstream stream miles (Table 4.2-12). Downstream water quality improvements are also expected in a moderate number of stream miles in the other four coal regions of Illinois Basin, Gulf Coast, Northern Rocky Mountain/Great Plains and Colorado Plateau, where Alternative 3 is expected to generate improvements in 33, 29, 16 and 4 stream miles respectively.

While the total number of stream miles currently degraded annually by coal mining activities under the No Action Alternative is not readily available; in one point of comparison, USACE permitted coal mining activities to occur on a range of 257 to 115 stream miles between 2012 and 2014 across four coal regions. The majority (between 69 and 86 percent over the three year timeframe) of these affected stream miles occurred in Illinois Basin followed by Appalachian Basin, with a collective, three-year average in these two coal regions of 146 stream miles per year. These data suggest the water quality improvements generated under Alternative 3 in the Appalachian and Illinois Basins may represent a potentially substantial share of the overall stream miles affected by coal mining activities annually under current regulations. For this reason, impacts of Alternative 3 on the water quality of downstream intermittent and perennial streams in the Appalachian and Illinois Basin are considered Major Beneficial.

Ephemeral streams are also anticipated to benefit under Alternative 3 due to rule elements that require the permittee to restore the hydrologic function of ephemeral streams to the extent required by geomorphic reclamation. Specifically, these rule elements are expected to result in the restoration of 22 miles of ephemeral streams annually. The majority of these ephemeral stream miles are expected to occur in three coal regions, the Illinois Basin, Gulf Coast and the Northern Rocky Mountains/Great Plans regions where Alternative 3 is expected to result in the annual restoration of seven, six and five ephemeral stream miles, respectively.

As a result of more frequent monitoring, Alternative 3 is also expected to allow earlier detection of emerging groundwater and drinking water quality issues as compared to the No Action Alternative. Additionally, Alternative 3 would improve groundwater quality through AOC variance conditions. Specifically, for AOC variances for mountaintop removal operations, Alternative 3 would require a demonstration of no increase in parameters of concern in discharges to groundwater. Groundwater usage for private supplies is susceptible to changes in water quality and quantity because wells may not be monitored consistently and treated accordingly. The Appalachian Basin has the greatest percentage of withdrawn groundwater used for private supply (20 percent), suggesting a relatively high potential for groundwater benefits in this region. Groundwater benefits may be more moderate in the Western Interior where the percent of withdrawn groundwater used for private supply is more modest at five percent annually. The share of groundwater withdrawals used for private supply is even lower in the Northern Rocky Mountains/Great Plains and Gulf Coast (three percent), the Colorado Plateau (two percent) and in the Illinois Basin (0.1 percent of groundwater withdrawals is used for private supply).

In summary, Alternative 3 is expected to provide Major Benefits to water resources over an indefinite period of time, in the large coal regions of the Appalachian and Illinois Basins. As stated above, in these regions, Alternative 3 is expected to improve the water quality across a wide geographic area in these two coal regions, a total of 207 stream miles annually. The water resource benefits of Alternative 3 are classified as Moderate in the Colorado Plateau, Gulf Coast and Northern Rocky Mountains/Great Plains regions because the alternative would improve a moderate number of intermittent, perennial and ephemeral streams in these regions relative to the No Action Alternative.

At the national level, Alternative 3 is classified as Major Beneficial because it is expected to generate long-term positive benefits on water resources across an extensive geographic region, specifically Major Benefits in the two large coal-producing regions and Moderate Benefits in an additional three coal regions.

4.2.1.6.4 Alternative 4

Similar to Alternatives 2 and 3, Alternative 4 includes a number of rule elements that are expected to improve downstream water quality as compared to the No Action Alternative. Improvements to surface water quality are not limited to onsite streams, but are expected to persist downstream of the mine sites as the water flows through and off of the mine. In particular, Alternative 4 requires enhanced monitoring before and during mining activities relative to the No Action Alternative, which should improve understanding of the premining hydrology as well as the probable hydrologic consequences of mining activities, possibly allowing earlier detection of water quality degradation during mining operations and mining reclamation activities. In addition to enhanced monitoring, rule elements defining material damage to the hydrologic balance and establishing evaluation thresholds serve as an additional preventative measure designed to increase the likelihood that water quality problems are detected early, when more effective and less costly corrective measures are possible. Requirements for AOC restoration should further reduce stream filling and improve water quality and preserve water flow by requiring permit applicants to restore the surface configuration to a condition that more closely resembles and functions like the premining landforms, with convex and concave patterns, and ephemeral channels. Alternative 4 would also require a 300-foot streamside vegetative corridor for intermittent and perennials streams; streamside vegetative corridors improve water quality by decreasing flow velocity and capturing suspended sediment, thereby limiting the mobility of sediment to receiving surface water bodies.

Collectively these rule elements are expected to generate annual water quality improvements across approximately 263 stream miles of intermittent and perennials streams relative to the No Action Alternative. The majority of improved stream miles are expected to occur in Appalachia (174 of 262 stream miles annually), as small mine size and high stream density leads to high per-ton effects on downstream stream miles (Table 4.2-12). Downstream water quality improvements are also expected in a moderate number of stream miles in the other four coal regions of Illinois Basin, Gulf Coast, Northern Rocky Mountain/Great Plains and Colorado Plateau, where Alternative 4 is expected to generate improvements in 33, 29, 16 and 4 stream miles respectively.

While the total number of stream miles currently degraded annually by coal mining activities under the No Action Alternative is not readily available; in one point of comparison, USACE permitted coal mining activities to occur on a range of 257 to 115 stream miles between 2012 and 2014 across four coal regions. The majority (between 69 and 86 percent over the three year timeframe) of these affected stream miles occurred in Illinois Basin followed by Appalachian Basin, with a collective, three-year average in these two coal regions of 146 stream miles per year. These data suggest the water quality improvements generated under Alternative 4 in the Appalachian and Illinois Basins may represent a potentially substantial share of the overall stream miles affected by coal mining activities annually under current regulations. For this reason, impacts of Alternative 4 on the water quality of downstream intermittent and perennial streams in the Appalachian and Illinois Basin are considered Major Beneficial.

Alternative 4 would also reduce the filling of streams by prohibiting surface mining activities in or within 100 feet of intermittent and perennial streams unless the applicant demonstrates that the activity would not: (1) preclude premining stream uses; (2) have more than a minimal adverse impact on the premining biological condition of the stream segment; or (3) cause material damage to the hydrologic balance outside the permit area. In the Appalachian Basin, these limitations are expected to avoid the filling of four streams annually, a modest amount when compared to one study which estimated coal mining activities filled 18 streams in 2012 in West Virginia.

Ephemeral streams are also anticipated to benefit under Alternative 4 due to rule elements that require the permittee to restore the hydrologic function of ephemeral streams to the extent required by geomorphic reclamation. Specifically, these rule elements are expected to result in the restoration of 22 miles of ephemeral streams annually. The majority of these ephemeral stream miles are expected to occur in three coal regions, the Illinois Basin, Gulf Coast and the Northern Rocky Mountains/Great Plans regions where Alternative 4 is expected to result in the annual restoration of seven, six and five ephemeral stream miles, respectively.

As a result of more frequent monitoring, Alternative 4 is also expected to allow earlier detection of emerging groundwater and drinking water quality issues as compared to the No Action Alternative. Additionally, Alternative 4 would improve groundwater quality through AOC variance conditions. Specifically, for AOC variances for mountaintop removal operations, Alternative 4 would require a demonstration of no increase in parameters of concern in discharges to groundwater. Groundwater usage for private supplies is susceptible to changes in water quality and quantity because wells may not be monitored consistently and treated accordingly. The Appalachian Basin has the greatest percentage of withdrawn groundwater used for private supply (20 percent), suggesting a relatively high potential for groundwater benefits in this region. Groundwater benefits may be more moderate in the Western Interior where the percent of withdrawn groundwater used for private supply is more modest at five percent annually. The share of groundwater withdrawals used for private supply is even lower in the Northern Rocky Mountains/Great Plains and Gulf Coast (three percent), the Colorado Plateau (two percent) and in the Illinois Basin (0.1 percent of groundwater withdrawals is used for private supply).In summary, Alternative 4 is expected to provide Major Benefits to water resources over an indefinite period of time, in the large coal regions of the Appalachian and Illinois Basins. As stated above, in these regions, Alternative 4 is expected to improve the water quality across a wide geographic area in these two coal regions, a total of 207 stream miles annually. The water resource benefits of Alternative 4 are classified as Moderate in the Colorado Plateau, Gulf Coast and Northern Rocky Mountains/Great Plains regions because the alternative would improve a moderate number of intermittent, perennial and ephemeral streams in these regions relative to the No Action Alternative.

At the national level, Alternative 4 is classified as Major Beneficial because it is expected to generate long-term positive benefits on water resources across an extensive geographic region, specifically Major Benefits in the two large coal-producing regions and Moderate Benefits in an additional three coal regions.

4.2.1.6.5 Alternative 5

The benefits accruing to water resources under Alternative 5 are concentrated in the Appalachian Basin areas because this alternative limits the applicability of the rule to areas where mining operations place excess spoil outside of the mined area or where coal mine refuse disposal occurs in in perennial or intermittent streams. These practices are restricted to the Appalachian Basin and as such, Alternative 5 is not expected to generate quantitative benefits to water resources are in any of the other coal regions (see Tables 4.2-10 to 4.2-13).

Alternative 5 is expected to be Moderately Beneficial to water resources in the Appalachian Basin because of rule elements that avoid the filling of four intermittent and perennial streams annually, the restoration of one ephemeral stream per year and water quality improvements across 174 downstream intermittent and perennial stream miles annually. Although, the magnitude of any water quality improvements realized under Alternative 5 is likely constrained because this alternative does not contain a definition of “material damage to the hydrologic balance outside the permit area,” preserves the existing definitions for ephemeral, intermittent and perennial streams and would not require evaluation thresholds.

In summary, while Alternative 5 is expected to provide Moderate Benefits to the Appalachian Basin, the rule’s limited applicability in other coal regions suggests this alternative provides only a Minor Benefit at the national level.

4.2.1.6.6 Alternative 6

Alternative 6 is limited to mining activities conducted in intermittent or perennial streams or within 100 feet of those streams. In these areas, Alternative 6 would prohibit all mining activities unless the regulatory authority makes specific findings concerning the environmental impacts of the proposed operation. In the Appalachian Basin, these limitations are expected to avoid the filling of four streams annually, a modest amount when compared to one study which estimated coal mining activities filled 18 streams in 2012 in West Virginia. Notably, rule elements requiring restoration of ephemeral streams generate quantitative benefits across all but one coal region, with the greatest benefits accruing to ephemeral streams in the three coal regions of Illinois Basin, the Gulf Coast and the Northern Rocky Mountains/Great Plains.

As highlighted in Table 4.2-12, Alternative 6 is expected to generate improvements to 263 miles of intermittent and perennial streams annually, the majority of which occur in the Appalachian Basin. A number of rule elements contribute to water quality improvements under Alternative 6, including but not limited to limitations on mining activities (or the impacts thereof) in or within 100 feet of intermittent and perennial streams, requirements to restore the hydrologic function of ephemeral streams to the extent required by geomorphic reclamation principles, requirements to establish streamside vegetative corridors at least 100 feet in width along the entire reach of all streams, including ephemeral streams, within the permit area after completing mining and regulatory authority to prohibit mining of high-value habitats within the proposed permit area.

While these water quality improvements are expected to be long-term in nature (i.e., extending beyond the life of the mine), the geographic extent of such improvements would be limited within coal mining permit boundaries. The rules for mining activities in all other areas of the permit remain relatively unchanged from the No Action Alternative. In addition, while Alternative 6 does require some incremental baseline data collection and monitoring, the alternative does not require a definition of material damage to the hydrologic balance or establish evaluation thresholds. As a result, the potential for alerting regulators to groundwater quality and quantity issues is lower and the alternative contains less clear standards for restoring groundwater quality under Alternative 6. For these reasons, across the four coal-producing regions and at the national level, Alternative 6 is anticipated to provide Moderate Beneficial impacts to water resources.

4.2.1.6.7 Alternative 7

Under Alternative 7, additional permitting requirements are focused on a smaller subset of mining operations involving factors that OSMRE has determined pose additional risk to the environment and warrant enhanced permitting requirements (e.g., steep slope areas, and riparian areas). Because the conditions warranting enhanced permitting requirements exist throughout most of the Appalachian Basin, Alternative 7 is expected to generate Major Benefits to water resources in this coal region. As discussed in Section 4.2.1.4, Alternative 7 would avoid the filling of approximately four miles of intermittent and perennial miles per year, the restoration of one mile of ephemeral steams per year and the preservation of one mile of intermittent and perennial streams per year. These water resources benefits appear modest when compared to one study which estimated coal mining activities filled 18 streams in 2012 in West Virginia. In addition to these benefits, the Alternative would also result in improvements to the water quality of 159 miles of downstream intermittent and perennial streams in the Appalachian Basin. For these streams, water quality improvements are expected to be significant and long-term in nature (i.e., extending beyond the life of the mine) because the stringency of additional permitting requirements are the same as Alternative 2, with one exception; Alternative 7 includes no standard material damage to the hydrologic balance definition but rather defines material damage to the hydrologic balance on a permit-specific basis.

While the benefits to water resources in Appalachian Basin may be substantial under Alternative 7, the applicability of Alternative 7 in other coal regions is more limited. For example, in all other coal regions, the geographic extent of water quality improvements to downstream intermittent and perennial streams is relatively modest with six stream miles affected annually in the Gulf Coast and between one to three stream miles affected annually in the other five coal regions of Colorado Plateau, Illinois Basin, Northern Rocky Mountains/Great Plans and the Western Interior. In most of these regions, conditions that warrant enhanced permitting exist in only ten (Illinois Basin, Northwest and Western Interior) to 20 percent (Gulf Coast and Northern Rocky Mountains) of mines in these regions. While Alternative 7 is expected to affect up to 60 percent of mines in Colorado Plateau, this translates to a modest two miles of intermittent and perennial streams per year.

Because of the stringency of the additional permitting required, Alternative 7 is expected to generate benefits to water resources that are long-term in nature (i.e., extending beyond the life of the mine). The geographic extent of such benefits, however, is concentrated in the Appalachian Basin with limited applicability in the other coal regions. As such, the benefits to water resources are considered Major Beneficial in the Appalachian Basin and only Moderately Beneficial in the other coal regions of Colorado Plateau, Gulf Coast, Illinois Basin and Northern Rocky Mountains/Great Plains. Because of the limited geographic extent of Alternative 7, this alternative is classified as Moderately Beneficial at the national level.

4.2.1.6.8 Alternative 8 (Preferred)

Alternative 8 (Preferred) includes a number of rule elements that are expected to improve downstream water quality as compared to the No Action Alternative. Improvements to surface water quality are not limited to onsite streams, but are expected to persist downstream of the mine sites as the water flows through and off of the mine. In particular, Alternative 8 (Preferred) requires enhanced monitoring before and during mining activities relative to the No Action Alternative, which should improve understanding of the premining hydrology as well as the probable hydrologic consequences of mining activities, possibly allowing earlier detection of water quality degradation during mining operations and mining reclamation activities. In addition to enhanced monitoring, rule elements defining material damage to the hydrologic balance and establishing evaluation thresholds should serve as an additional preventative measure designed to increase the likelihood that water quality problems are detected early, when more effective and less costly corrective measures are possible. Requirements for AOC restoration should further reduce stream filling and improve water quality and preserve water flow by requiring permit applicants to restore the surface configuration to a condition that more closely resembles and functions like the premining landforms, with convex and concave patterns, and ephemeral channels. Alternative 8 (Preferred) would also require a 100-foot streamside vegetative corridor (on either side of stream banks) for all stream types, ephemeral, intermittent and perennial; streamside vegetative corridors improve water quality by decreasing flow velocity, thereby limiting the mobility of sediment to receiving surface water bodies.

Collectively these rule elements are expected to generate annual water quality improvements across approximately 263 stream miles of intermittent and perennials streams relative to the No Action Alternative. The majority of improved stream miles are expected to occur in Appalachia (174 of 263 stream miles annually), as small mine size and high stream density leads to high per-ton effects on downstream stream miles (Table 4.2-12). Downstream water quality improvements are also expected in a moderate number of stream miles in the other four coal regions of Illinois Basin, Gulf Coast, Northern Rocky Mountain/Great Plains and Colorado Plateau, where Alternative 8 (Preferred) is expected to generate improvements in 33, 29, 16 and 4 stream miles respectively.

While the total number of stream miles currently degraded annually by coal mining activities under the No Action Alternative is not readily available; in one point of comparison, USACE permitted coal mining activities to occur on a range of 257 to 115 stream miles between 2012 and 2014 across four coal regions. The majority (between 69 and 86 percent over the three year timeframe) of these affected stream miles occurred in Illinois Basin followed by Appalachian Basin, with a collective, three-year average in these two coal regions of 146 stream miles per year. These data suggest the water quality improvements generated under Alternative 8 (Preferred) in the Appalachian and Illinois Basins may represent a potentially substantial share of the overall stream miles affected by coal mining activities annually under current regulations. For this reason, impacts of Alternative 8 (Preferred) on the water quality of downstream intermittent and perennial streams in the Appalachian and Illinois Basin are considered Major Beneficial.

Alternative 8 (Preferred) would also reduce the filling of streams by setting limitations on the type of mining activities that can occur within 100 feet of intermittent and perennial streams. In the Appalachian Basin, these limitations are expected to avoid the filling of four streams annually, a modest amount when compared to one study which estimated coal mining activities filled 18 streams in 2012 in West Virginia.

Ephemeral streams are also anticipated to benefit under Alternative 8 (Preferred) due to rule elements that require the permittee to restore the hydrologic function of ephemeral streams to the extent required by geomorphic reclamation. Specifically, these rule elements are expected to result in the restoration of 22 miles of ephemeral streams annually. The majority of these ephemeral stream miles are expected to occur in three coal regions, the Illinois Basin, Gulf Coast and the Northern Rocky Mountains/Great Plans regions where Alternative 8 (Preferred) is expected to result in the annual restoration of seven, six and five ephemeral stream miles, respectively.

As a result of more frequent monitoring, Alternative 8 (Preferred) is also expected to allow earlier detection of emerging groundwater and drinking water quality issues as compared to the No Action Alternative. Additionally, Alternative 8 (Preferred) would improve groundwater quality through AOC variance conditions. Specifically, for AOC variances for mountaintop removal operations, Alternative 8 (Preferred) would require a demonstration of no increase in parameters of concern in discharges to groundwater. Groundwater usage for private supplies is susceptible to changes in water quality and quantity because wells may not be monitored consistently and treated accordingly. The Appalachian Basin has the greatest percentage of withdrawn groundwater used for private supply (20 percent), suggesting a relatively high potential for groundwater benefits in this region. Groundwater benefits may be more moderate in the Western Interior where the percent of withdrawn groundwater used for private supply is more modest at five percent annually. The share of groundwater withdrawals used for private supply is even lower in the Northern Rocky Mountains/Great Plains and Gulf Coast (three percent), the Colorado Plateau (two percent) and in the Illinois Basin (0.1 percent of groundwater withdrawals is used for private supply).In summary, Alternative 8 (Preferred) is expected to provide Major Benefits to water resources over an indefinite period of time, in the large coal regions of the Appalachian and Illinois Basins. As stated above, in these regions, Alternative 8 (Preferred) is expected to improve the water quality across a wide geographic area in these two coal regions, a total of 207 stream miles annually. The water resource benefits of Alternative 8 (Preferred) are classified as Moderate in the Colorado Plateau, Gulf Coast and Northern Rocky Mountains/Great Plains regions because the alternative would improve a moderate number of intermittent, perennial and ephemeral streams in these regions relative to the No Action Alternative.

At the national level, Alternative 8 (Preferred) is classified as Major Beneficial because it is expected to generate long-term positive benefits on water resources across an extensive geographic region, specifically Major Benefits in the two large coal-producing regions and Moderate Benefits in an additional three coal regions.

4.2.1.6.9 Alternative 9

Alternative 9 would require the repromulgation of the currently vacated 2008 Stream Buffer Zone rule. This Alternative would require minimization of excess spoil generation, place limits on excess spoil fill capacity to match the anticipated amount of excess spoil to be generated, and prohibit mining activities in or within 100 feet of an intermittent or perennial stream unless the applicant demonstrates and the regulatory authority finds that avoidance is not reasonably possible. The model mines analysis indicates that the impacts of Alternative 9 would not differ significantly from those of the No Action Alternative because the Clean Water Act requirements and policies discussed in the Regulatory Impact Analysis for this rulemaking and the state AOC and excess spoil policies identified in Section 4.2.3.1 of this FEIS have effectively achieved implementation of this Alternative in Central Appalachia, which is the region in which the 2008 Stream Buffer Zone rule would have had its greatest impact if it had remained in effect. Therefore, if repromulgated, Alternative 9 would now have Negligible effects on water resources.

4.2.1.7 Potential Minimization and Mitigation Measures

The effects of Action Alternatives on water resources are beneficial, themselves comprising minimization and mitigation measures in many cases. Thus, potential minimization and mitigation measures are not relevant to this evaluation.

4.2.2 Biological Resources

This section evaluates the potential effects of the Alternatives on biological resources in each of the coal mining regions. Chapter 3 provides an overview of the terrestrial and aquatic habitats occurring in coal-producing areas, describing vegetative cover for terrestrial systems as well as the features of flowing and ponded aquatic systems. Changes to the quality and quantity of these resources in turn affect the wildlife communities they support.

This chapter assesses the potential impacts of the Action Alternatives on these biological resources by comparing relative levels of protection afforded by the Action Alternatives as compared to the No Action Alternative (Alternative 1) at typical (model) mine sites within each coal region. The section is organized as follows:

- It first describes the existing regulatory environment to assist the reader in understanding the impacts of the No Action Alternative on biological resources.
- Second, the discussion identifies the biological resources most likely to be affected by implementation of the Action Alternatives and the rationale for these findings.
- It then describes the methods for assessing the expected magnitude of impact of the Action Alternatives on these resources.

- Next, the results of the quantitative analysis are presented, along with additional qualitative evaluation of other potential impacts.
- The section concludes with a summary of the expected effects of the Action Alternatives, characterizing the impacts by coal region and Alternative.

4.2.2.1 Effects of the Current Regulatory Environment (the No Action Alternative)

Coal mining alters the surface landscape by changing its configuration and physical properties. The short- and long-term disturbance created by surface and underground coal extraction significantly changes the biological resources of surface lands. Specifically, coal mining affects: (1) the biological composition, which is the number and proportion of habitat types (e.g., the amount of forest, length of stream habitat); (2) the biological structure, which is the geographical arrangement of the habitat types; and (3) the biological function, which is how these arranged habitat types interact with their respective plant and animal species. These effects vary in temporal and spatial scale; in some instances, these effects extend past the coal mining permit boundary and after final bond release.

Several existing laws and regulations address protection of the terrestrial and aquatic biological resources that occur near coal mining areas. The following discussion identifies the laws and regulations protecting fish, terrestrial fauna, and endangered species, with a focus on key aspects of SMCRA and the Endangered Species Act.

4.2.2.1.1 SMCRA

Section 515 of SMCRA requires that, "to the extent possible using the best technology currently available," surface coal mining operations "minimize disturbances and adverse impacts of the operation on fish, wildlife, and related environmental values, and achieve enhancement of such resources where practicable" (30 U.S.C. §1265(b)(24)). This provision applies to any fish, wildlife, or related environmental values identified during the permitting process that could benefit from protective measures to minimize disturbances and adverse impacts or enhancement of such resources.

Fish, wildlife, and related environmental values are addressed directly within the implementing regulations of SMCRA. To achieve the mandate of section 515, OSMRE regulations include specific requirements for these resources at the permit application stage, during mining through the requirement for enhancement measures, and during consideration and implementation of the post mining land use.

The implementing regulations for SMCRA require the permit application to contain information on fish and wildlife resources within the permit and adjacent area (30 CFR 780.16(a)). The regulatory authority determines the required scope and level of detail for such information in consultation with state and federal agencies responsible for fish and wildlife. Each application must include a description of how, to the extent possible using the best technology currently available (BTCA), the operator would minimize disturbances and adverse impacts on fish and wildlife and related environmental values, including compliance with the Endangered Species Act. This is the protection and enhancement plan specifically required by 30 CFR 780.16(b).

The protection and enhancement plan is required to be consistent with applicable performance standards at 30 CFR 816.97 and 817.97 that require the operator to include protective measures for use during active phases of the mining operation, and to include proactive measures to minimize or avoid impacts.

For example, 30 CFR 816.97(e) and 817.97(e) require that each operator shall, to the extent possible using the BTCA:

- Ensure that electric power lines and other transmission facilities used for, or incidental to, surface mining activities on the permit area are designed and constructed to minimize electrocution hazards to raptors, except where the regulatory authority determines that such requirements are unnecessary;
- Locate and operate haul and access roads so as to avoid or minimize impacts on important fish and wildlife species or other species protected by state or federal law;
- Design fences, overland conveyors, and other potential barriers to permit passage for large mammals, except where the regulatory authority determines that such requirements are unnecessary; and
- Use fencing, covers, or other appropriate methods to exclude wildlife from ponds that contain hazardous concentrations of toxic-forming materials.

The regulations at 30 CFR 816.97(f) and 817.97(f) provide additional protections for wetlands and habitats of unusually high value for fish and wildlife. The operator must avoid disturbances to, enhance where practicable, restore, or replace, wetlands and streamside vegetation along rivers and streams and bordering ponds and lakes. Surface mining activities must avoid disturbances to, enhance where practicable, or restore, habitats of unusually high value for fish and wildlife.

The regulations also require an applicant who intends to select certain postmining land uses to incorporate specific measures to the benefit of fish and wildlife resources. The regulations at 30 CFR 816.97(g) and 817.97(g) require that, where fish and wildlife habitat would be part of the postmining land use, the reclamation plan must include plant species selected on the basis of the following criteria:

- Their proven nutritional value for fish or wildlife;
- Their use as cover for fish or wildlife; and
- Their ability to support and enhance fish or wildlife habitat after the release of performance bonds. The selected plants must be grouped and distributed to optimize edge effect, cover, and other benefits to fish and wildlife.

The regulations at 30 CFR 816.97(h) and 817.97(h) require that, where cropland would be the postmining land use, and where appropriate for wildlife- and crop-management practices, the operator must intersperse fields with trees, hedges, or fence rows throughout the harvested area to break up large blocks of monoculture and to diversify habitat types for birds and other animals. Likewise, 30 CFR 816.97(i) and 817.97(i) require that, where residential, public service, or industrial uses are to be the postmining land use, and where consistent with the approved postmining land use, the operator must intersperse reclaimed lands with greenbelts using species of grass, shrubs, and trees useful as food and cover for wildlife.

Beyond these specific requirements that pertain to consideration and protection of fish, wildlife and related environmental values there are many aspects of the implementing regulations that affect the mining operation and in turn affect the impacts of this operation on biological resources. For example, current SMCRA implementing regulation requirements for spoil placement, activities in and within streams, and reclamation all have impacts either directly or indirectly on biological resources by allowing activities to occur in certain habitats, and by restricting them in others. Scientific findings on impacts to biological resources under the full suite of existing regulations are discussed more thoroughly below in the section entitled "Documented Impacts under the No Action Alternative."

4.2.2.1.2 ESA Consultations Related to this Rulemaking

Prior to the enactment of SMCRA, Congress, in 1973, enacted the ESA to, among other purposes, "provide a means whereby the ecosystems upon which endangered species and threatened species depend may be conserved [and] to provide a program for the conservation of such endangered species and threatened species…" (16 U.S.C. § 1531(b)). Through the ESA, Congress declared "that all Federal departments and agencies shall seek to conserve endangered species and threatened species and shall utilize their authorities in furtherance of the purposes of the [ESA]" (16 U.S.C. § 1531(c)).

To carry out these purposes and the policies, ESA section 7(a)(1) requires all federal agencies, in consultation and with the assistance of the U.S. Fish & Wildlife Service (U.S. FWS), to exercise their authorities to carry out programs for the conservation of endangered and threatened species (16 U.S.C. § 1536(a)(1)). Section 7(a)(2) requires each federal agency, in consultation with the U.S. FWS, "to insure that any action authorized, funded, or carried out…is not likely to jeopardize the continued existence of any endangered species or threatened species or result in the destruction or adverse modification of [critical] habitat" (16 U.S.C. § 1536(a)(2)). Section 7(a)(4) requires federal agencies to confer with the U.S. FWS on any agency action that is likely to jeopardize the continued existence of any species proposed for listing or result in adverse modification of proposed critical habitat (16 U.S.C. § 1536(a)(4)). Each agency is required to use and provide the U.S. FWS with the best scientific and commercial data available when undergoing consultation in order to determine the effects of its action upon listed species or critical habitat (*Id.*; 50 CFR 402.14(d)(2)). The ESA regulations outlining the substantive and procedural requirements for section 7(a)(2) consultation are codified at 50 CFR Part 402. The regulations require the federal agency taking the action to formally consult with the U.S. FWS if its action "may affect" a listed species (50 CFR 402.14(a)).

On September 24, 1996, the U.S. FWS issued a biological opinion (BO) and conference report to OSMRE (OSMRE, 1996) on the continuation and approval and conduct of surface coal mining and reclamation operations under state and federal regulatory programs adopted pursuant SMCRA where such operations may adversely affect species listed as threatened or endangered or designated critical habitat under the ESA. After reviewing SMCRA, its implementing regulations, the effects of the proposed action, and the cumulative effects of future state, tribal, local or private actions that are reasonably certain to occur, the U.S. FWS concluded in the 1996 BO that surface coal mining and reclamation operations conducted in accordance with properly-implemented regulatory programs under SMCRA are not likely to jeopardize the continued existence of ESA-listed or proposed species or future listed species and are not likely to result in the destruction of adverse modification of designated or proposed critical habitat. The Incidental Take Statement (ITS) in the 1996 BO exempted OSMRE or the state regulatory authority from the prohibitions of section 9 of the ESA if it complied with the terms and conditions included in the ITS.

The terms and conditions are as follows:

1. The regulatory authority, acting in accordance with the applicable SMCRA regulatory program, must implement and require compliance with any species-specific protective measures developed

by the U.S. FWS field office and the regulatory authority (with the involvement, as appropriate, of the permittee and OSMRE).

2. Whenever possible, the regulatory authority must quantify the take resulting from activities carried out under this program. Whenever a dead or impaired individual of a listed species is found, the local U.S. FWS office must be notified within one (1) working day of the discovery.
3. Whenever the regulatory authority decides not to implement one or more of the species-specific measures recommended by the U.S. FWS, it must provide a written explanation to the U.S. FWS. If the U.S. FWS does not concur, the issue must be elevated through the chain of command of the regulatory authority, the U.S. FWS, and (to the extent appropriate) OSMRE for resolution.

The "fish, wildlife, and related environmental values" described in section 515 of SMCRA clearly encompass threatened or endangered species or their critical habitats. Existing OSMRE regulations require that applicants for surface coal mining operations provide sufficient fish and wildlife resources information for the proposed permit area and adjacent area to design a protection and enhancement plan (PEP) that complies with sections 7 and 9 of the ESA and minimizes disturbances and adverse impacts on fish, wildlife, and related environmental values, and enhances those resources where practicable (30 CFR 780.16). Before the regulatory authority can approve the permit application, the regulatory authority must find that the "operation would not affect the continued existence of endangered or threatened species or result in destruction or adverse modification of their critical habitats, as determined under the Endangered Species Act of 1973" (30 CFR 773.15(j)).

U.S. FWS field staff provides technical assistance and recommendations to OSMRE and the appropriate regulatory authority. The regulatory authority ensures that any listed species or designated critical habitats are considered as the application is developed. As part of the process of ensuring full compliance with SMCRA and the ESA, OSMRE and state regulatory authorities have worked with U.S. FWS to develop comprehensive protection and enhancement plans/guidelines (PEPs) for commonly encountered threatened and endangered species. As of 2013, PEPs were developed for the Indiana Bat (*Myotis sodalist*) and the blackside dace (*Chrosomus cumberlandensis*) (OSMRE, 1996; U.S. FWS, 2004b).

As provided in 50 CFR 402.16, reinitiation of formal consultation is required when discretionary federal agency involvement or control over the action has been maintained (or is authorized by law) and if (1) new information reveals that the agency action may affect listed species or critical habitats in a manner or to an extent not considered in the original opinion, or (2) the agency action is modified in a manner that causes an adverse effect to listed species or critical habitat that was not considered in the original opinion.

4.2.2.1.3 Documented Impacts under the No Action Alternative

Under the existing regulations (the No Action Alternative), scientific studies have found a correlation between the effects of SMCRA permitted mining operations on the hydrologic balance and adverse impacts to biological resources downstream of the mine site. These impacts to biological resources include habitat loss and habitat degradation. Documented downstream effects to the hydrologic balance on biological resources include:

- Effects to the thermal regime (the fluctuation of water temperature throughout the year);
- Effects to the flow regime (the baseline flow, or minimum flow of water throughout the year, and the pulses of water due to significant precipitation events);

- Effects to downstream chemistry (e.g., water pH and conductivity); and
- Changes in downstream sedimentation (e.g., the amount and particle size of sand, silt, and decaying organic matter deposited onto streambeds).

Adverse impacts on ecological communities continue to occur in coal mining regions, as documented in studies discussed below. Many of the available studies were conducted in the Appalachian Basin region (e.g., U.S. EPA et al., 2003; Pond et al., 2008; Palmer et al., 2010; Presser and Luoma, 2010; Woody et al., 2010; Bernhardt et al., 2012; Pond, 2012; Presser, 2013; Pond et al., 2014). However, studies are available from other coal-producing areas, e.g., Big Black River tributaries in Mississippi (Rohasliney and Jackson, 2009), Hocking River drainage basin in southeastern Ohio (Verb and Vis, 2000), and streams in British Columbia (Harding et al., 2005). Two other states, Colorado and Indiana, have studies reporting directly on stream effects of coal mining; however, these studies were performed before 1983 (Canton and Ward, 1981; and Wangsness, 1982) and may not be representative of impacts that are occurring under existing regulations.

The discussion below reviews key studies that have documented adverse mining impacts on biological resources under current regulations. The first subsection reviews literature examining how activities in or near streams have affected aquatic ecosystems; the second subsection focuses on postmining land use and reclamation, and its influence on biological systems.

4.2.2.1.4 Documented Impacts Related to Activities in or Near Streams

Under the No Action Alternative, the regulatory authority may authorize mining activities within 100 feet of a stream, including placement of spoil, only after finding that the proposed activities would not cause or contribute to a violation of applicable federal or state water quality standards under the Clean Water Act and would not adversely affect the water quantity and quality or other environmental resources of the stream (30 CFR 816.57). However the studies presented in the paragraphs below show that mining continues to have effects on aquatic habitats due to chemical effects to the water column itself, removal of streamside vegetation which then can cause thermal effects to the water, diversion of the waters of the stream, or changes to the texture and composition of the stream substrates. The studies described below also indicate that mining related degradation of aquatic habitats may cause shifts in species composition, changes in demographics and dynamics of aquatic populations, and loss of taxa.

Changes in the aquatic biological community as a result of mining have been demonstrated through surveys of macroinvertebrate communities. Macroinvertebrates are organisms that are large (macro) enough to be seen with the naked eye and lack a backbone (invertebrate). They inhabit all types of running waters, and most live part or most of their life cycle attached to submerged rocks, logs, and vegetation. Examples of aquatic macroinvertebrates include insects in their larval or nymph form, crayfish, clams, snails, and worms.

Water quality assessment relies so heavily on macroinvertebrate surveys because these organisms:

- Are affected by the physical, chemical, and biological conditions of the stream;
- Cannot escape pollution and thus do show the effects of short- and long-term pollution events;
- May show the cumulative impacts of pollution;
- May show the impacts from habitat loss not detected by traditional water quality assessments; and

- Differ by genus and species in their tolerance of pollution.

The abundance and diversity of macroinvertebrate species can, therefore, be a first order indicator of the relative health of a stream. In general, a stream that contains robust populations of pollution-sensitive macroinvertebrate species may imply a healthier system relative to a stream dominated by pollution-tolerant species.

Mining has impacts on downstream water chemistry conditions even when done in compliance with existing regulations (Palmer and Hondula, 2014; Pond et al., 2014). Under existing federal regulations, measurement of conductivity in water discharged from mine sites is not required. At elevated levels of conductivity stream water can be directly toxic to freshwater aquatic organisms by disrupting osmoregulation (Pond et al., 2008). Further, elevated levels of stream conductivity have been correlated with the lower abundance and diversity of macroinvertebrates, diatoms, and fish species (Chambers and Messinger, 2001; Hartman et al., 2005; Carlisle et al., 2008; Smucker and Vis, 2009; Kimmel and Argent, 2010; and Bernhardt et al., 2012).

Pond et al. (2008) characterized macroinvertebrate communities in 37 streams in West Virginia (10 unmined sites and 27 sites near coal mining activity) and found that coal mining affected the condition of streams in the following four respects: shifts in species assemblages; losses of Ephemeroptera (mayfly) taxa; and changes in water chemistry. Additionally, Pond, et al. (2008) showed that benthic macroinvertebrate communities in streams below valley fills in West Virginia were impaired at conductivity levels as low as 500 µS/cm. More recently, EPA has proposed a year round benchmark for aquatic life in the Appalachian region of 300 µS/cm, above which conductivity can be directly toxic to aquatic life. Pond et al. (2008) also found a nearly complete absence of mayflies in streams below mined sites. Pond (2010) showed that relative mayfly abundance was negatively correlated with specific conductance. A follow-up study published by Pond (2012) studied headwater stonefly (Plecoptera) and caddisfly (Trichoptera) assemblages in reference, mined, residential, and residential/mined areas. Much like Ephemeropteran declines seen by Pond, et al. (2008), Plecopteran and Trichopteran communities were radically altered in streams near mining and residential areas. In West Virginia, Green, et al. (2000) found that median conductivity was strongly negatively correlated with the condition of streams assessed under the West Virginia Stream Condition Index. Howard, et al. (2001) found a strong negative correlation between conductivity and biological condition in streams in Kentucky. Pond (2004) showed a strong negative correlation between conductivity and biological condition as well as wholesale loss of mayflies (Ephemeroptera) below mined sites in Kentucky.

In addition, Palmer, et al. (2010) reported that several metals known to be stressors of aquatic life (e.g., selenium, aluminum, and iron) were associated with sulfate, which is highly correlated with conductivity. Streams with selenium-impacted mine runoff have exhibited decreased abundance of salamander, fish, and bird populations (Patnode et al., 2005; U.S. EPA, 2011b; Hitt and Chambers, 2014). Aluminum is also toxic to invertebrates and fish, and can occur in higher concentrations downstream of mine runoff (Chambers and Messinger, 2001). These and other metal pollutants have the potential to bioaccumulate and biomagnify in ecosystem-based food webs (e.g., Presser and Luoma, 2010; Presser, 2013). Because the main route of selenium exposure is dietary, even low concentrations in stream waters have the potential to bioaccumulate in the food web through the consumption of contaminated food. Thus, EPA has recommended expanded selenium criteria to include biomass tissue-based thresholds as indicators of aquatic life toxicity (U.S EPA, 2014i). EPA released updated aquatic life ambient water quality criteria in 2016 to reflect the importance of toxicity through contaminated food (U.S. EPA, 2016).

Current OSMRE regulations require baseline data and monitoring but are not preventing all impacts to water quality. Only some of these adverse impacts are linked to pollutants (substances at levels high enough to cause damage to biological resources) that must be identified as part of the water quality and quantity measurements required by the regulations implementing SMCRA and the CWA. As discussed above, coal mining is known to change the concentration of total dissolved solids downstream to an extent sufficient to adversely affect downstream biological communities (e.g., Locke et al., 2006; U.S. EPA et al., 2003; Hartman et al., 2005; Pond et al., 2008; Palmer et al., 2010). In addition, high levels of total suspended solids (i.e., sediment) below mining operations have also been shown to be predictive of downstream biological communities. For example, high levels of total suspended solids have been shown to be correlated to lower species diversity of macroinvertebrates (e.g., aquatic insects and mussels), and reduced abundance of salamanders and fish downstream of mining operations (Chambers and Messinger, 2001; Wood and Williams, 2013).

Under current federal regulations, mining through streams requires the complete reconstruction of the streambed. Mining-related effects to biological resources occur both directly (at the mine and fill sites during mining and after final reclamation) and indirectly (impairing downstream water quality and quantity, more thoroughly described in Subsection 4.2.2.1). Generally, when streams are mined through, a majority of the biota is lost (OSMRE, 2008; Pond et al., 2008). In many cases where streams are buried by overburden, the streams are eliminated along with the biota that once inhabited them (U.S. EPA et al., 2003; Pond et al., 2008; Palmer et al., 2010). Reclamation of the stream often focuses only on its return to form (e.g., the length of the stream, how it interacts with surface and groundwater) and does not include restoration of the stream function (e.g., returning the streambed habitat to a state where wildlife present before mining can return) (OSMRE, 2008; Pond et al., 2008; Northington et al., 2011; Petty, et al., 2013). The species composition of aquatic systems in areas surrounding mining activities has been shown to become more homogenized and dominated by generalist species more tolerant of disturbance as a result (Weed and Rutschky, 1971; Chapin et al., 1997; Walters et al., 2003; Carlisle et al., 2008; Pond et al., 2008; Pond, 2012).

Macroinvertebrates are often the most directly damaged by these downstream effects (e.g., U.S. EPA, et al., 2003; Pond, et al., 2008; Fritz, et al., 2010; Palmer, et al., 2010; Woody, et al., 2010; Bernhardt, et al., 2012; Pond, 2012; Pond, et al., 2014). Macroinvertebrates provide an important food source to amphibians, fish, bats, and other wildlife, have an important influence on nutrient cycling within streams, and serve as valuable indicators of stream degradation (U.S. EPA, 2005; U.S. EPA, 2011b). Wildlife that feed on macroinvertebrates (fish, bats, birds, etc.) may be indirectly affected through reduced prey populations or through the bioaccumulation of pollutants from feeding on contaminated prey (Woodward, et al., 1997; Harding, et al., 2005; Kimmel and Argent, 2010; Hopkins, et al., 2013). Loss of diversity and abundance of macroinvertebrates and contamination of these organisms is important therefore not only as an indication that a stream is degraded but also because of the implications for other important functions these organisms perform.

Valley fills are currently permitted under the existing regulations implementing SMCRA as part of certain mining methods (notably area mines and mountaintop removal mines), and in several coal basins these fills permanently bury ephemeral, intermittent, and perennial streams (U.S. EPA, et al., 2003; Pond, et al., 2008). Under the current regulations, operators can be allowed to place spoil directly into streams under certain circumstances. Spoil placed directly into streams (a notably common practice at area mines, mountaintop removal mines, and when using durable rock fills) permanently buries sections of streams (U.S. EPA, et al., 2003; Pond, et al., 2008). Organisms that cannot escape may experience immediate mortality or may experience longer-term mortality or stress as they are subjected to unsuitable habitat conditions.

Valley fills also affect aquatic systems through contamination; precipitation and groundwater percolate through the unconsolidated overburden and dissolve minerals until they discharge from the bottom of the fills as surface water (Pond et al., 2008). The dissolved minerals are then transported into the on-site and downstream surface waters and can alter water quality and the corresponding biological resources. Pollutants originating from valley fills can affect aquatic organisms as toxic substances in the water or as toxins in the food chain (Woodward et al., 1997; Kimmel and Argent, 2010; Hopkins et al., 2013). These effects can last for decades (Pond et al., 2014).

4.2.2.1.5 Documented Impacts Related to Land Alteration, Vegetation, and Wildlife

During the process of site preparation prior to coal mining the site must be cleared of vegetation to provide access to the materials below. This activity unavoidably results in the loss of terrestrial species habitat throughout the duration of the mining activity, which continues until reclamation of the site has successfully occurred. Postmining management of the land influences the habitat value of the reclaimed land. Under the No Action Alternative, vegetative cover must be established following mining activity, in accordance with the approved permit and reclamation plan (30 CFR 816.116 and 817.116). While this protection emphasizes revegetation with native species, the existing regulations do allow the use of introduced species (30 CFR 816.111 and 817.111). Permittees often choose to replant trees on mined sites, and this is promoted by OSMRE's Appalachian Regional Reforestation Initiative (ARRI); however, reforestation is not required under the No Action Alternative. Restoration of full habitat value within these replanted forests occurs over a long time frame. Under favorable growth conditions and management, forest canopy closure can occur within 15 to 20 years after mine closure (Groninger et al., 2007). Succession of mined lands to native forest may take hundreds of years (Angel et al., 2005).

The No Action Alternative contains minimal requirements for creating favorable growth conditions to return forest land to its premining condition. For instance, the regulations do not require the operator to salvage and redistribute all soil horizons (30 CFR 816.22 and 817.22). As a result the seed bank contained within the topsoil is not returned to the site to facilitate reestablishment of vegetation; and the loss of soil organic matter reduces the quality of the soil for vegetative regrowth, as does the compaction of the soil during filling and grading. The return to full site productivity may be delayed as a result (Angel, et al., 2005; Zipper, et al., 2011).

The existing implementing regulations at 30 CFR Part 810 establish the permanent program performance standards, including requirements that pertain to stockpiling of materials, site disturbance and revegetation to address and prevent erosion. Erosion remains a commonly encountered concern on mine sites despite these regulations, as it would with any activity that requires intensive land disturbance. When land is cleared for mining, the exposed and disturbed surface can result in erosion of particles from the land surface and increased runoff of these particles to downstream bodies of water. Sediment can have adverse impacts on the quality of receiving streams. For example, the diversity and population size of fish species, mussels, and benthic macroinvertebrates associated with coarse substrates can be greatly reduced if the substrates are covered with sand and silt (Appendix C of Berry et al., 2003). Amphibians are reported to avoid areas in streams with excessive siltation (Humphries and Pauley, 2005).

Other ways in which suspended sediments can interfere with ecosystem processes include: reduction of water clarity, impairment of food capture for sight-feeding fish and invertebrate species; absorption of sunlight and associated reduction in plant photosynthesis; warming of the stream; and filling of interstitial spaces that would otherwise provide shelter and foraging habitat for aquatic invertebrates (Bernhardt and Palmer, 2011). Impacts of sediment release are not always limited to near-field habitats (Chambers and Messinger, 2001). Sediments can be transported downstream, and large influxes of sediment can impair many miles of a stream system. Excess fine sediment runoff from mining activities has been shown to increase in the downstream reaches of streams below valley fills and decrease habitat quality for species that are sensitive to higher levels of turbidity (Wiley and Brogan, 2003; Pond et al., 2008).

As discussed previously the regulatory authority must consider fish, wildlife, and related environmental resources during the review of proposed mining operations, and the proposed operation would be required to address associated concerns including proposed destruction of riparian habitat (30 CFR 816.97). Removal of riparian vegetation and alteration of valley contours adversely impact aquatic ecosystems. These activities alter the patterns by which water flows through the affected valleys and change how water is delivered to streams below valley fills (Palmer et al., 2010). Riparian buffers are important for the nesting, movement, and feeding behaviors of some species. Narrowing the width of these buffers can also have adverse effects on the quality of the habitat (e.g., Klapproth and Johnson, 2000). Mining activities in the stream also result in the removal or alteration of components (substrate composition and particle size, riparian vegetation, temperature, and organic matter) of the stream and riparian zone that are important to the quality of the habitat for the organisms that use that habitat (Feminella, 1996).

Under existing regulations of the No Action Alternative surface water degradation through water contamination continues to occur, as described in the preceding section (4.2.1) on impacts of activities in and near streams. Water contamination can affect terrestrial wildlife that relies on aquatic systems for at least some of their life cycle requirements. Wildlife that feed on fish and other aquatic organisms may be indirectly affected through reduced prey or directly affected through food chain bioaccumulation of pollutants with potential to produce adverse impacts (Harding et al., 2005). Selenium is a pollutant of concern in association with coal mining, and has also been shown to accumulate in live animal tissues (U.S. EPA, 2016, Palmer et al., 2010). Selenium is known to be toxic to wildlife and livestock (Merck Sharp & Dohme Corp, 2008).

The existing regulations (No Action Alternative) allow mining through intermittent and perennial streams when the regulatory authorities makes a finding that diversion of the stream will not adversely affect water quantity, water quality, and related environmental resources of the stream (see 30 CFR 816.43(b) and 817.43(b)). The No Action Alternative requires that a permanent stream-channel diversion or a restored stream channel be designed and constructed so as to approximate the premining characteristics of the original stream channel, including riparian vegetation (30 CFR 816.43(a)(3)), but it does not require restoration of the stream's biological condition or ecological function. Fragmentation of stream channels has resulted from coal mining (U.S. EPA et al., 2003). Direct stream fragmentation occurs on permitted sites when roads, culverts, fills, dams, and other built features impede organisms from moving upstream and downstream and cause an interruption in the natural connections within a stream network (i.e., reduce stream connectivity) (Freeman et al., 2007). This stream fragmentation may cause distinct patch formation within a stream and may produce negative effects to both the abiotic and biotic factors of the stream (Kirkham and Fischer, 2004). Stream fragmentation can strongly influence population dynamics and species survival in spatially structured populations (Smucker and Vis, 2009; Letcher et al., 2007).

The requirements of 30 CFR 816.43 provide for restoration of stream flow and riparian vegetation, but do not require restoration of biological communities. Studies have shown that it can be difficult to restore biological characteristics in an engineered stream channel (e.g., Northington et al., 2011). In another example, Fritz, et al. (2010) compared ephemeral, intermittent, and perennial streams at reclaimed valley fills to naturally occurring forested streams. They detected significant differences in leaf litter breakdown (a critical process that provides nutrients and energy to the stream ecosystem beyond the mine site) and invertebrate assemblage when comparing valley fill reclaimed (constructed) perennial and intermittent streams to naturally occurring forested perennial and intermittent streams. The study also detected significant differences in coarse benthic organic matter and invertebrate assemblage (important parts of the foundation to the stream ecosystem) between reclaimed and natural ephemeral streams.

Finally, current regulations contain requirements for the construction of siltation and discharge structures to prevent additional contributions of suspended solids outside the permit area to the extent possible (30 CFR 816/817.46 and 816/817.47). When present, these engineered features retain water, by design, until sediments have settled out to allow the effluent from the structure to meet state and federal effluent limitations. As a result, while these structures are in place, they alter the timing and amount of water that reaches streams, which in turn adversely impacts downstream habitats (U.S. EPA et al., 2003; Woody et al., 2010). The creation of artificial water bodies alters flow dynamics and flood regimes, promotes the biotic homogenization of in-channel environments, and can alter the influx of allochthonous organic materials that are essential to the energy flow and biological productivity in stream ecosystems (Jackson, 2005; Rohasliney and Jackson, 2009; Fritz et al., 2010; Palmer et al., 2010).

4.2.2.1.5.1 Documented Impacts on Forest and Other Ecosystems

Mining activities can greatly influence forests and other terrestrial habitats due to the necessity to initially clear vegetation from the site to accommodate the mining activity. Land clearing for any activity, including coal mining, results in localized reduction in the extent of natural forest, shrubland, grassland, and arid (e.g., cryptobiotic soil) communities, and may reduce populations of locally important medicinal and culturally sensitive plants. Those reductions become long-term if the use of the land changes after mining is complete, or if the restoration of the impacted environmental component itself occurs only over a long timeframe, as with cryptobiotic soils.

Mining activity under existing regulations frequently leads to a changed land use on the reclaimed site in comparison to the use of the land prior to mining. When mining occurs on federal lands the federal land managing agency determines the postmining land use and OSMRE as the regulatory authority is required to consult with the managing agency to determine any special requirements related to achieving the postmining land use (30 CFR 740.4(c)(2)). Otherwise the permanent program performance standards at 30 CFR 816.33 and 817.133 require that all disturbed areas be restored to a condition capable of supporting the uses they were capable of supporting before the mining, or to support a higher or better use. The regulatory authority may approve a change to a "higher or better use" if the landowner or land management agency successfully demonstrates the proposed change would be safe, compliant with other state and federal laws and reasonably certain to be achievable. Mining can facilitate conversion of land by making it economically feasible to clear and recontour a site, since these activities would transpire as a matter of course during the mining activity.

Land transformation reduces the availability of habitats for some species, and increases the availability for others. The conversion of a site from forest to grassland for example is positive for grassland bird species, but negative for forest-dwelling bird species. Habitat loss is a leading cause of decline of some organisms (Vitousek et al., 1997) including salamanders in West Virginia (Wood and Williams, 2013), and mining activities cause acute changes to the landscape that often create unsuitable conditions for a variety of species (e.g., Carlisle et al., 2008).

In addition to the reduction in the acreage of premining habitats, this land transformation produces discontinuous patches, or fragments, within the original habitat that remains. Where continuous habitat once existed, patches of premining and postmining (i.e. transformed) habitat now exists, and in general the size of a habitat is the primary determinant of the number of species it can support (Rosenzweig, 1995). This habitat fragmentation often does not provide sufficient continuous cover, forage, or area to support the original wildlife populations that existed before mining, which can threaten local species (Rosenzweig, 1995). Bird, mammal, and insect species of forest interiors may be unable to cross even very short distances of open areas (e.g., land transformed by mining), thus reducing their ability to feed, reproduce, and maintain healthy populations (Primack, 2002).

As species of plants and animals are often adapted to narrow ranges of environmental conditions, changes in those conditions may make the habitat unsuitable once it is fragmented. Habitat fragmentation also produces more edge habitat where interior habitat once existed. These edge habitats are of reduced quality for some species due to changes in light, temperature, humidity, and wind, as well as increases in the incidence of fire (Stevens and Husband, 1998). Nests located along the edge may be more vulnerable to discovery and predation. Each effect can significantly influence the vitality and composition of species within the fragment (Primack, 2002). Shade-tolerant plant species and humidity-sensitive animals, such as amphibians, are often rapidly eliminated in edge habitats; invasive plants along the habitat edge can disperse seeds into the habitat interior where they may become established (Primack, 2002).

As with any type of land clearing activity, land clearing for mining increases the likelihood that invasive species can take hold within the cleared areas and encroach into surrounding intact habitats (Hobbs and Humphries, 1995). Surface mining techniques (such as area mining) involve more surface disturbance and therefore a higher potential for encouraging encroachment of invasive species Land clearing continues in phases through the active operation of the mine; invasive plant species that colonize one area then become established and spread to other areas as mining progresses (Richardson et al., 2000).

Because many invasive species are aggressive early colonizers of disturbed areas, even temporary spoil/overburden piles can offer invasive plants a foothold for establishment (Richardson et al., 2000). This is not universally true, however. In a study of terrestrial plant populations of forested and reclaimed sites, Handel (2003) found few invasive species on mined sites within the study area. The magnitude of the adverse impacts of invasive species may differ among coal extraction methods, depending on their methods of disposal. The dragline method of area mining has relatively lower potential for adverse impacts, as the excess spoil is placed in the cut or strip, reducing the area required for disposal, which in turn reduces the area available for invasive species to become established. Other mining methods, such as open-pit mining, and mountaintop removal mining may have moderate to high adverse impacts related to the spread of invasive species, as they often require larger areas for spoil disposal compared to other coal extraction methods.

Generally, it is a combination of threats that leads to a species population being threatened, endangered, or extinct. That is, it is typically not the case that an individual activity, such as coal mining, is a sole cause of adverse impacts to a species or its habitat. However, coal mining is described as a threat to the existence of multiple sensitive species, including both aquatic species (e.g., it is described as a threat to multiple listed mussel and fish species) and terrestrial species. For example, coal mining in Kentucky and West Virginia has resulted in large-scale forest habitat loss for the cerulean warbler, potentially leading to a significant effect on the species' total population size (71 FR 70725). While the federal listing status of some affected species would trigger requirements to avoid adverse effects (e.g., via ESA section 7 consultation) even absent the SPR, managing coal mines to reduce adverse water quality impacts and forest habitat loss will reduce the potential for coal mining to be a contributing factor in species and habitat decline. Furthermore, the guidance provided by the SPR regarding water quality management and forest reclamation informs coal mining interests how to best manage mine site to avoid the potential for adverse impacts on listed species.

In summary, existing regulations under the No Action Alternative contain many mechanisms for ensuring protection of fish, wildlife, and related environmental resources but coal mining practices occurring under these regulations continue to have adverse effects on aspects of the biological, chemical, and physical environment. These adverse impacts include: fragmentation of habitats; degradation of habitat quality; exposure of biota to changed chemical conditions in aquatic environments; and permanent loss of terrestrial and aquatic habitat. Adverse impacts would continue to occur, as described above, with all mining methods and in all coal regions under the No Action Alternative.

4.2.2.2 Action Alternatives and Potential Effects on Biological Resources

The Action Alternatives include elements intended to reduce the adverse effect of coal mining activities on biological resources. Table 4.2-16 describes the specific elements of the Alternatives that may affect biological resources. The discussion below describes how the rule elements vary by Alternative, and how they may affect the biological resources described in Table 4.2-16.

4.2.2.2.1 Protection of the Hydrologic Balance

As described more fully in Chapter 2, the rule elements described under this functional group are related to direct water sampling procedures, collection and review of stream hydrologic parameters, clarifying a federal definition for *material damage to the hydrologic balance*, and establishing the early detection of impending material damage to the hydrologic balance to promote prevention (i.e., evaluation thresholds). These elements focus on reducing the effect of mining activities on water quality at and in the vicinity of mine sites.

Table 4.2-16. Action Alternative Elements and Potential Effects on Biological Resources in Coal Mining Regions

Action Alternative Element	Forest Land Cover/ Habitat	Streamside Habitat	Fish and Wildlife, Including T&E Species
Baseline Data Collection and Analysis		■	■
Monitoring During Mining and Reclamation		■	■
Definition of Material Damage to the Hydrologic Balance		■	■
Evaluation Thresholds		■	■
Mining Through Streams	■	■	■
Activities In or Near Streams Including Placement of Excess Spoil and Coal Refuse	■	■	■
Revegetation, Topsoil Management, and Reforestation	■	■	■
Fish and Wildlife Protection and Enhancement	■	■	■

Under the No Action Alternative, regulatory authorities have approved stream-channel diversions and reconstructed stream channels that focus primarily on creation of a stable channel instead of the restoration of stream form and function. Consequently, reconstructed streams often neither look nor act in the way they did before mining. Frequently, these reconstructed stream channels no longer support the same abundance or diversity of benthic organisms and aquatic communities after mining.

The rule elements related to protection of the hydrologic balance have implications for biological resources that may not be readily apparent. These benefits derive primarily from the water quality described in Section 4.2.1. Protection of the hydrologic balance is achieved through several interrelated elements. For instance, newly collected monitoring data on selenium may show elevated concentrations in water. A clearly defined evaluation threshold may facilitate prompt changes in the mining operation to limit selenium contamination. This action may help avoid bioaccumulation of selenium in fish and in wildlife that consume fish (e.g., raptors). In this way, rule elements that improve water quality are also likely to benefit aquatic and streamside fish and wildlife communities.

4.2.2.2.2 Activities in or Near Streams: Mining Through Streams

The No Action Alternative allows for exemptions from general prohibitions against mining in or through streams. While it is feasible to restore the form and function of stream segments that are mined through or permanently diverted as a result of mining, there is no requirement to restore ecologic function. In addition it may be difficult to restore ecologic function of certain high gradient streams and or high quality streams. As a result, biological resources may be negatively impacted.

The Action Alternatives limit the circumstances under which streams may be mined through and increase ephemeral stream restoration, providing benefits to biological resources. Specifically:

- Alternatives 2 and 7 (in areas warranting enhanced permitting requirements) would prohibit all mining activities in or within 100 feet of a perennial stream and require hydrologic form and ecologic function restoration for all perennial and intermittent streams. Ephemeral streams would be restored in form only. These additional requirements would result in increased protection of in-stream and streamside habitat, ensuring that fewer streams are negatively affected by mining activities. Where forest land cover occurs within 100 feet of a perennial stream, this rule element would also reduce deforestation within a coal region. With less disruption of the aquatic resources at the mine site, there may be improved water quality, greater similarities between premining and postmining stream flow, and reduced impacts on aquatic habitat downstream. While this benefit applies to all mine sites under Alternative 2, Alternative 7 would only be applicable to a limited subset of mines, as described in Chapter 2. As a result, Alternative 2 restrictions on mining through streams and additional stream restoration requirements are expected to generate the greatest benefits to biological resources. The benefits would accrue primarily in the Appalachian Basin, with other regions realizing more limited benefits.

- Alternatives 3, 4, 5, 6, and 8 (Preferred) would implement additional protections to all streams, including requiring that at least some ephemeral streams be restored in form. These additional protections would likely improve water quality and positively impact downstream biological communities as described above for Alternatives 2 and 7, but to a lesser extent. In addition, Alternative 5 pertains specifically to the Appalachian region and therefore generates benefits in a more limited geographic region than Alternatives 3, 4, 6, and 8 (Preferred).
- Alternatives 7 (in areas not warranting enhanced permitting requirements) and 9 are identical to the No Action Alternative with respect to mining through streams and would in these circumstances continue the same degree of impact.

4.2.2.2.3 Activities In or Near Streams: Excess Spoil and Coal Refuse

Mining activities in and within 100 feet of streams, and the treatment of excess spoil and coal refuse, may adversely affect onsite streamside and downstream habitat. Excluding Alternative 9, all of the Action Alternatives (Alternatives 2 through 8) increase the stringency of the historic requirements that guide mining activities near streams and the placement of excess spoil and refuse. In particular, under Alternative 2, mining operations would be prohibited from filling perennial streams. In special circumstances (see section 2.4.7), Alternative 7 would also prohibit these activities. All Alternatives would also restrict mining activities within 100 feet of perennial and intermittent streams, providing benefits for both water quality and wildlife.[22]

4.2.2.2.4 Postmining Land Use and Enhancement: Revegetation, Topsoil Management, and Reforestation

This rule element dictates the types and levels of postmining revegetation, including reforestation, required under each of the Action Alternatives. As such, this rule element most directly influences the quantity and quality of forest land cover and other vegetative communities within the coal mining regions. The loss of forest and other habitat at mine locations under the No Action Alternative has a direct adverse effect on wildlife by reducing the total quantity of available habitat, as well as an indirect effect through habitat fragmentation. Impaired habitat conditions adversely affect the ability of a coal mining region to support particular species and may in turn negatively affect wildlife-related recreational activities, including hunting and wildlife viewing (as described in Section 4.3.3). Forest and other vegetated lands

[22] Peer reviewers emphasized the importance of stream buffers and habitat enhancement. In particular, the Galum Creek forested riparian corridor documented by Willard, et al. (2013) exemplifies a successful postmining wildlife habitat restoration effort. Communication from Jack Nawrot, “OSM Proposed Stream Rules: Comments – Water and Biological Resources.”

also provide benefits by increasing the terrestrial carbon sequestration potential of the landscape (i.e., reducing the amount of carbon in the atmosphere). This benefit is described in the "Potential Climate Stabilization Benefits of Reforestation" text box below, and is detailed in Section 4.2.4.

In addition, reduced forest land cover and streamside vegetation impairs water quality, as described in Section 4.2.1. Specifically, the vegetation provides a filter for pollutants as runoff travels across the landscape to receiving water bodies. This rule element focuses on increasing forest and vegetative habitat following mining, but may also benefit the quality of adjacent streamside and aquatic habitats.

The Action Alternatives propose a mix of regulatory changes with respect to revegetation, topsoil management, and reforestation:

- Alternatives 2, 3, 4, 5, 6, 7 (in areas subject to the enhanced permitting requirements), and 8 (Preferred) require reforestation of previously forested areas and of lands that would revert to forest under conditions of natural succession (with an exception for prime farmland). Reforestation would be implemented in a manner that expeditiously enhances the recovery of the native forest ecosystem.
- Alternatives 2, 3, 4, 5, 7, and 8 (Preferred) additionally specify that the revegetation be completed using only native species unless the postmining land use is actually implemented before the end of the revegetation responsibility period. To promote vegetation growth, these Action Alternatives also require the salvage and redistribution of all topsoil (A and E soil horizons) and of the B and C soil horizons to the extent necessary to achieve optimal rooting depths to restore premining land use capability or comply with revegetation requirements.
- Alternatives 2, 4, and 7 require salvage and redistribution or reuse of all vegetative organic materials above the A soil horizon to promote reestablishment of diverse native vegetation and prohibits burning or burying of vegetation or other organic materials. However, Alternatives 3 and 5 require salvage and redistribution of materials from native vegetation above the A soil horizon and root balls only to the extent determined necessary by a qualified ecologist or similar expert. Under those alternatives, the remaining debris from native vegetation could be buried, but not burned. Alternative 8 (Preferred) is similar to Alternatives 3 and 5, but it also prohibits burying of native vegetation.
- Alternatives 7 (in areas not subject to the enhanced permitting requirements) and 9 are identical to the No Action Alternative with respect to revegetation, topsoil management, and reforestation.

4.2.2.2.5 Postmining Land Use and Enhancement: Wildlife Protection and Enhancement

The Action Alternatives contain elements that would improve the quality and/or quantity of habitat within a permit boundary, increasing wildlife species richness and abundance within the permit boundary and on adjacent lands. These benefits to wildlife species may improve wildlife-related recreational experiences in the coal regions, as described in Section 4.3.3.

4.2.2.2.6 ESA Consultation

OSMRE requested formal consultation with the U.S. FWS on the preferred Alternative. Further details on this consultation will be provided in the Biological Assessment and Biological Opinion for the Stream Protection Rule, which will be available at www.osmre.gov and on www.regulations.gov under the SPR docket upon issuance of the Record of Decision. These documents will contain the final species lists on which the consultations were based, as well as the terms under which this consultation would be reinitiated.

Because implementation of the rule would potentially take several years, OSMRE and the U.S. FWS have agreed that in the interim period between finalization of the rule and its implementation nationwide, the 1996 biological opinion on OSMRE's regulatory program is still valid and will remain in effect. OSMRE and the U.S. FWS are in the process of finalizing a MOU (referred to as the "ESA MOU" elsewhere in this FEIS) to provide guidance to OSMRE, the U.S. FWS, and regulatory authorities for demonstrating compliance with the terms and conditions of the Incidental Take Statement accompanying the 1996 biological opinion, which provides incidental take coverage for any take resulting from a proposed coal mining and reclamation operation.

The OSMRE has determined that adoption of the proposed rule (or any of the Action Alternatives) would have no direct or indirect effects on species and would not impact any proposed or designated critical habitat under the jurisdiction of the National Marine Fisheries Service (NMFS). This finding is based on OSMRE's analysis that found that direct and indirect effects of the proposed action would occur far enough from any listed or proposed species or designated or proposed critical habitat under NMFS jurisdiction that any potential direct or indirect effects from our proposed would be undetectable and would therefore have no impact on those species or habitats.

**POTENTIAL CLIMATE STABILIZATON
BENEFITS OF REFORESTATION**

Carbon dioxide and other greenhouse gases released into the atmosphere contribute to climate change. Carbon sequestered by and stored in soils and vegetative biomass reduces the total amount of carbon present in the atmosphere, mitigating adverse effects of climate change (e.g., crop damage, coastal protection costs, land value changes, and human health effects). In other words, the value of carbon sequestered reflects the avoided damage generated by that carbon if it is present in the atmosphere. Where forest land cover is lost or is less productive, the carbon storage potential of the landscape is reduced.

Changes in carbon storage potentials are not quantified in this analysis due to the significant uncertainty surrounding carbon sequestration rates over time for forests according to varying revegetation and forest management practices. As forest and other vegetated land is cut for the purpose of coal mining, there is a loss in the carbon storage capacity of the landscape. This is the case under the No Action and Action Alternatives. As the revegetation practices of the Action Alternatives are focused on expeditiously returning productive forest land cover postmining, however, some level of associated benefit in terms of increased carbon sequestration rates on improved acres is likely.

A number of studies have measured carbon sequestration rates for forests and soils at reclaimed mine sites, particularly in the Midwest and Appalachia (e.g., Amichev et al., 2008; Chaudhuri et al., 2012; Zipper et al., 2011; and Midwest Regional Carbon Sequestration Partnership (MRCSP), 2011). These studies generally found that reforestation, as opposed to revegetation to grass or pastureland, increases carbon sequestration rates at the reclamation sites. Carbon sequestration rates of reforested mine sites were, however, less than non-mined forested stands. For example, non-mined hardwood stands in Appalachia contained 62 percent more carbon than the average mined and reforested stands (Amichev et al., 2008). This indicates that reforestation practices in the region have increased carbon sequestration rates as compared to other revegetated land cover, but did not recover the premining carbon sequestration potential of the forested sites.

More recently, the ARRI has encouraged the creation of more valuable timber stands on reclaimed forest land through voluntary implementation of soil management and planting practices referred to as the Forestry Reclamation Approach (FRA). The soil management and planting practices described by OSMRE’s Action Alternatives are similar to FRA practices. The objective is to promote more productive forest stands postmining, which would increase carbon sequestration potential of the reclaimed stands. While implementation of FRA practices is increasing, the approach is still relatively new. The oldest FRA-reclaimed sites are less than a decade old. As a result, additional time and study are required to determine the extent to which these practices are restoring forest ecosystem services, including carbon sequestration, to mined sites (Zipper et al., 2011).

With respect to wildlife protection and enhancement, the Action Alternatives differ in the following ways:

- Under Alternatives 2, 6, and 8 (Preferred) all stream reaches within or adjacent to coal mining operations require a 100-foot streamside vegetative corridor (whereas the No Action Alternative provides qualitative guidance on activities bordering waterways). By implementing specific criteria to be met during and after coal mining operations, the likelihood of disrupting habitats and associated wildlife is decreased. This buffer benefits not only the flora and fauna occupying the streamside habitat, but also the connected terrestrial and aquatic communities beyond the permitted site.
- Alternatives 3 and 4 require establishment of a 300-foot streamside vegetative corridor along intermittent and perennial streams. These Alternatives also specifically detail the scenarios in which enhancement measures for fish and wildlife resources would be mandatory, including the long-term loss of native forest or plant communities, or the filling of perennial or intermittent streams. Similar to Alternative 2, Alternatives 3 and 4 decrease the probability that wildlife habitat, both aquatic and terrestrial, would be negatively impacted as a result of mining activity. While the benefit to intermittent and perennial streams is greater due to the 300-foot as opposed to 100-foot streamside vegetative corridor, Alternatives 3 and 4 do not include a streamside vegetative corridor requirement for ephemeral streams. The relative benefits of Alternative 2, 6, and 8 (Preferred) as compared with 3 and 4 accordingly depend on the types of streams present at a mine site. For example, where ephemeral streams are abundant and intermittent and perennial streams scarce, Alternative 2 likely provides a greater benefit.
- Alternatives 5 and 7 require a 100-foot streamside vegetative corridor for all streams, similar to Alternatives 2, 6, and 8 (Preferred). However, because the regulations under Alternatives 5 and 7 would only apply under specific circumstances (as described in Chapter 2), associated benefits to streamside and aquatic biological communities apply to a more limited geographic region.
- Alternative 9 would make no changes and bring no additional benefits to these resources in comparison to the No Action Alternative. Under these alternatives the regulatory authority could authorize activities within 100 feet of perennial and intermittent streams, and there would be no additional specific requirement to create a preserved buffer along the length of the stream.

With respect to federally listed threatened and endangered species, all Action Alternatives but Alternatives 6 and 9 also require the fish and wildlife protection and enhancement plan in the SMCRA permit application to include any steps taken to comply with the Endangered Species Act of 1973, 16 U.S.C. 1531 et seq., including any biological opinions developed under section 7 of that law and any species-specific habitat conservation plans developed in accordance with section 10 of that law. The regulatory authority may not approve the permit application before there is a demonstration of compliance with the Endangered Species Act of 1973.

4.2.2.3 Analytic Methods for Assessing Forest Land Cover

The Action Alternatives benefit forest resources to varying degrees. Available data allow characterization of potential impacts for two quantitative indicators:

- The number of improved forest acres; and
- The number of preserved forest acres.

The subsections below present the data and analytic methods used to evaluate the Action Alternatives with respect to these two quantitative indicators.

In addition, the Action Alternatives have the potential to benefit streamside habitat as well as fish and wildlife (including threatened and endangered species). Data are not sufficient to support a quantitative analysis of these impacts, so the results discussion evaluates them qualitatively, allowing comparison of the Alternatives.

4.2.2.3.1 Methods for Assessing Improved Forest Acres

The improved forest acres metric quantifies the amount of land that would benefit from improved postmining forest land cover due to the Action Alternatives, either because: (a) the land would have been restored to grassland, pastureland, or an alternative postmining land use under the No Action Alternative; or (b) the land would have been reforested under the baseline without practices that promote expeditious growth of healthier forest (e.g., Forestry Reclamation Approach (FRA) with practices similar to those reforestation practices described under Alternative 2 in Chapter 2).

The volume of forest acreage that typically exists before mining at mine sites is a useful starting point for assessing how the Action Alternatives differ with respect to reforestation benefits and for identifying regions where reforestation benefits may be greatest. To estimate this acreage, this analysis uses available historical land cover data (the oldest comprehensive dataset was 1992) at sites that have since been mined. The oldest comprehensive dataset is used to represent premining vegetative cover as closely as possible. As such, Table 4.2-17 summarizes the land cover in 1992 that was present at mine sites that were developed after 1992 in each of the coal regions in order to understand premining land cover conditions in each region. This analysis of land cover at mine sites relies upon the following information for each coal region: (1) GIS-based 1992 land cover data;[23] (2) GIS data describing locations of mines;[24] and (3) the size of the typical disturbed area for surface and underground model mines in each region, as determined by the engineering analysis (i.e., model mine analysis) described in Section 4.1. This acreage was used as a buffer around the mine site locations to understand the typical land cover at study sites.

[23] This analysis applies historical land cover data from the USGS's National Land Cover Dataset (NLCD). The NLCD identifies land cover data from 1992 accordingly to 21 land cover classes.

[24] GIS data on historic mines (mine sites developed after 1992) are from: the National Mine Map Repository; Arkansas Department of Environmental Quality; Colorado Division of Reclamation Mining and Safety; Illinois State Geological Survey; Indiana Geological Survey; and Texas Railroad Commission.

Table 4.2-17. Premining Land Cover at Historic Mine Sites

Number of Reference Points*	49	18	117	55	1	4	24	95	44	17	2

Notes: Due to limited historic mining activity in the Northwest region, data are not available to describe typical land cover at historic mining locations in the Northwest region.

* The number of reference points describes the number of relevant mines site for which GIS data were available to describe locations and land cover.

Source: USGS, 2011c.

The overlap between minable coal and forested landscapes is most prevalent in the Appalachian Basin, as demonstrated in Table 4.2-17.[25] Total premining forested land cover ranges between 55 percent (for underground mines in Northern Appalachia) to 93 percent (for surface mines in Central Appalachia). Premining forest cover is also prevalent at Colorado Plateau mining sites.

This analysis quantifies "improved" forest acres according to the following methods:

4.2.2.3.1.1 Step 1: Estimate the acres of forest cut per million tons of coal produced at surface and underground mines in each region and under each Alternative.

a) Determine the land area (in acres) disturbed by surface and underground mines at model mines in each region under each Alternative.

This first step references the estimated "disturbed area" at each of the Model Mines under each of Alternatives 1 through 9, as described in the engineering analysis in Section 4.1. The disturbed areas vary only slightly across Alternatives. Specifically, under Alternative 2 in Appalachia the disturbed area for surface mines is slightly decreased reflecting a change in the design of mines to comply with the Alternative 2 rule elements (e.g., avoiding streams and reducing fills).

b) Determine proportion of the disturbed area likely to be forest land cover premining for each mine type (surface and underground) in each region.

To accomplish this, this analysis references the premining "typical" land cover types for surface and underground mines in each region based on historical precedence, as described in Table 4.2-17. This information is summarized in Column A of Table 4.2-18 (discussed below). The analysis assumes that the percentage of forested land cover at a mine site does not vary across Alternatives.

c) Calculate the number of forest acres disturbed by typical mines for each mine type and region under each Alternative.

Multiply the total disturbed area (Step 1a) by the proportion likely to be forest (Step 1b). The result is the number of forest acres cut at typical surface and underground mines in each region.

d) Calculate disturbed (i.e., cut) forest acres per million tons of coal produced for each mine type and region.

Divide the total disturbed forest acres at each Model Mine calculated in Step 1c by the level of coal produced at each Model Mine as determined by the engineering Model Mine analysis (described in Section 4.1).

The result of this step is a series of multipliers used to calculate the amount of forest cut per million tons of coal produced by surface and underground mining methods in each region. There is limited variation in these multipliers across Alternatives because the disturbed areas and tons of coal produced at the

---

[25] While this analysis focuses specifically on forested lands, mines may affect multiple types of vegetative cover, as described in Table 4.2-17 (including grass, shrub, and cropland). However, the Action Alternatives do not identify explicit differences with regard to revegetation practices for other land cover types beyond native species requirements and soil management practices.

Model Mines do not vary measurably across Alternatives. The exception is an estimated reduction in the disturbed area for Central Appalachian surface mines under Alternative 2 (resulting in a slightly lower multiplier for forested acres disturbed per volume of coal produced under this Alternative). These multipliers are described in Column B of Table 4.2-18 below.

4.2.2.3.1.2 Step 2: Establish reforestation practices under the No Action Alternative.

a) Determine level of reforestation occurring under the No Action Alternative in each region.

Although not required, reforestation of mine sites is occurring in some regions. In particular, in Appalachia reforestation has become increasingly practiced in recent years. Based on this recent experience, OSMRE estimates that approximately 70 percent of all mining permits are being reclaimed as forestland in the Appalachian Basin region.[26] According to OSMRE's postmining land use data for 2007 through 2010, reforestation is occurring to a lesser extent in the Gulf Coast (approximately four percent of reclaimed acreage) and the Illinois Basin (approximately 11 percent). All other regions are implementing reforestation at negligible rates.[27] The level of baseline reforestation occurring under the No Action Alternative is provided in Column C of Table 4.2-18.

b) Determine level of reforestation occurring under the No Action Alternative in each region that complies with the "improved" reforestation practices (i.e., revegetation, topsoil management, and reforestation elements) described by the Action Alternatives.

With the exception of some sites in Appalachia, the improved reforestation practices (i.e., FRA practices) required in Alternatives 2, 3, 4, 5, 7 and 8 are generally not being implemented under the No Action Alternative. The improved reforestation practices were first implemented at limited sites in Appalachia beginning in about 2006 (Zipper, et al., 2011). According to data gathered by the ARRI, approximately 37 percent of the trees planted at reclaimed mine sites in Appalachia in 2012 were planted according to the improved reforestation methods.[28] As described in Column D of Table 4.2-18, this analysis assumes that 37 percent of disturbed forest in Appalachia is being reclaimed according to improved reforestation practices.

4.2.2.3.1.3 Step 3: Determine expected reforestation levels under the Action Alternatives.

Action Alternatives 2, 3, 4, 5, 7, and 8 (i.e., all except Alternative 6 and 9) require that reforestation be implemented according to improved reforestation practices to varying degrees (as described in Subsection

---

[26] Information provided by OSMRE forestry staff to IEc on July 26, 2013.

[27] Information on reforestation rates for all coal regions except Appalachia is derived from OSMRE data on postmining land use (PMLU) by state and region for 2007 through 2010; these data are compiled from OSMRE's Annual Oversight Reports. Note that the PMLU figures are not directly equivalent to reforestation rates. Specifically, while the reforestation rate is the percent of premining forest land that is reforested, the PMLU forestry rate is the percent of all mined land on which forests are planted. The PMLU forestry rate will be less than the true reforestation rate to the extent that forest land is returned to another use (e.g., agriculture). The PMLU rates are presented to acknowledge that mine operators in some regions appear to implement modest reforestation efforts as part of postmining land use programs.

[28] ARRI data provided by OSMRE on August 13, 2013, "ARRI FRA Data: 2012 Appalachian Region Tree Planting Numbers." While these data reference the percentage of trees planted according to FRA practices, this analysis relies on this percentage as a proxy for the share of the reforested acres planted according to FRA practices.

4.2.2.2). In addition to specifying reforestation practices, these Alternatives also require that all previously forested acres and lands that would revert to forest under conditions of natural succession be reforested. All of the Action Alternatives include an exception for prime farmland. Absent specific information on the share of previously forested area that would be eligible for exception, this analysis conservatively assumes that 70 percent of the previously forested acres would be forested in each region under the Action Alternatives (Column E of Table 4.2-18). This assumption likely leads to an understatement of potential benefits in terms of improved forest acres, as less than 30 percent of the mine sites may be eligible for exceptions to reforestation requirements.

4.2.2.3.1.4 Step 4: Calculate number of reforested acres according to improved reforestation practices under the No Action Alternative from 2020 to 2040.

a) Calculate the estimated forest cut by surface mine activity in each region.

Multiply surface coal production under the No Action Alternative across the timeframe of the analysis by the forested acres cut per million tons of coal produced by surface mines (Step 1, Column B of Table 4.2-18). This calculation yields an estimate of the amount of forest cut in each region due to surface mine activity.

b) Calculate the estimated forest cut in each region by underground mine activity.

Repeat step 4a for underground mine activity.

c) Estimate the total regional forest cut.

Sum the expected forest cut due to surface and underground coal mining activity to estimate total forest cut at the regional level across the timeframe of the analysis.

d) Calculate the acres reforested according to improved practices under the baseline.

Multiply the acres of forest cut by the baseline improved reforestation rate for each region (Column D of Table 4.2-18). This represents acres reforested according to improved practices, similar to the FRA, under the baseline. For example, in Appalachia this estimate is 37 percent but is zero in all other regions.

4.2.2.3.1.5 Step 5: Calculate number of reforested acres according to improved reforestation practices under the Action Alternatives (Alternatives 2, 3, 4, 5, 7, and 8) from 2020 to 2040.

Repeat Step 4 using the coal production, forest acres cut per million tons of coal produced (Step 1, Column B of Table 4.2-18), and reforestation rates (Column E of Table 4.2-18) for each of the relevant Action Alternatives (Alternatives 6 and 9 are the same as the No Action Alternative).

4.2.2.3.1.6 Step 6: Calculate total forest acres improved.

Subtract the No Action Alternative reforested acres (Step 4) from the Action Alternative reforested acres (Step 5) to determine the number of forest acres that are improved due to implementation of each Action Alternative in each region.

4.2.2.3.1.7 Step 7: Calculate average annual forest acres improved.

To estimate average annual acres improved in each region, divide the total improved acres (2020 to 2040) by the 21-year timeframe of the analysis.

Table 4.2-18. Assumptions of Land Cover and Reforestation Practices for the Improved Forest Acres Analysis

		A	B	C	D	E
Mine Region (Type)		**Percent Premin ing Forest Land Cover**	**Forest Acres Cut per Million Tons of Coal Produced**	**No Action: Percent Reforested (Postmining Land Use)**	**No Action and Alternatives 6 and 9: Percent Reforested Applying Improved Methods**	**Alternatives 2, 3,4,5,7, 8: Percent Reforested Applying Improved Methods**
SURFACE MINES						
Appalachia	**North**	63%	73.1 (63.8 for Alt 2)[b]	70%	37%	70%
	Central	93%				
Colorado Plateau		55%	19.8	0%	0%	70%
Gulf Coast		26%	12.7	4%	0%	70%
Illinois Basin		19%	16.4	11%	0%	70%
Northern Rocky Mountains and Great Plains		5%	0.3	0%	0%	70%
Northwest		5%[a]	0.7	0%	0%	70%
Western Interior		88%	75.7	0%	0%	70%
UNDERGROUND MINES						
Appalachia	**North**	55%	6.9	70%	37%	70%
	Central	78%	6.9	70%	37%	70%
Colorado Plateau		55%	1.2	0%	0%	70%
Illinois Basin		17%	0.7	11%	0%	70%
Northern Rocky Mountains and Great Plains		5%	0.4	0%	0%	70%
Western Interior		88%	0.6	0%	0%	70%

Notes:

[a] Absent specific information on land cover at typical surface mines in the Northwest region, this analysis relies on the Northern Rocky Mountains and Great Plains region as a proxy.

[b] The cut forest acres per ton of coal produced is slightly less under Alternative 2 as mines in this region under this Alternative disturb less total acreage but produce the same total amount of coal.

4.2.2.3.2 Methods for Assessing Preserved Forest Acres

Preserved forest areas are forest areas that are left undisturbed because of a decrease in surface coal mining activity.[29] Implementation of the Action Alternatives may benefit forest habitat in the coal regions by reducing overall levels of coal production or by shifting coal production from surface methods (which require cutting more forest) to underground methods.

This analysis quantifies "preserved" forest acres according to the following methods:

4.2.2.3.2.1 Step 1: Estimate the acres of forest cut per million tons of coal produced at surface and underground mines under the No Action Alternative.

Similar to Step 1 of the methods for calculating improved acres, the evaluation of preserved acres first requires calculating region-specific multipliers describing the amount of forest cut per million tons of coal produced by surface and underground mining methods.

a) Determine the land area (in acres) disturbed by surface and underground mines at the Model Mines in each region under the No Action Alternative.

This first step references the estimated "disturbed area" at each of the Model Mines under the No Action Alternative (Alternative 1).

b) Determine proportion of the disturbed area likely to be forest land cover premining for each mine type (surface and underground) in each region.

This information is summarized in Column A of Table 4.2-18 above.

c) Calculate the number of forest acres disturbed by the Model Mines for each mine type and region under the No Action Alternative.

Multiply the total disturbed area (Step 1a) by the proportion likely to be forest (Step 1b). The result is the number of forest acres cut at the model surface and underground mines in each region under the No Action Alternative.

d) Calculate disturbed (i.e., cut) forest acres per million tons of coal produced for each mine type and region.

Divide the total disturbed forest acres at each Model Mine calculated in Step 1c by the level of coal produced (in terms of millions of tons) at each Model Mine as determined by the engineering Model Mine analysis (described in Section 4.1).

---

[29] In this analysis, "preserved" forest acres are those areas not cleared for mining during the study period. The forests are not preserved in perpetuity, i.e., they may be cleared for other purposes at some point in the more distant future.

4.2.2.3.2.2 Step 2: Calculate forest acres cut under the No Action Alternative in each region across the timeframe of the analysis.

Multiply surface coal production under the No Action Alternative across the timeframe of the analysis by the relevant region-specific cut forest acres multiplier for surface mining from Step 1. Undertake the same calculation for underground coal production. Sum the total acres of forest cut to accommodate surface and underground coal production from 2020 to 2040 to estimate total acres of forest cut for coal mining under the No Action Alternative.

4.2.2.3.2.3 Step 3: Calculate forest acres cut under the Action Alternatives in each region across the timeframe of the analysis.

Conduct the same calculation as in Step 2, but rather than basing acres cut on baseline production, base acres cut on estimated coal production (by region and surface or underground mine methods) for each of the Action Alternatives.

4.2.2.3.2.4 Step 4: Calculate total and average annual forest acres preserved due to implementation of the Action Alternatives.

Subtract the total forest acres cut under the Action Alternatives (2020 to 2040) from the total forest acres cut under the No Action Alternative (2020 to 2040). The difference reflects forest acres preserved due to implementation of the Alternatives. Divide the total number of preserved acres by the 21-year timeframe of the analysis to estimate average annual forest acres preserved by region.

4.2.2.4 Analytic Results for Assessing Forest Land Cover

4.2.2.4.1 Estimate of Improved Forest Acres

Table 4.2-19 and Figure 4.2-3 present the results of the analysis of improved forest acres. While Alternative 2 prescribes similar reforestation improvements to several other Action Alternatives (Alternatives 3, 4, and 8 (Preferred)), the benefits associated with Alternative 2 in terms of acres of improved forest are less. This result occurs because the estimated amount of coal produced under Alternative 2 is less than under the other Action Alternatives. As a result, fewer forest acres are cut under Alternative 2, which results in more preserved forest acres and fewer improved forest acres. Moreover, as noted above, typical surface mines in Central Appalachia designed according to the requirements of Alternative 2 are associated with a reduced disturbed area compared to the other Alternatives. The amount of forest acres cut per million tons of coal produced under Alternative 2 in Appalachia is therefore slightly less than under the other Action Alternatives.

Alternatives 5 and 7 apply to a more limited geographic area and therefore benefit fewer acres than Alternatives 3, 4, and 8 (Preferred). Alternatives 6 and 9 do not require reforestation of previously forested areas; therefore, they generate no additional forest improvement benefits in comparison to the No Action Alternative.

Table 4.2-19. Average Annual Improved Forest Acres Analysis Results (2020 to 2040)

Alternative	Appalachian Basin	CO Plateau	Gulf Coast	Illinois Basin	Northern Rocky Mountains and Great Plains	Northwest	Western Interior	Total Over the 21 Year Study Period (2020 to 2040)
Alternative 2	1,004	274	397	256	78	0	166	45,713
Alternative 3	1,346	274	397	256	78	0	166	52,890
Alternative 4	1,312	274	397	256	78	0	166	52,179
Alternative 5	1,313	0	0	0	0	0	0	27,567

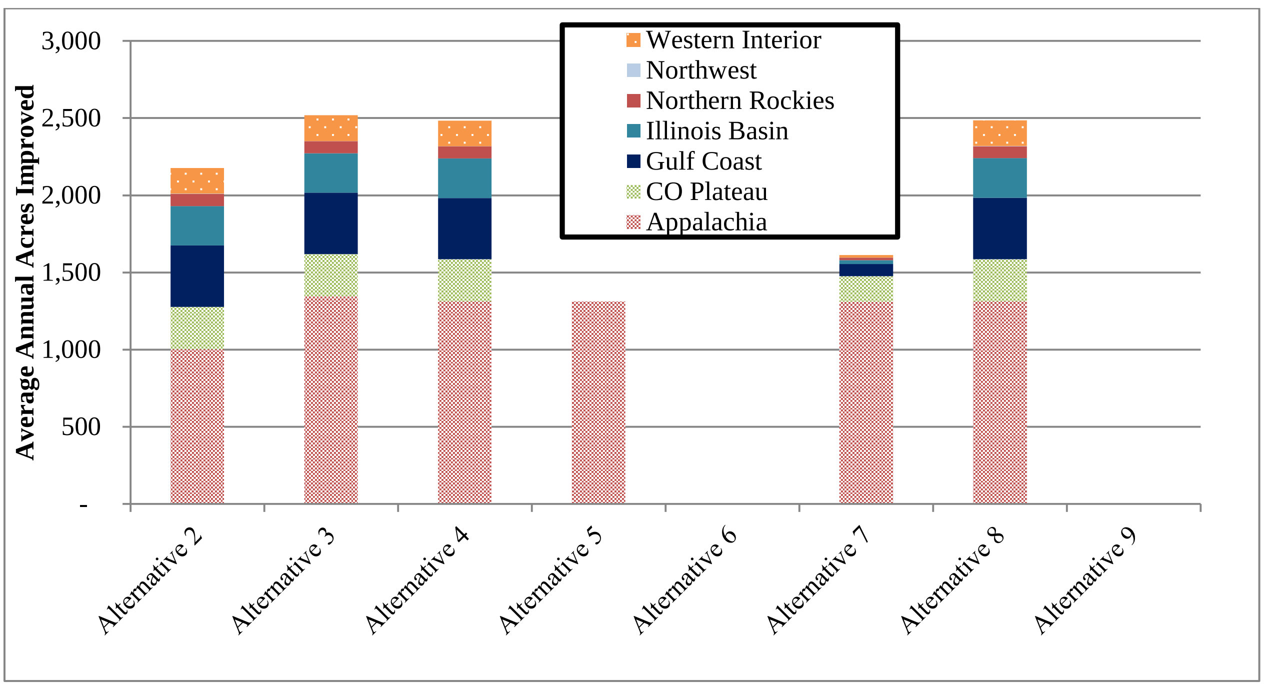
Alternative 7	1,311	164	79	26	16	0	17	33,880
Alternative 8 (Preferred)	1,313	274	397	257	78	0	166	52,211
Alternative 9	0	0	0	0	0	0	0	0

Figure 4.2-3. Improved Forest Acres Analysis Results by Coal Region and Alternative



4.2.2.4.2 Estimate of Preserved Forest Acres

Table 4.2-20 and Figure 4.2-4 present the results of the preserved forest acres analysis. The benefits are largely limited to the Appalachian coal region for two reasons. First, coal mining (particularly surface production methods) requires cutting more forest in Appalachia than in other regions (see forest acres cut per million tons of coal produced multipliers in Table 4.2-18). Second, implementation of the Action Alternatives affects overall coal production levels in Appalachia to a greater degree than in the other regions. As a result of these factors, implementation of the Action Alternatives in Appalachia reduces the amount of forest cut. The effect is generally zero or Negligible in the other coal mining regions. Alternative 2 generates the greatest benefit in terms of preserving forest land cover as this Alternative is associated with the greatest reduction in surface coal production.

Table 4.2-20. Average Annual Estimate of Preserved Forest Acres (2020 to 2040)

Alternative	Appalachian Basin	CO Plateau	Gulf Coast	Illinois Basin	Northern Rocky Mountains and Great Plains	Northwest	Western Interior	Total Over the 21 Year Study Period (2020 to 2040)
Alternative 2	21	0	0	1	0	0	0	458
Alternative 3	13	0	0	1	0	0	0	295
Alternative 4	10	0	0	1	0	0	0	239
Alternative 5	9	0	0	0	0	0	0	184
Alternative 6	5	0	0	1	0	0	0	116
Alternative 7	11	0	0	1	0	0	0	249

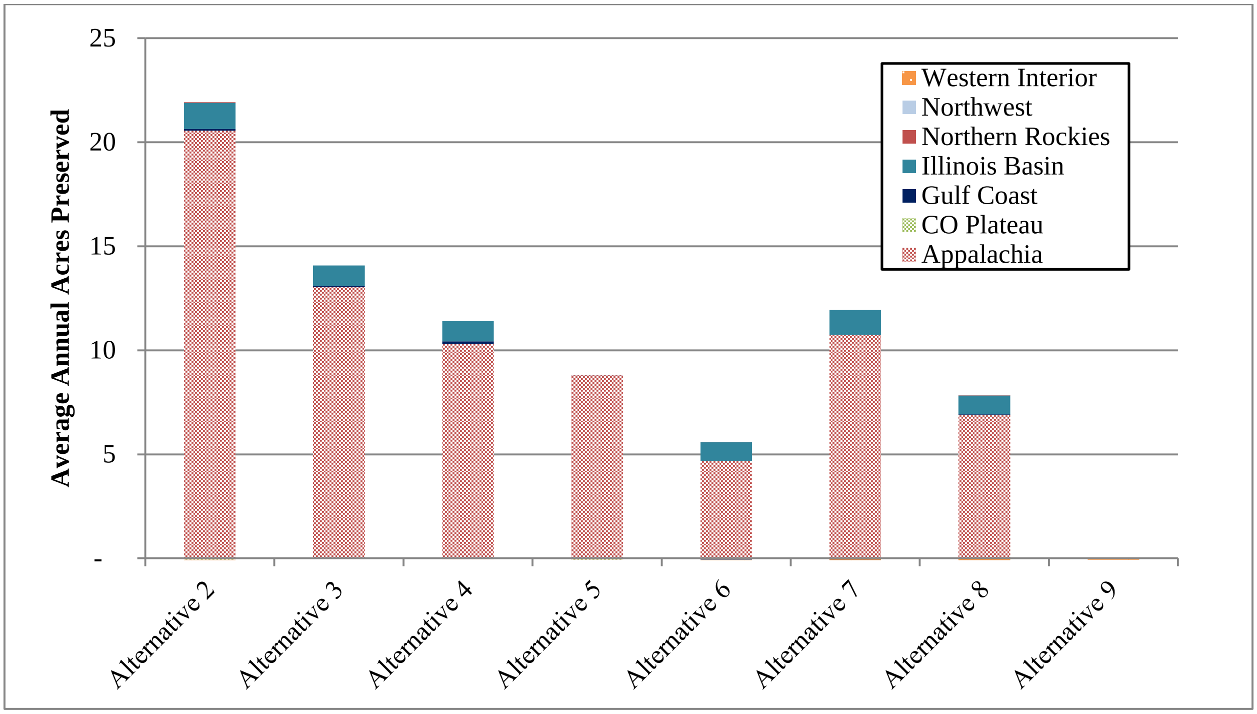
Alternative 9	0	0	0	0	0	0	0	0

Figure 4.2-4. Estimate of Preserved Forest Acres, by Coal Region and Alternative



4.2.2.5 Qualitative Analysis of Effects on Streamside Habitat

A key focus of the Action Alternatives is also to improve streamside habitat. As discussed in Subsection 4.2.2.2, multiple elements within each Action Alternative benefit the quantity and quality of streamside habitat in the coal regions, most directly the establishment of streamside vegetative corridors. In addition, rule elements that benefit water quality on and downstream of mine sites (e.g., protection of hydrologic balance and limitations on activities in or near streams) may likewise reduce the effects of mining on streamside habitats surrounding streams.

Requirements to implement streamside vegetative corridors with native, non-invasive vegetation provide the most direct benefit to streamside habitat. The purpose of the streamside vegetative corridors is to support restoration of the ecological function of streams impaired by mining activities. Consequently, in addition to increasing the overall availability of streamside habitat and supporting streamside species, these buffers protect water quality downstream and the aquatic communities contained within them.

Requirements for streamside vegetative corridors vary across the Action Alternatives. Alternatives 2, 5, 6, 7, and 8 (Preferred) require that all restored or permanently diverted stream reaches (perennial, intermittent, or ephemeral) implement a minimum 100-foot streamside vegetative corridor. On the other hand, Alternatives 3 and 4 specify a minimum 300-foot buffer comprising native, woody species but limit this requirement to restored or permanently diverted intermittent and perennial streams. While the benefit to intermittent and perennial streams is likely greater under Alternatives 3 and 4 due to the 300-foot, as opposed to 100-foot buffer, these two Alternatives do not include a buffer requirement for ephemeral streams. Alternative 9 would require a 100-foot buffer with allowable exceptions, and would be functionally similar to the No Action Alternative.

It is difficult to predict at a given mine site, or at the regional level, whether the larger, but more geographically limited buffers under Alternatives 3 and 4, or the smaller but more broadly implemented buffers under Alternatives 2, 5, 6, 7, and 8 (Preferred) would generate greater streamside and aquatic community benefits. The effects of the streamside vegetative corridors would depend on the relative presence of intermittent, perennial, and ephemeral streams. At sites, where limited or no ephemeral stream reaches are affected by mining, Alternatives 3 and 4 provide a greater benefit to the streamside and aquatic habitats within and downstream of the site. Conversely, where the majority of affected streams are ephemeral at a given site, Alternatives such as Alternative 2 provide the greater benefit.

Alternatives 5, 6, and 7 require a 100-foot streamside vegetative corridor for all streams, similar to Alternative 2. However, because the requirements under Alternatives 5 and 7 apply only under specific circumstances (as described in Chapter 2), the associated benefits to streamside and aquatic biological communities would be more limited than under Alternative 2, which is applicable to all surface coal mining operations. Likewise, Alternative 6 effects would be more limited. Under Alternative 6, streamside vegetative corridors (on any type of stream) would be required only for the portions of those streams within the 100-foot streamside vegetative corridor of an intermittent and perennial stream impacted by the mining activity. For example, Alternative 6 would require a 100-foot streamside vegetative corridor around the ephemeral stream segments occurring within 100 feet in any direction (including upstream) from impacted intermittent or perennial stream segments.

Although not directly quantifiable, each of the Action Alternatives (except Alternative 9) provide some benefit to streamside habitat above and beyond the protections of the No Action Alternative. As discussed below, the expected level of benefit (Negligible, Minor, Moderate, or Major) for each Alternative is based on the number of potential affected streams at the regional level (as quantified in Section 4.2.1) and the particular streamside vegetative corridor requirement of the rule elements.

4.2.2.6 Qualitative Analysis of Effects on Fish and Wildlife, and Threatened and Endangered Species

The negative effects of mining on specific features of habitats (soils, topography, water quality, and vegetation) may make it more difficult for wildlife species to reestablish after a mining disturbance and may increase the proliferation of non-native species on reclaimed landscapes. It follows that elements of the Action Alternatives that require the reestablishment of these landscape characteristics are likely to benefit associated fish and wildlife species. To evaluate impacts of the Action Alternatives on fish and wildlife species, this analysis accordingly considers effects on vegetation, topography, water quality, and soils on which the fish and wildlife depend.

Most elements of the Action Alternatives (e.g., water quality and quantity protection, revegetation/reforestation, topography, soils, and streamside vegetative corridors) influence habitat quality and quantity at the regional level either directly or indirectly. For example, undisturbed soils contain a seed bank that promotes rapid re-establishment of native species. By returning topsoil to mined areas (as required by Alternatives 2, 3, 4, 5, 7, and 8), some of the original seed bank material may be returned and promote regrowth (though some of the natural seed bank may be destroyed during surface mining). Natural topographical features addressed by rule elements related to approximate original contour variances and surface configuration (as described in Chapter 2) also support multiple species and habitats necessary for diverse ecosystem functioning; restoring these topographical features is therefore expected to benefit species diversity and habitat. Furthermore, physical characteristics that may influence habitat suitability (e.g., erosion, runoff, rainfall infiltration, level of soil compaction) are themselves affected by changes to topography, soils, and the vegetation characteristics. Thus improvements to topography, soils, and vegetation characteristics may improve habitat suitability. Other sections of this chapter provide a more in-depth discussion of the impacts of the Action Alternatives on these features.

The potential for coal mining to adversely affect fish and other wildlife is most directly addressed by the elements of the Action Alternatives designed to protect and enhance the fauna inhabiting the mine site and adjacent areas, including downstream aquatic life. As described in Subsection 4.2.2.1, under the No Action Alternative, disturbances to fish and wildlife resources must be avoided and habitats restored or replaced. The enhancement of these resources is required where practicable under the No Action Alternative. These protections, however, offer only general guidance for treatment of habitats of unusually high value.

Current regulations specify that no surface or underground mining activity “shall be conducted which is likely to jeopardize the continued existence of endangered or threatened species listed by the Secretary or which is likely to result in the destruction or adverse modification of designated critical habitats of such species in violation of the Endangered Species Act of 1973, as amended (16 U.S.C. 1531 et seq.)” (30 CFR 816.97(b) and 817.97(b)). Under the No Action Alternative, a species-specific protection and enhancement plan is recommended under the 1996 BO. As stated above, Action Alternatives 2, 3, 4, 5, 7, and 8 are the same as the No Action Alternative except that they also *require* under SMCRA regulations the development of a species-specific protection and enhancement plan. It is difficult to forecast physical impacts to threatened and endangered species that would result from changing the protection and enhancement plan recommendation to a requirement. While the No Action Alternative provides extensive protection of federally listed species (i.e., federal regulations already protect listed species and their critical habitats, and recommend development of a species plan), the Action Alternatives further benefit these species in terms of improved quality and quantity of stream, streamside, and forest habitats within the coal regions. As the conservation and recovery of threatened and endangered species is inextricably linked to the quality and quantity of their habitats, this analysis finds that the Action Alternatives likely benefit listed species to an extent commensurate with their relative benefits to stream, streamside, and forest habitats.

4.2.2.7 Summary of Effects

Table 4.2-21 summarizes the impacts to biological resources under each of the Action Alternatives as compared to the No Action Alternative.

To evaluate the impacts of Action Alternatives on biological resources, OSMRE considered potential changes to the quality and quantity of terrestrial and aquatic habitats occurring in coal-producing areas, vegetative cover for terrestrial systems, and features of flowing and ponded aquatic systems. Impacts on these habitats in turn affect the wildlife communities they support. Coal mining adversely affects: (1) the biological composition, or the number and proportion of habitat types (e.g., the amount of forest, length of stream habitat); (2) the biological structure, or the geographical arrangement of the habitat types; and

(3) the biological function, or how these arranged habitat types interact with their respective plant and animal species. Thus, the extent to which the Action Alternatives would impact biological resources is in part dependent upon the extent to which the Action Alternatives would affect coal production. Because the Action Alternatives generally result in minor reductions in the volume of coal anticipated to be mined, and also attempt to reduce adverse impacts to habitats, impacts on biological resources are generally anticipated to be beneficial, although the EIS does not quantify these benefits. Impacts are generally likely to extend beyond the period of active mining (long-term). Specifically, determinations were made using the following analytic categories:

- Negligible: Minimal measurable impacts (adverse or beneficial) are expected; or short term effects to a small geographic area, community or economy.
- Minor Beneficial: Benefits to native forest, streamside, and stream habitat could be detectable, but would likely be limited to localized areas. A reduction in infrequent or insignificant disturbances to locally suitable habitat could occur.
- Moderate Beneficial: Benefits to native forest, streamside, and stream habitat could be measureable but limited to local and adjacent areas. A reduction in occasional disturbances to local and adjacent areas could be expected. These reductions in disturbances could benefit the local habitat but would not be expected to affect regional stability. Some beneficial impacts could occur in key habitats, which would help local habitat retain function and maintain viability both locally and in adjacent areas.
- Major Beneficial: Benefits to native forest, streamside, and stream habitat could be measurable and widespread. Reduced frequency of disturbances to habitat could be expected, with benefits to both local and regional systems. These benefits could positively affect rangewide habitat stability. Some impacts could occur in key habitats, and impacts could positively affect the viability of the habitat both locally and throughout its range.

Under the No Action Alternative current trends of mining impacts on these resources are expected to continue. In general, the effects of the Action Alternatives on biological resources are expected to be Negligible or beneficial across all coal regions.

With respect to biological resources, the following broad observations guide the summary and categorization of impacts:

- Impacts to forest land cover are expected to be long-term. While forest land cover may naturally return to reclaimed mine sites absent improved forest practices, available literature suggested this transition can take decades (e.g., Angel, et al., 2005). Accordingly, preserved and improved forests resulting from the Action Alternatives are more productive. Preserved and improved forests result in increased carbon storage potential, improved habitat quality, and improved conditions for recreational and aesthetic benefits (Stephenson, et al., 2014). For four of the regions, the reforestation impacts are relatively limited in geographic scope due to the naturally low level of forest land cover premining. The benefits vary by Alternative, depending on where the reforestation benefits apply. In general, however, for Alternatives that apply the reforestation requirements, benefits to forest land cover are expected to be Moderate Beneficial in the Colorado Plateau, Illinois Basin, Gulf Coast, and Northern Rocky Mountains and Great Plains regions. In the Northwest and Western Interior regions, benefits associated with Action

Alternatives are Negligible due to the very limited level of mining activity and associated affected forest expected to be improved. Only in Appalachia are benefits likely to be Major Beneficial. This region features the most forested land cover and a significant level of mining activity.

- Benefits to streamside habitat are expected to persist long-term. Establishing streamside vegetative corridors ensures expanded streamside habitat and enhances the quality of adjacent stream waters by buffering and filtering pollutants. As described in Chapter 3 and Section 4.2.1, negative effects of mining on water quality can persist beyond the life of the mine. It follows then that reduced water quality impairments supported by the streamside vegetative corridors generate long-term benefits to fish and wildlife.
- The characterization of impacts to fish and wildlife are informed by the broader improvements to ecological conditions (i.e., water quality, forest and other vegetative land cover, and topography/soils).

Under the No Action Alternative, no further regulations or corrective measures in addition to those already in place would be implemented. Therefore, ongoing trends in biological resources would continue.

The annual quantity of coal demanded and associated production is anticipated to be approximately 10 percent lower in 2040 than in 2020, even without implementation of the Alternatives (i.e., under the No Action Alternative). This reduction in production would reduce adverse impacts of ongoing coal mining activities on biological resources under the No Action Alternative.

Population growth is a primary driver of changes in biological resources associated with land clearing and development, as well as overall resource use. The socioeconomic section of Chapter 3 describes demographic trends in the coal-producing regions. In the period from 2000 to 2010, the coal regions seeing the greatest growth tended to be those in western states. The Northern Rocky Mountains and Great Plains region showed a 21 percent growth in population during this period, making it the fastest growing coal region. Other rapidly growing regions include the Colorado Plateau and the Gulf Coast regions. In terms of 2010 population, the most populous coal regions are the Appalachian Basin and the Illinois Basin. These population growth pressures are likely to increase adverse impacts to biological resources under the No Action Alternative.

Trends in forestry under the No Action Alternative would also affect biological resources. As noted above, approximately 60 percent of land in the Appalachian Basin is deciduous forest and several large National Forests exist in the region. While trends vary by sub-region, some portions of the Appalachian Basin have seen increased timber harvests in recent years. For instance, West Virginia production of industrial roundwood roughly doubled from 1979 to 2007, totaling nearly 190 million cubic feet (Piva and Cook, 2011). In the Gulf Coast region, Mississippi and Louisiana have extensive commercial forestry operations. Forest products were the highest value crop harvested in Louisiana in 2010, worth over three billion dollars (Louisiana Forestry Association, 2011). In Mississippi, the timber harvest was valued at $1.1 billion in 2013 (Mississippi State University, 2014). In addition, the Texas timber industry is concentrated almost exclusively in the northeast portion of the state (near Louisiana), meaning that it is almost fully contained in the Gulf Coast coal region (Texas Almanac, 2014). The delivered value of Texas timber was roughly $500 million in 2011. State forestry programs may promote best management practices (BMPs) that are intended to protect biological resources, among other resources. For example, Tennessee's BMP guide recommends practices such as establishment of streamside buffer zones, soil stabilization through reforestation, and use of sediment control structures (Tennessee Department of Agriculture, 2003). In conjunction with the proposed action, these BMPs could reduce forestry impacts such as sedimentation and streamside vegetation removal.

Trends in agriculture also affect biological resources within the study area. As noted above, relative to the other coal-producing regions, the Illinois Basin has the greatest amount of cultivated cropland. Cropland accounts for over 48 percent of the land use in this coal region. Illinois had approximately 22 million acres of harvested cropland in 2012, roughly unchanged from 2007. The total value of all agricultural products sold in 2012 was about $17.2 billion, up significantly from 2007 when sales totaled $13.3 billion (USDA, 2014). Livestock grazing is common in several coal-producing regions. In the Western Interior region, pasture and grazing operations account for over 38 percent of the land use in Kansas and Oklahoma. Likewise, the Gulf Coast region is over 26 percent pastureland.

In concert with the above, efforts to improve biological conditions, such as, water quality programs; mining rules intended to improve or expedite restoration activities; habitat conservation and management initiatives; and forestry and agricultural programs designed to conserve watershed integrity may continue to improve conditions under the No Action Alternative.

The following summaries of Action Alternatives 2 through 9 discuss impacts relative to the No Action Alternative. Action Alternatives are generally anticipated to benefit biological resources at the national scale when compared to the No Action Alternative, with Alternatives 2, 3, 4, 7, and 8 (Preferred) providing Moderate Beneficial impacts, and Alternatives 5 and 6 providing Minor Beneficial impacts at a national scale. Alternative 9 is anticipated to be functionally similar to the No Action Alternative and is anticipated to result in Negligible effects on biological resources.

On a regional scale, and similar to water resources, Major Beneficial impacts are anticipated in the Appalachian Basin and the Illinois Basin under Alternatives 2, 3, 4, and 8 (Preferred). Major Beneficial impacts are also anticipated in the Appalachian Basin under Alternative 5. Moderate Beneficial impacts are anticipated in the Colorado Plateau, Gulf Coast, and Northern Rocky Mountains and Great Plains regions under Alternatives 2, 3, 4, 7, and 8 (Preferred). Moderate Beneficial impacts are also anticipated in the Appalachian Basin and the Illinois Basin under Alternative 7. Other effects on biological resources are anticipated to be Minor Beneficial or Negligible at the regional scale when compared to the No Action Alternative.

Table 4.2-21. Summary of Impacts of the Action Alternatives on Biological Resources Compared to the No Action Alternative

Coal Region	Alt. 2	Alt. 3	Alt. 4	Alt. 5	Alt. 6	Alt. 7	Alt. 8 (Preferred)	Alt. 9
Appalachian Basin	Major Beneficial	Major Beneficial	Major Beneficial	Major Beneficial	Minor Beneficial	Moderate Beneficial	Major Beneficial	Negligible
Colorado Plateau	Moderate Beneficial	Moderate Beneficial	Moderate Beneficial	Negligible	Minor Beneficial	Moderate Beneficial	Moderate Beneficial	Negligible
Gulf Coast	Moderate Beneficial	Moderate Beneficial	Moderate Beneficial	Negligible	Minor Beneficial	Moderate Beneficial	Moderate Beneficial	Negligible
Illinois Basin	Major Beneficial	Major Beneficial	Major Beneficial	Negligible	Minor Beneficial	Moderate Beneficial	Major Beneficial	Negligible
Northern Rocky Mountains and Great Plains	Moderate Beneficial	Moderate Beneficial	Moderate Beneficial	Negligible	Minor Beneficial	Moderate Beneficial	Moderate Beneficial	Negligible
Northwest	Negligible	Negligible	Negligible	Negligible	Negligible	Negligible	Negligible	Negligible
Western Interior	Negligible	Negligible	Negligible	Negligible	Negligible	Negligible	Negligible	Negligible
National	Moderate Beneficial	Moderate Beneficial	Moderate Beneficial	Minor Beneficial	Minor Beneficial	Moderate Beneficial	Moderate Beneficial	Negligible

Note: For a discussion of the impacts of the No Action Alternative (Alternative 1), see Subsection 4.2.2.1 above.

4.2.2.7.1 Alternative 2

Alternative 2 includes many protective elements for biological resources. With respect to forest land cover, benefits are determined to be Major Beneficial in Appalachia; Moderate Beneficial in Colorado Plateau, Illinois Basin, Gulf Coast, and Northern Rocky Mountains and Great Plains regions; and Negligible in the Northwest and Western Interior regions.

The stream (water quality) benefits of this Alternative, as described in Section 4.2.1, reflect similar findings as the forest land cover, with the exception that benefits are Major in Illinois Basin. This conclusion results from the large number of streams and associated streamside habitat present in the region. As such, the fish and wildlife species dependent upon these habitats would experience similar levels of benefit in the Illinois Basin region.

Benefits are Negligible in the Northwest and Western Interior regions, where mining activity generally has fewer impacts on forest, streamside, and stream habitat.

4.2.2.7.2 Alternative 3

Alternative 3 includes a number of elements that would reduce the adverse effect of coal mining activities on biological resources, both aquatic and terrestrial. For example, Alternative 3 would implement a number of additional protections that will improve water quality in intermittent, perennial and ephemeral streams currently affected by coal mining activities. Rule elements that improve water quality are also likely to generate improvements in downstream aquatic and streamside fish and wildlife communities that depend on the habitat provided by these streams.

Alternative 3 also includes a mix of elements related to revegetation, topsoil, management and reforestation that collectively would improve the quantity and quality of forest land cover and other vegetative communities within coal mining regions. With respect to forest land cover, benefits under Alternative 3 are determined to be Major Beneficial in Appalachia; Moderate Beneficial in Colorado Plateau, Illinois Basin, Gulf Coast, and Northern Rocky Mountains and Great Plains regions; and Negligible in the Northwest and Western Interior regions.

The stream (water quality) benefits of this Alternative, as described in Section 4.2.1, reflect similar findings as the forest land cover, with the exception that benefits are Major in Illinois Basin. This conclusion results from the large number of streams and associated streamside habitat present in the region. As such, the fish and wildlife species dependent upon these habitats would experience similar levels of benefit in the Illinois Basin region.

Benefits are Negligible in the Northwest and Western Interior regions, where mining activity generally has fewer impacts on forest, streamside, and stream habitat.

4.2.2.7.3 Alternative 4

Similar to Alternatives 2 and 3, Alternative 4 also includes a number of elements that would reduce the adverse effect of coal mining activities on biological resources, both aquatic and terrestrial. Rule elements that improve water quality are also likely to generate improvements in downstream aquatic and streamside fish and wildlife communities that depend on the habitat provided by these streams. Proposed changes related to revegetation, topsoil, management and reforestation would collectively improve the quantity and quality of forest land cover and other vegetative communities within coal mining regions.

With respect to forest land cover, benefits under Alternative 3 are determined to be Major Beneficial in Appalachia; Moderate Beneficial in Colorado Plateau, Illinois Basin, Gulf Coast, and Northern Rocky Mountains and Great Plains regions; and Negligible in the Northwest and Western Interior regions. The stream (water quality) benefits of this Alternative, as described in Section 4.2.1, reflect similar findings as the forest land cover, with the exception that benefits are Major in Illinois Basin. This conclusion results from the large number of streams and associated streamside habitat present in the region. As such, the fish and wildlife species dependent upon these habitats would experience similar levels of benefit in the Illinois Basin region. Benefits are Negligible in the Northwest and Western Interior regions, where mining activity generally has fewer impacts on forest, streamside, and stream habitat.

4.2.2.7.4 Alternative 5

As explained in Chapter 2, Alternative 5 has little effect on any coal region other than the Appalachian Basin. As such, the predicted impacts for the other six coal regions are Negligible. For the Appalachian Basin region, however, the predicted level of biological resource protection is Major Beneficial. This designation reflects the abundance of forest, streamside, and stream habitat present in the region.

4.2.2.7.5 Alternative 6

Under Alternative 6, the analysis of water quality (Section 4.2.1) indicates that benefits to stream habitat are Moderate in the Appalachian Basin, Colorado Plateau, Gulf Coast, Illinois Basin, and Northern Rocky Mountains and Great Plains regions, and Negligible in the Northwest and Western Interior regions. However, Alternative 6 does not incorporate the same reforestation and revegetation requirements as other Action Alternatives. As a result, overall biological resource benefits are generally Minor Beneficial

(Appalachian Basin, Colorado Plateau, Gulf Coast, Illinois Basin, and Northern Rocky Mountains and Great Plains) or Negligible (Northwest and Western Interior).

4.2.2.7.6 Alternative 7

Alternative 7 applies to a more limited number of mine sites (i.e., those sites where enhanced permitting requirements apply). As a result, benefits to forest, stream, and streamside habitats are more geographically limited relative to the Alternatives with a broader geographic range. Specifically, biological resource benefits are Moderate (Appalachian Basin, Colorado Plateau, Gulf Coast, Illinois Basin, and Northern Rocky Mountains and Great Plains) or Negligible (Northwest and Western Interior) for Alternative 7.

4.2.2.7.7 Alternative 8 (Preferred)

Alternative 8 (Preferred) is very similar to Alternatives 3 and 4 in terms of the level of protection afforded to streams. For example, Alternatives 3, 4 and 8 (Preferred) require enhanced baseline characterization and monitoring before and during mining activities. In addition to limits on the types of activities that can occur in, near and through streams, Alternative 8 (Preferred) includes a definition of material damage to the hydrologic balance outside the permit area and establishes evaluation thresholds. Both of these rule elements provide an objective early warning system that further protects biological resources by preventing adverse impacts from developing to the point that they cause material damage to the hydrologic balance of affected streams. Alternative 8 (Preferred) is also similar to Alternatives 3 and 4 in terms of forest benefits, although the estimate of preserved forest acres is slightly lower given the slightly lower decreases in coal production. Despite these minor differences, the impact classifications for Alternative 8 (Preferred) are the same as those under Alternatives 3 and 4 with respect to biological resources.

4.2.2.7.8 Alternative 9

Alternative 9 would require the repromulgation of the currently vacated 2008 Stream Buffer Zone rule. This Alternative would require minimization of excess spoil generation, place limits on excess spoil fill capacity to match the anticipated amount of excess spoil to be generated, and prohibit mining activities in or within 100 feet of an intermittent or perennial stream unless the applicant demonstrates and the regulatory authority finds that avoidance is not reasonably possible. The model mines analysis indicates that the impacts of Alternative 9 would not differ significantly from those of the No Action Alternative because the Clean Water Act requirements and policies discussed in the Regulatory Impact Analysis for this rulemaking and the state AOC and excess spoil policies identified in Section 4.2.3.1 of this FEIS have effectively achieved implementation of this Alternative in Central Appalachia, which is the region in which the 2008 Stream Buffer Zone rule would have had its greatest impact if it had remained in effect. Therefore, if repromulgated, Alternative 9 would now have Negligible effects on biological resources.

4.2.2.8 Potential Minimization and Mitigation Measures

The Action Alternatives of the Stream Protection Rule are not expected to result in adverse environmental consequences in the context of biological resources. Therefore, identifying potential minimization and mitigation measures is not applicable for this analysis.

4.2.3 Topography, Geology, and Soils

Chapter 3 describes general characteristics of topography, geology, and soils at the regional level. This section of Chapter 4 analyzes how the Action Alternatives under consideration for the SPR would affect topography, geology, and soils. The extent to which the Action Alternatives would impact topography, geology, and soils is in part dependent upon the extent to which the Action Alternatives would affect coal production because the process of coal mining necessarily disturbs the topography, geology, and soils of the mine site.

The discussion is organized as follows:

- It first describes the existing regulatory environment to assist the reader in understanding the impacts of the No Action Alternative on topography, geology, and soils.
- Second, the discussion identifies the aspects of topography, geology, and soil resources most likely to be affected by implementation of the Action Alternatives and the rationale for these findings.
- It then describes the method for assessing the expected magnitude of quantified impacts of the Action Alternatives on these resources.
- Next, it presents the results of the quantitative analysis.
- The section concludes with a summary of the expected effects of the Action Alternatives, including additional qualitative evaluation of other beneficial impacts, and characterizes the impacts by coal region and Alternative.

4.2.3.1 Effects of the Current Regulatory Environment (the No Action Alternative)

4.2.3.1.1 Topography

Coal mining alters the landscape by removing coal resources and changing the configuration and physical properties of rock and other earthen materials overlying the coal seam. Depending on the original topography, the thickness of the coal seam, the relative thickness of overburden, and mining method, significant changes in topography can result. Under SMCRA, mined land must be backfilled and graded to restore its approximate original contour (AOC), with limited exceptions.

4.2.3.1.1.1 Current AOC Requirements

Section 515(b)(3) of SMCRA (30 U.S.C §1265(b)(3)) requires that mined lands be backfilled and graded to restore the AOC, with certain exceptions. The implementing regulations at 30 CFR 816.102 and 817.102 require that areas disturbed by mining operations be backfilled and graded to achieve AOC, with the exception of sites with thin or thick overburden, mountaintop removal mining operations, those portions of steep-slope operations for which the regulatory authority has granted a variance from AOC restoration requirements, previously mined areas for which complete highwall elimination is not required, and, for underground mines, settled and revegetated fills. The regulations at 30 CFR 701.5 define AOC as follows:

Approximate original contour (AOC) means that surface configuration achieved by backfilling and grading of the mined areas so that the reclaimed area, including any terracing or access roads, closely resembles the general surface configuration of the land prior to mining and blends into and complements the drainage pattern of the surrounding terrain, with all highwalls, spoil piles and coal refuse piles eliminated. Permanent water impoundments may be permitted where the regulatory authority has determined that they comply with 30 CFR 816.49[,] 816.56, [and] 816.133 or 817.49, 817.56, and 817.133.

Figure 4.2-5 contains a reconstruction of an illustration in the legislative history of SMCRA that demonstrates how the authors of SMCRA envisioned implementation of the backfilling and grading requirements of section 515(b)(3), both for operations required to restore the approximate original contour and for certain operations that are exempt from that requirement (mountaintop removal mining and sites with thin or thick overburden).

4.2.3.1.1.2 State and Regional AOC Studies

In the Appalachian Basin, OSMRE conducted special oversight studies in the late 1990s in Kentucky, Virginia, and West Virginia (OSMRE, 1999a) to determine how these state regulatory authorities were implementing their approved regulatory programs with respect to AOC restoration, exceptions to AOC restoration, and the postmining land uses needed to justify certain exceptions to AOC restoration. After examining permit files and reclaimed mine sites, OSMRE found that it was difficult to distinguish between the final surface configuration of operations for which AOC restoration was required and the final surface configuration of those operations with an approved exception to AOC restoration. There was no clear difference in the number and size of excess spoil fills on sites that had been reclaimed to AOC and those that had not. Furthermore, operators could have retained more spoil on the mined-out area under applicable AOC restoration requirements instead of placing it in excess spoil fills that were designed to be larger than necessary. The larger size of these fills meant that operations were disturbing more land outside the mined-out area than was necessary.

OSMRE and state regulatory authorities in Kentucky, West Virginia, and Virginia (along with industry and environmental representatives) subsequently developed guidance on restoration of AOC and excess spoil management. Guidance documents produced include: Kentucky Department of Natural Resources (KY DNR) Reclamation Advisory Memorandum # 145 (KY DNR, 2009); Virginia Department of Mines, Minerals and Energy Guidance Memoranda 4-02 (VA DMME, 2002); and West Virginia's Final AOC Document Guidance Policy commonly referred to as AOC-Plus (WV DEP, 1999). Additionally, OSMRE's Knoxville Field Office developed a guidance document titled *Engineering Procedure 2.1: Steep Slope Mining: AOC and Excess Spoil Determination* for the federal program in Tennessee (OSMRE, 2001). These policy documents are not part of those states' approved programs, and they do not have the force of law or regulation.

Each policy guidance document provides a systematic and objective process for achieving AOC in certain steep-slope areas. The documents focus on calculating the volume of spoil that can be returned to the mined-out area and minimizing both the total volume of excess spoil that the operation generates and the footprints of excess spoil fills, while choosing the most efficient excess spoil disposal location. The policies also contain guidelines addressing stability and drainage control. They promote the construction of excess spoil fills with flat top decks rather than placing additional excess spoil on that deck and regrading it to resemble the ridge-and-valley topography that is predominant in the region. Overall, these fill minimization policies are designed to retain more spoil on the mined-out area, produce fewer and smaller fills, and promote contemporaneous reclamation.

In evaluation year 2010, OSMRE conducted a nationwide evaluation of how states were implementing the AOC restoration provisions of their approved programs. The areas studied included AOC interpretation, documentation of AOC-related permitting decisions, the process for on-the-ground verification of the premining surface configuration, and field verification that backfilling and grading are following the approved plan. Detailed permit file reviews of selected sites were performed and the premining and postmining topography of the sites were compared to determine how well the surface configuration of the reclaimed site matched the topographic restoration plan approved in the permit. OSMRE also evaluated other AOC-related factors, including reestablishment of premining drainage patterns. These evaluations found that most states have a satisfactory process for determining the premining surface configuration and ensuring that the postmining surface configuration closely resembles the configuration before mining (OSMRE, 2010a). However, many states do not have written policies outlining how the regulatory authority is to determine whether AOC restoration has been achieved.

Furthermore, some states do not verify or document that the final grading of disturbed areas complies with the plan approved in the permit (OSMRE, 2010a).

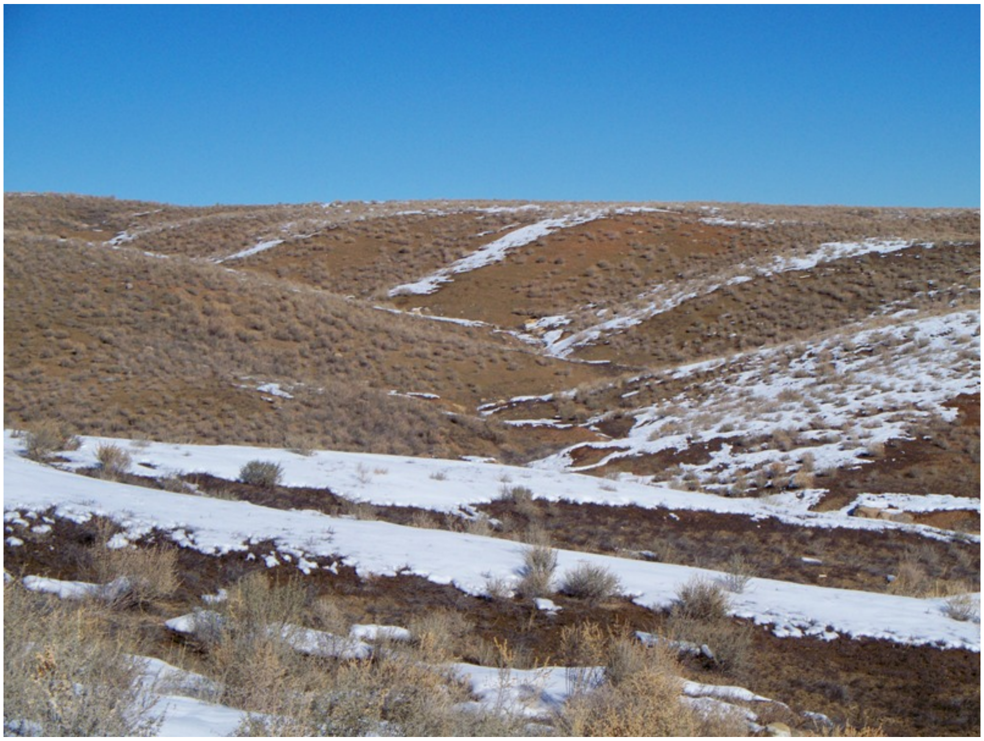
In some states, where no formal method or reproducible process was available for evaluating AOC, implementation of AOC requirements was found to be inconsistent and highly variable. In addition, in several states OSMRE noted that readily available electronic data and technology could be used more efficiently and precisely to ensure the return of mined land to AOC. Applicable technologies include digital terrain modeling or the use of GPS data to more precisely evaluate premining and postmining topography (OSMRE, 2010a).

In Oklahoma, the AOC study determined that three of the five mine permits investigated were not being reclaimed to AOC and/or had serious flaws in the approved reclamation plan or field implementation. At one mine site, an after-the-fact revision to a reclamation plan that originally required restoration of AOC approved the creation of a long narrow spoil ridge with side slopes of approximately 25 percent in an area where premining topography was generally flat with slopes of 3.5 percent or less. On another mine site, a reclamation plan change resulted in the creation of a long remnant spoil ridge immediately adjacent to a minimally backfilled and graded mine pit. The originally approved plan required the backfilling of the mine pit with graded spoil. This change resulted in the creation of a non-AOC postmining configuration with excessive slopes compared to the premining topography and the originally approved plan. At a third site, the reclamation plan approved by the regulatory authority allowed the placement of a large, steeply sloped spoil ridge adjacent to a large final pit, which was approved as a permanent impoundment despite the lack of documentation that it would hold sufficient water for that purpose. OSMRE reviewers could not fully determine whether the pit would fill with water. Ultimately, the pit remained dry. However, even if the pit had held water, the existence of a large final pit impoundment immediately adjacent to a large spoil ridge does not meet AOC restoration requirements. All three cases were in the administrative review process at the time of preparation of this FEIS.

Conversely, some companies elsewhere in the country are applying innovative technology, geomorphic reclamation techniques, and landforming principles in a manner that improves upon conventional AOC restoration techniques. Landforming is a design and grading technique that attempts to replicate the appearance of the natural terrain as well as the water transport and water retention functions of that terrain by constructing slopes, drainage ways, and other surface features that blend with the natural surroundings in an environmentally compatible fashion while meeting any relevant stability requirements (Schor and Gray, 2007).

The use of landforming principles to reclaim mined lands results in greater topographic diversity and stability than conventional backfilling and grading techniques; as such, it is compatible with stream restoration. In the past, conventional techniques have resulted in the creation of long, continuous, uniform, linear slopes that often required terracing and conveyance structures like diversions and downdrains to control surface runoff. However, terraces and diversions are of limited long-term function and stability and ultimately require maintenance. The use of landforming principles also enhances vegetative diversity, fish and wildlife habitat, and aesthetic values (see Figure 4.2-6).

Figure 4.2-6. Reclaimed Landscape Designed and Constructed Using Landforming Reclamation Principles



Source: OSMRE, [n.d.], *LaPlata Mine, New Mexico*, U.S. Department of the Interior.

4.2.3.1.1.3 Exceptions to Approximate Original Contour Restoration Requirements

Both SMCRA and its implementing regulations allow exceptions to AOC restoration requirements. For example, the surface mining regulations at 30 CFR 816.102(a)(1) provide that the disturbed area must be backfilled and graded to achieve AOC, except as provided in paragraph (k), which states that the postmining slope may vary from the AOC when—

(1) The standards for thin overburden in 30 CFR 816.104 are met;

(2) The standards for thick overburden in 30 CFR 816.105 are met; or

(3) Approval is obtained from the regulatory authority for

(i) Mountaintop removal operations in accordance with 30 CFR 785.14;

(ii) A variance from approximate original contour requirements in accordance with 30 CFR 785.16 [variances to AOC requirements for steep-slope mining]; or

(iii) Incomplete elimination of highwalls in previously mined areas in accordance with 30 CFR 816.106.

In addition, the underground mining regulations at 30 CFR 817.102(l) contain an exception for settled and revegetated "fills" containing spoil from the face-up of the underground mine and nontoxic-forming and non-acid-forming underground development waste, provided those fills meet specified conditions.

These variations and exceptions are discussed in detail below.

4.2.3.1.1.4 Thin and Thick Overburden

Thin overburden exists chiefly in the Powder River Basin of the Northern Rocky Mountains and Great Plains region. Thick overburden most commonly occurs in parts of the Appalachian Basin, although it may exist to a very limited extent in other regions.

The federal regulations at 30 CFR 816.104(a) define thin overburden as follows:

Thin overburden means insufficient spoil and other waste materials available from the entire permit area to restore the disturbed area to its approximate original contour. Insufficient spoil and other waste materials occur where the overburden thickness times the swell factor, plus the thickness of other available waste materials, is less than the combined thickness of the overburden and coal bed prior to removing the coal, so that after backfilling and grading the surface configuration of the reclaimed area would not:

(1) Closely resemble the surface configuration of the land prior to mining; or

(2) Blend into and complement the drainage pattern of the surrounding terrain.

Paragraph (b) of 30 CFR 816.104 provides that, where thin overburden occurs, the permittee must use all spoil and other waste materials available from the entire permit area to attain the lowest practicable grade, but not more than the angle of repose. In addition, the permittee must comply with the backfilling and grading requirements of 30 CFR 816.102 (a)(2) through (j); i.e., all requirements other than AOC restoration.

The federal regulations at 30 CFR 816.105 define thick overburden as follows:

Thick overburden means more than sufficient spoil and other waste materials available from the entire permit area to restore the disturbed area to its approximate original contour. More than sufficient spoil and other waste materials occur where the overburden thickness times the swell factor exceeds the combined thickness of the overburden and coal bed prior to removing the coal, so that after backfilling and grading the surface configuration of the reclaimed area would not:

(1) Closely resemble the surface configuration of the land prior to mining; or

(2) Blend into and complement the drainage pattern of the surrounding terrain.

Paragraph (b) of 30 CFR 816.105 provides that, where thick overburden occurs, the permittee must restore AOC and then use the remaining spoil and other waste materials to attain the lowest practicable grade, but not more than the angle of repose. In addition, the permittee must comply with the backfilling and grading requirements of 30 CFR 816.102 (a)(2) through (j); i.e., all requirements other than AOC restoration, and must dispose of any excess spoil in accordance with 30 CFR 816.71 through 816.74.

4.2.3.1.1.5 Mountaintop Removal Mining Operations and Steep-Slope Mining AOC Variances

Section 515(c)(1) of SMCRA (30 U.S.C. 1265(c)(1)) provides that each state program may and each federal program must allow mountaintop removal mining operations. Paragraph (c)(2) defines mountaintop removal mining as an operation that "will remove an entire coal seam or seams running through the upper fraction of a mountain, ridge, or hill…by removing all of the overburden and creating a level plateau or a gently rolling contour with no highwalls remaining." The postmining surface configuration must be capable of supporting an industrial, commercial, agricultural, residential or public facility (including recreational facilities) postmining land use. The remainder of paragraph (c) establishes additional permit application requirements and performance standards for mountaintop removal mining operations. Among other things, the application must include specific plans for the proposed postmining land use, the postmining surface configuration must drain inward except at specified points, and the operation must not damage natural watercourses. The federal regulations include corresponding permitting requirements and performance standards in 30 CFR 785.14 and 824.11.

Section 515(e) of SMCRA (30 U.S.C. § 1265(e)) also allows the regulatory authority to approve a variance from AOC restoration requirements for non-mountaintop removal mines in steep-slope terrain if the variance will render the reclaimed land suitable for an industrial, commercial, residential, or public use (including recreational facilities). Unlike for mountaintop removal mining operations, an agricultural postmining land use is not an acceptable basis for a steep-slope AOC variance.

SMCRA and the implementing regulations at 30 CFR 785.16 also impose other requirements and limitations on the AOC variance. For example, the highwall must be completely eliminated in a stable fashion and the variance must improve watershed control of the area relative to the premining condition or the condition that would exist if AOC was restored. Only that amount of spoil necessary to achieve the postmining land use, ensure stability of the spoil retained on the mine bench, and meet other applicable SMCRA requirements may be placed off the mine bench. All spoil not retained on the bench must be placed in accordance with the regulations governing excess spoil disposal (30 CFR 816.71-816.74).

4.2.3.1.1.6 Previously Mined Areas

The existing regulations at 30 CFR 816.106 and 817.106 (the No Action Alternative) apply where remining operations occur on previously mined areas that contain a pre-existing highwall. As defined in 30 CFR 701.5, the term "remining" refers to surface coal mining and reclamation operations that affect previously mined areas. Under 30 CFR 816.106 and 817.106, a remining operation must eliminate all highwalls that the operation re-affects unless the volume of all reasonably available spoil is demonstrated to be insufficient to completely backfill the re-affected highwall. In that case, the operator must eliminate the highwall to the maximum extent technically practicable. The operator must use all reasonably available spoil in the immediate vicinity of the remining operation, grading to a slope that provides adequate drainage and long-term stability, and ensuring that any highwall remnant is stable and does not pose a hazard to public health and safety or to the environment.

4.2.3.1.1.7 Excess Spoil

Surface mining methods involve the fracturing of the rock strata overlying the coal to facilitate excavation of the overburden and extraction of the coal. Fracturing formerly solid rock into multiple fragments increases its overall volume because of the numerous void spaces between the rock fragments. This increase in volume is known as "swell" or "bulking."

In areas with steep slopes, the swell factor commonly results in the generation of excess spoil because the volume of overburden removed, after swell, is greater than the volume that can be safely returned to the mined-out area or used to blend the mined-out area with the surrounding terrain. Re-establishment of the premining topography is limited by the physical properties of the spoil material, the associated angle of repose, and regulatory requirements related to angle of repose and stability. Typically, excess spoil is placed in fills constructed in valleys adjacent to the mined-out area. More than 98 percent of excess spoil fills are located in Central Appalachia (eastern Kentucky, southwest Virginia, West Virginia, and northern Tennessee) (OSMRE, 2008).

In non-steep slope areas, mines seldom generate excess spoil. Instead, it is possible to return the spoil to the mined-out area and grade it to closely resemble the premining topography. Because of the increase in volume caused by the swell factor, the backfilled and graded area generally will have a higher elevation than it did before mining, but the edges can be graded to blend with the surrounding terrain, consistent with the definition of AOC.

4.2.3.1.1.8 Types of Excess Spoil Fills

Prior to the passage of SMCRA, excess spoil fills generally were constructed with minimal engineering and placed at locations that were most convenient and least costly to the mining operation. Sometimes spoil was simply pushed over the slope below the mine bench. Section 515(b)(22) of SMCRA (30 U.S.C. 1265(b)(22)) established standards for excess spoil fill construction that focus on engineering and safety, with a goal of ensuring long-term fill stability. Among other things, SMCRA requires that excess spoil be placed within the permit area in a controlled manner to prevent mass movement and to assure mass stability. In addition, the operation must comply with drainage requirements to prevent spoil erosion and movement. The design of the excess spoil fill must be certified by a registered professional engineer in conformance with professional standards.

A study published in 2005 found that excess spoil fills in Appalachia are quite stable, with fewer than 20 reported slope movements out of more than 6,800 fills constructed since 1985 (U.S. EPA et al., 2005). However, the fills studied were constructed prior to the implementation of fill minimization and optimization requirements; they also were generally constructed lower in the watershed and on flatter foundation slopes than fills being constructed today. Fill minimization policies adopted in Kentucky and West Virginia since the completion of the study require fill placement higher in the watershed and on steeper slopes, thus creating the potential for greater instability. Fills placed on steeper foundations would inherently have a lower slope stability factor of safety.

The federal regulations at 30 CFR 816.71 through 816.74 and 817.71 through 817.74 expand upon the statutory requirements. General requirements for constructing excess spoil fills are contained in 30 CFR 816.71 and 817.71. The fill must be designed to achieve a minimum long-term static safety factor of 1.5 and a qualified registered professional engineer with appropriate experience must certify the design. The design must include underdrains constructed of durable rock or perforated pipe if the footprint of the fill contains springs, natural or man-made water courses, or wet weather seeps. Excess spoil must be transported and placed in a controlled manner and concurrently compacted in horizontal lifts that do not exceed 4 feet unless the design engineer certifies that the design will ensure the stability of the fill and meet all other applicable requirements. A qualified registered professional engineer (or other qualified professional specialist under the direction of the engineer) must inspect the fill at least quarterly throughout construction. The engineer must provide a certified report to the regulatory authority after each inspection describing how the fill is being constructed and maintained in accordance with the approved design and regulatory requirements.

The federal regulations at 30 CFR 816.72 and 817.72 contain special requirements applicable to "valley fills" and "head-of-hollow fills," which are two types of fills constructed in steep-slope areas (existing valleys with side slopes greater than 20 degrees) or where the average slope of the profile of the existing valley from the toe of the fill to the top of the fill is greater than 10 degrees. A head-of-hollow fill differs from a valley fill in that the top surface of the fill, when completed, is at approximately the same elevation as the adjacent ridgelines, which means that there is no significant area of natural drainage above the fill. By way of comparison, valley fills are constructed further down the valley and therefore have significant surface drainage from the watershed above the fill that must be diverted around the fill. The regulations allow both valley fills and head-of-hollow fills to use a specially constructed rock-core chimney drain in place of the underdrains and surface diversions that otherwise would be required under 30 CFR 816.71 and 817.71. However, a rock-core chimney drain may only be constructed where the fill is not located in an intermittent or perennial stream. In addition, if the fill is a valley fill, the volume of the fill may not exceed 250,000 cubic yards and upstream drainage must be diverted around the fill.

Durable rock fills are the most commonly constructed excess spoil fill in the Appalachian Basin. The federal regulations at 30 CFR 816.73 and 817.73 require that 80 percent of the spoil volume in a durable rock fill consist of durable, non-acid, and non-toxic-forming rock that does not slake in water and will not degrade to soil material. Durable rock fills are constructed by end-dumping excess spoil into valleys, generally in single lifts, but occasionally in multiple lifts. This construction technique relies upon gravity segregation of the end-dumped material to naturally form an underdrain concurrent with fill placement because the larger rocks roll to the base of the fill. Typically, this process results in a highly permeable zone of large-sized durable rock in the lower one-third of the fill. Existing durable rock fills generally contain single lifts ranging in size from 30 to over 400 feet in thickness. Following completion of spoil placement, the face of the fill typically is graded to a terraced configuration that may not exceed a 2h:1v slope ratio. Durable rock fills must be designed to attain a minimum long-term static safety factor of 1.5 and a seismic safety factor of 1.1.

Both state and federal regulatory programs have recognized that proper drainage control, including the construction of a functioning permeable underdrain, is critical to the long-term stability of durable rock fills. Hence, Kentucky and OSMRE have developed permitting and inspection guidance to address these concerns. See KY DNR's "Reclamation Advisory Memorandum #141, Review of Durable Rock Fill Designs" (2002); and OSMRE's *Final Environmental Impact Statement on Excess Spoil Minimization, Stream Buffer Zones* (2008).
